Special Populations: An Introduction

126

Giuseppe Carrà and Nady el-Guebaly

Abstract

The challenge of this section is to select special populations with needs not otherwise covered by the rest of the textbook. The barriers encountered in the design of gender-specific programs, the special needs of seniors, LGBT-specific programs, the health of physicians, and increase in substance use in people displaced by conflicts across the world, and in those affected by disasters, all are addressed in the section. The section also highlights the international paucity of statistical data related to 96 special needs groups as compared to the available general population data.

A systematic research effort will be required.

The challenge of this section is to select special populations with needs not otherwise covered by the rest of the textbook. Six such groups are highlighted.

The first chapter addresses the special needs of women. We recognize the awkwardness of addressing half of humanity as a "special population," and indeed, a separate section can be devoted to women in future editions. Drs. Moran-Santa Maria and Brady present a masterful synopsis of the scientific endeavors focusing on women. Remaining gender disparities in research are acknowledged. The prevalence difference of various substance use disorders between men and women across the life cycle is outlined. These data for a number of African and Asian countries remain unavailable. This part of the chapter also addresses the increased exposure of female sex workers. While the "telescoping course" of

females addicted to alcohol and the related biologic causes are well known, the chapter also addresses parallel reactivity to other drugs as well as areas for further study. The treatment section describes different responses to pharmacotherapy as well as the barrier encountered in the design of gender-specific programs and the parameters of improved outcome.

The second chapter describes the special needs of seniors, soon to become a quarter of humanity but with disproportionately higher service needs as compared to other age groups. Dr. Crome summarizes the available prevalence figures of older people with substance misuse in the United Kingdom and the United States. The related costs to a developed community are outlined. The chapter's middle section carefully details distinctive issues in substance use among the elderly and provides a window on the higher comorbid health conditions. This perspective leads to a thorough consideration of the issues central to the assessment of older people: the barriers to detection and the benefits and limitations of the available screening instruments in this population. A paucity of data addresses the disproportionate need for pharmacological and psychological treatments. Among clinical trials, there remains a lack of evidence about safety issues in this age group. There are few trials of psychological treatment despite the observation that older people may in fact do better than their younger counterparts. Effective ingredients of comprehensive service programs and models are becoming identified. The chapter aptly concludes with the significant need for training of a competent workforce.

The third chapter is the first one to address a smaller subgroup of the international community burdened by significant stigmatization, the LGBT group. This chapter reviews the empirical evidence focusing by necessity on the North American scene, due to the shortage of data from elsewhere. Despite the challenges encountered in epidemiological surveys, the consensus is that the prevalence for substance use disorders is higher than for the general population due to stressors related to social rejection and various forms of homophobia. Examples of particular significance are the impact on adolescents "coming out" and individuals, members of "double minorities." The bars and circuit parties and more recently the Internet become the social foci of an underground community. The second half of the chapter addresses treatment and other remedial measures including for which LGBT-specific programs may be required as well as the competencies needed from care providers. The developing world being comparatively more opened to the subgroups described, it is plausible to assume that the various challenges described are more severe in the developing world.

The fourth chapter focuses on the health of physicians with implications for other caregivers as a special group. The chapter by Drs. Braquehais, Casas, et al. is based on the experience of the Galatea clinic in Barcelona (▶ Chap. 130, "Addictions in Physicians: An Overview"). A review of the literature concerning prevalence, possible causes, and drugs of abuse in various medical careers on both sides of the Atlantic is presented. The Physician Health Programs have attracted attention in the field due to their demonstrated excellent outcomes. These programs have evolved from a culture of denial and unrealistic expectations in the medical community to the development of successful strategies aimed at protecting patients and helping the physician recover back to the practice of medicine. A table lists the

various approaches in North America, Europe, and Australia, and key factors for prevention and treatment of physicians with substance use disorders are identified including among others confidentiality, specialized staff training, group approaches, and lengthy monitored follow-up. The chapter concludes with a description of the respected PAIMM program in Barcelona and its extended activities across Spain. The target is the range of mental disorders and voluntary help-seeking is encouraged.

The last two chapters deal with populations not commonly covered in our textbooks, but appearing regularly in our global media. Dr. Ezard reports on the staggering 45 million people currently displaced by conflicts across the world, two-thirds of whom in a "protracted situation" of more than 5 years. Patterns of substance use reflect a combination of pre-displacement patterns, host population patterns, and substance availability. The experience of various displaced groups, and they are unfortunately many, is described. Particular risk factors include being male, older age, multiple traumatic episodes, and economic drivers. While experiences of interventions to reduce substance-related harm among refugees are limited, a harm reduction approach is recommended from thiamine provision for heavy alcohol users to more structural interventions including community mobilization, alternate income strategies, and equity-based initiatives. Quantitative evaluations may be difficult to conduct and qualitative ones may be more realistic with common end points such as violence prevention.

The final chapter is an overview of the impact of disasters particularly on youth. Following an inventory of the challenges arising from biases inherent to the unpredictability of the events, the results of well-designed US studies following Hurricane Katrina but also the 9/11 attack on the World Trade Center as well as bushfire in Australia are presented analyzing the relation between disaster exposure and substance use. Higher levels of objective and subjective disaster exposure are linked with greater psychological symptoms and increase in substance use. Of the young people experiencing distress, the majority recover within a year. Post-disaster interventions are described based on the phase of recovery, e.g., immediate aftermath, within a year and over a year. Little research so far addresses pathways leading to substance abuse/PTSD comorbidity among youth. Identified remedial programs involve some type of family treatment, an evaluation of mental health and substance treatment needs, and provision of environmental resources.

The section also highlights the international paucity of statistical data related to special needs groups as compared to the available general population data. A systematic research effort will be required.

Women and Addiction

differences in epidemiology, etiology, risk and protective factors, clinical presentation, psychiatric comorbidity, course of illness, and treatment outcomes of substance use disorders (SUDs), particularly in developing countries, is critical to the implementation of effective treatment and prevention strategies that address both sexual risk and drug use.

127.1 Introduction

The definition, prevalence, assessment, and management of addictive disorders are dramatically influenced by social, ethnic, and cultural contexts. This is particularly true for understanding addictive disorders in women. Women from various cultures maintain diverse roles in society which can lead to a variety of coping mechanisms and behavioral adaptations that influence the prevalence and presentation of mental health problems and substance use–related issues. In this chapter, we present an overview of substance use disorders (SUDs) in women with an emphasis on international issues including social and cultural influences. Studies specifically focused on gender-related international issues in SUDs are reviewed.

127.2 Overview of Epidemiology

In 1993, the United States Congress approved legislation mandating that the National Institutes of Health (NIH) ensures that women and members of minority groups are included in clinical research studies that are pertinent to their health, the purpose of the research, and all other conditions that may be designated as appropriate by the director of the NIH (U.S. Congress Public Law 103-43 1993). Since then, the number of published research reports examining multiple aspects of SUDs in women and gender differences in SUDs in the United States has risen tremendously. These studies have provided critical insights into the epidemiology, etiology, risk and protective factors, clinical presentation, psychiatric comorbidity, course of illness, and treatment outcomes of SUDs in women. While the number of international studies of SUDs among women is increasing, there are still significant gender disparities in our knowledge and understanding of SUDs at a global level.

127.2.1 United States

In 2011, approximately 20.6 million Americans 12 years of age or older met the Diagnostic Statistical Manual of Mental Disorder (DSM-IV) criteria for current substance/drug abuse or dependence (Mental Health Services Administration 2012a). The prevalence of SUDs in men (10.4 %) was significantly higher than for women (5.7 %). In addition, the prevalence of current illicit drug use among men (11.1 %) was significantly greater than the prevalence of illicit drug use in women (6.5 %). Compared with women, men were more likely to use

marijuana (9.3 vs. 4.9 %), cocaine (0.7 % vs. 0.4 %), prescription drugs (2.6 % vs. 2.2 %), and hallucinogens (0.5 % vs. 0.3 %). The prevalence of current alcohol (56.8 % vs. 47.1 %) and tobacco (32.3 % vs. 21.1 %) use was also higher in men than women. Of note, the gender differences in the prevalence of current tobacco use was consistent across all types of tobacco (cigarette, pipe, cigar, and smokeless).

A similar epidemiological study of adolescents (ages 12–17) found no gender differences in general prevalence of SUDs (6.9 % for males and females) (Mental Health Services Administration 2012b). In addition, no gender differences in the prevalence of current alcohol use (13.3 % for males and females) or cigarette smoking (8.2 % for males and 7.3 % for females) were reported. However, the prevalence of current illicit drug use among adolescent males (10.8 %) was greater than the prevalence in adolescent females (9.3 %). Adolescent males were more likely than females to be current marijuana users (9.0 % vs. 6.7 %). However, adolescent females were more likely than males to report nonmedical use of prescription pain relievers (2.6 % vs. 1.9 %) and psychotherapeutic drugs (3.2 % vs. 2.4 %).

Data from large-scale epidemiological studies demonstrate a relatively high prevalence of certain co-occurring psychiatric disorders among women with SUDs as compared to men. For example, alcohol-dependent women are more likely to suffer from mood disorders and have a higher prevalence of primary depression than alcohol-dependent men (Regier et al. 1990; Kessler et al. 1997; Helzer and Pryzbeck 1988; Schuckit 1983). Moreover, compared with treatment-seeking men, treatment-seeking women are more likely to have multiple comorbidities (i.e., three or more co-occurring diagnoses in addition to the substance use disorder) (Brady and Greenfield 2009). Eating disorders (EDs) are particularly common among women with SUDs (Gadalla and Piran 2007). A number of studies have found that over 50 % of women receiving treatment for a SUD have histories of physical and/or sexual abuse and a high percentage meet criteria for posttraumatic stress disorder (PTSD) (Greenfield et al. 2010; Brady et al. 2004). Moreover, the severity of childhood trauma has been associated with an increased risk for cocaine relapse in women but not in men (Hyman et al. 2008).

127.2.2 International Epidemiological Data

The United Nations Office on Drugs and Crime (UNODC) and the World Health Organization (WHO) have provided the most recent estimates of the prevalence of drug use and SUDs among men and women at a global level. Consistent with data from the United States, UNODC reported that the lifetime, 12-month, and past-month prevalence rates of cocaine, amphetamine, marijuana, and ecstasy use were greater among men than women. However, the prevalence of tranquillizer and sedative use among women exceeded that observed in men (United Nations Office on Drugs and Crime 2012). In Afghanistan, women were more than twice as likely as men to report daily use of tranquillizers (United Nations Office on Drugs and Crime 2009). In South America and Central America, the lifetime prevalence of tranquillizer and sedative use in women was nearly double the prevalence estimates

for men (6.6 % vs. 3.8 %). In Europe, the lifetime prevalence of tranquillizer and sedative use among women was 13 % compared with 7.9 % for men. These findings are consistent for both adult and adolescent populations (United Nations Office on Drugs and Crime 2012).

The WHO collected data from 147 countries (representing approximately 88 % of the global population) (World Health Organization 2010). Estimates were based on international disease classification systems such as the International Classification of Diseases (ICD) and the DSM-IV (Kehoe et al. 2007; Rehm et al. 2009). Among males age 15 years and older, the prevalence of alcohol use disorders was estimated to be highest in Eastern European countries, parts of Asia, and the Americas. Among females aged 15 and older, the highest prevalence rates of alcohol use disorders were found in Eastern European countries, regions of the Americas, and the Western Pacific. The estimated prevalence of alcohol use disorders was lowest among men and women living in African and Eastern Mediterranean countries. The highest prevalence rates of SUDs for both men and women were found in select regions of South, Central, and North America.

There are a number of limitations to the UNODC and WHO reports. Data from a number of African and Asian countries were unavailable and therefore not included in the UNODC report. Thus, gender differences in the prevalence of illicit drug use may be not be generalizable to African and Asian countries. In addition, these findings were based solely on data from countries for which gender-disaggregated data were available and thus may lead to an underestimation of SUDs among women at a global level.

Socioeconomic and cultural factors continue to be major challenges to accurate and reliable international assessments of SUDs among women. For example, in the United States, childhood sexual abuse is a strong predictor of SUDs in women (Boyd and Mackey 2000). Women living in socially conservative cultures may be reticent to disclose childhood sexual abuse with researchers. In addition, logistical challenges can prevent researchers from collecting data from women living in rural areas. Interpersonal violence and SUD data have often been collected in the emergency departments of urban hospitals and may not be generalizable to the entire population (Treno et al. 1998).

127.2.3 Substance Use in Sex Workers

One of the most consistent epidemiological findings is the high prevalence of substance use among female sex workers. Approximately 30 % of women who use injectable drugs (ID) work in the sex trade (El-Bassel et al. 2012; Poon et al. 2011). A high prevalence of cocaine and alcohol use was found in a study of female sex workers in South Africa (Wechsberg et al. 2006). In addition, a community-based survey of sex workers in India found that close to 100 % exhibited symptoms of alcohol dependence (Chakraborty et al. 1994). There is a strong reciprocal relationship between involvement in the sex trade and substance use. For example, sex workers are often from impoverished backgrounds so it is not

uncommon for them to use the sex trade as a means to support not only their own drug habit but also their partner's habit (Kumar and Sharma 2008). Female sex workers have a high risk of exposure to interpersonal violence and are often encumbered with economic challenges and childcare issues. Thus, substance use among female sex workers may be an attempt to self-medicate and alleviate stress and anxiety. Substance use reduces the likelihood of sex workers to engage in harm-reduction behaviors. In India, more than half (52 %) of female sex workers reported alcohol use prior to sex, and 38 % were less likely to use condoms after alcohol use (Kumar 2003). Female sex workers that use drugs have an elevated risk for HIV infection and other sexually transmitted diseases. In India, the prevalence of HIV infection among sex workers who use injectable drugs (IDs) was 16 %, which is nearly double the HIV prevalence estimate of 8.4 % for female sex workers. Studies have found that HIV infection among women who use IDs is escalating (Bridge et al. 2010; El-Bassel et al. 2010). In fact, a meta-analysis of drug use across 14 countries found that women who use IDs have a significantly greater risk for HIV infection than males that use IDs (Des Jarlais et al. 2012). Despite these data, few if any studies have employed a systematic approach to IDs use among women at a global level, and countries with the highest prevalence of HIV often fail to provide gender-disaggregated data. Moreover, underestimates of the prevalence SUDs among women in developing countries could undermine the implementation of effective prevention strategies addressing both sexual risk and drug use.

127.3 Gender Differences in Course of Illness

One of the most consistent findings in studies focused on gender differences in SUDs is the increased vulnerability of women to adverse medical and psychosocial consequences of addiction (Chatham et al. 1999; Gentilello et al. 2000; Henskens et al. 2005; Hernandez-Avila et al. 2004; Mann et al. 2005). Women advance more rapidly than men from initial to regular use and to the first treatment episode. Despite fewer years and smaller quantities of use at treatment entry, substance use severity is generally equivalent in men and women, and women average significantly more medical, psychiatric, and adverse social consequences from substance use (Hernandez-Avila et al. 2004; Mann et al. 2005; Randall et al. 1999). This has been called the "telescoping" of SUDs in women, and differences in biology as well as psychosocial factors contribute to this phenomenon.

127.4 Gender Differences in Biology and Pharmacotherapy

127.4.1 Biological Influences

Important gender differences exist in the physiologic effects of alcohol. Women have higher blood-alcohol concentration after drinking equivalent amounts of alcohol as compared to men. This is primarily because women have a lower

percentage of total body water (Marshall et al. 1983) and a lower concentration of gastric alcohol dehydrogenase, the primary enzyme responsible for the metabolism of alcohol (Frezza et al. 1990). These gender differences contribute to higher blood-alcohol concentrations in women which provide a biological basis for the heightened vulnerability to psychological and medical consequences of alcohol consumption in women. Women develop alcoholic liver disease after comparatively shorter and less-intense drinking as compared to men, and neuroimaging studies suggest increased sensitivity to alcohol-induced brain atrophy in women as compared to men (Mann et al. 2005; Fuchs et al. 1995; Hommer et al. 1996).

There is less data available concerning gender differences in physiologic effects and medical consequences of other drugs of abuse. Women generally metabolize nicotine more slowly than men (Benowitz and Hatsukami 1998). Some studies suggest that men are more sensitive to the rewarding effects of nicotine than women (Perkins et al. 2000). In addition, negative affect regulation may be a stronger motivation for nicotine use in women (Hogle and Curtin 2006; McGee and Williams 2006). Both animal studies and human laboratory data indicate that females are more sensitive to the subjective effects of stimulants (Kosten et al. 1996; Roth and Carroll 2004a, b). Of interest, cocaine-dependent women experience fewer cerebral perfusion defects (Levin et al. 1994) and less frontal cortical neuronal loss (Chang et al. 1999) compared to men with comparable drug use histories, findings that could be related to gender differences in cocaine-induced cerebral vasoconstriction (Kaufman et al. 2001). There have been many gender differences observed in the pharmacologic properties of opiates, including analgesic effects, but gender differences in abuse potential have not been systematically studied in humans. However, animal studies suggest that mu agonists may be reinforcing to females over a broader dose range, and females self-administer greater quantities of opiates as compared to males (Cicero et al. 2000, 2003).

Accumulating evidence from preclinical and clinical studies indicate that hormonal changes associated with the menstrual cycle may impact both craving and the behavioral responses to drugs. For example, estrogen augments behavioral responses to cocaine in female rats by modulating the mesocorticolimbic dopamine system (Lynch et al. 2002; Perrotti et al. 2001; Russo et al. 2003). In humans, this may explain reports of increased responsiveness to cocaine cues and higher quantities of use in women presenting for treatment (Robbins et al. 1999; Kosten et al. 1993). In one study, women reported less pleasurable effects of cocaine during the luteal phase, compared to women in the follicular phase and men (Sofuoglu et al. 1999). As such, women may be more vulnerable to relapse during the follicular phase, when progesterone levels are lower, compared with the luteal phase (Wilcox and Brizendine 2006). In another study, administration of progesterone to women during the follicular phase attenuated the positive subjective effects of cocaine (Evans and Foltin 2006). This is an area of active investigation which could have important implications for treatment.

Neuroimaging studies have also provided important information about the neural processes underlying sex differences in SUDs. During a stress task, female cocaine users showed greater left frontolimbic brain activation than males (Li et al. 2005).

Using positron emission tomography (PET) during cue-induced cocaine craving, Kilts and colleagues found greater activation in women in the dorsal striatum and anterior cingulate cortices and lower activity in the amygdala, which assesses the pleasure of an experience and connects it with its consequences (Kilts et al. 2004). In a recent exploration of sex differences in neurocognitive and brain responses to emotions, stress, and drug-related cues, Potenza and colleagues found that women had greater reactivity to stress-related cues and men showed higher responses to drug cues (Potenza et al. 2012).

Gender differences in the physiologic and subjective effects and medical consequences of opiates, marijuana, and other drugs of abuse are vastly under explored. Considering the important gender differences that have surfaced with careful investigation in the areas of alcohol, nicotine, and cocaine dependence to date, this is clearly an area that warrants attention in future studies and could have major implications for gender-sensitive prevention and treatment efforts.

127.4.2 Pharmacotherapy

The findings concerning gender differences in the neurobiology of substance use disorders and the potential impact of hormones on the subjective effects of substances of abuse and relapse suggest that there may be gender differences in the most efficacious approach to pharmacotherapeutic treatment. Findings from animal studies also indicate important gender differences in response to the medications that can be used to treat addictions. Campbell and colleagues reported that baclofen-treated female rats were less likely to acquire cocaine self-administration as compared to baclofen-treated male rats (Campbell et al. 2002). In another study, ketoconazole was found to decrease opiate self-administration more in female as compared to male rats (Carroll et al. 2001). However, there has been little clinical research exploring gender differences in response to agents currently used in the treatment of substance use disorders. Based on animal research studies demonstrating that progesterone decreases response to stimulants, Evans and Foltin explored the impact of exogenous progesterone on smoked cocaine and found an attenuation of the positive subjective effects of cocaine in women, but not in men (Evans and Foltin 2006). This is clearly an area which warrants further gender-specific investigation.

As detailed above, substance-dependent women are more likely to suffer from mood and anxiety disorders and to be victims of physical and sexual abuse as compared to men. As such, medication treatment of comorbid conditions is likely to be particularly important in the treatment of substance-dependent women. In this regard, one study comparing an SRI (sertraline) to a tricyclic antidepressant (imipramine) in the treatment of depression found that premenopausal women had a preferential response to sertraline (Kornstein et al. 2000). A recent study exploring treatment with a combination of sertraline and naltrexone in individuals with alcohol dependence and major depression found significantly improved alcohol-related and depression outcomes in the combination treatment group (Pettinati et al. 2010).

As such, while the evidence does not support the use of antidepressant medications in the absence of depression in substance-dependent individuals, careful evaluation of depression and psychiatric disorders and appropriate treatment will likely improve treatment outcomes. Other studies have provided preliminary evidence that bupropion, a pharmacologic agent with FDA approval for both the treatment of depression and smoking cessation, may be more efficacious in women as compared to men (Perkins et al. 2000).

127.5 Treatment

Although women are generally underrepresented in substance abuse treatment programs, retention and relapse rates for women are comparable to men (Greenfield et al. 2007; Hser et al. 2001; Mangrum et al. 2006). Data from several studies suggest that women exhibit more favorable treatment outcomes than men. For example, studies have demonstrated that women have shorter relapse periods and a higher incidence of abstinence at 6 months (79.3 % women vs. 54 % men) and 5 years (odd ratio = 1.9) following treatment (Henskens et al. 2005; Dawson et al. 2005; McKay et al. 1996; Moos et al. 2006). In addition, women have a greater improvement in physical health and are more likely than men to seek support after a relapse episode (McKay et al. 1996; Hser et al. 2005; Project Match Research Group 1997).

127.5.1 Gender-Specific Treatment Programs

Arguments in favor of gender-specific treatment include differences in interaction styles and men's traditional societal dominance, which might negatively affect women in mixed-gender programs. Moreover, women and men with SUDs differ significantly in terms of risk factors, co-occurring psychiatric conditions, motivations for treatment, and risks for relapse. Gender-sensitive treatments can address these issues directly and may improve treatment seeking, retention rates, and treatment satisfaction. However, data from studies examining effectiveness of gender-specific treatment programs for women are mixed (Greenfield et al. 2007; Ashley et al. 2003; Copeland et al. 1993; Niv and Hser 2007). For example, residential programs that allow children to accompany their mothers have higher retention rates (Hughes et al. 1995; Szuster et al. 1996). In addition, women enrolled in women-focused outpatient or residential treatments have higher completion rates than women enrolled in standard substance abuse treatment programs (Brady and Ashley 2005; Dahlgren and Willander 1989). Although other studies have found that women-only programs provide similar treatment outcomes as mixed-gender programs, these studies have noted that socioeconomic status, addiction severity, and comorbid psychiatric diagnoses are significant factors in determining the effectiveness of women's treatment programs (Greenfield et al. 2007; Niv and Hser 2007).

Prevention strategies and treatment programs for women must incorporate the culture and diversity of each region. For example, in India, the UNODC has distributed guidebooks outlining prevention strategies to women's groups, health-care providers, legislators, and the public and also sponsored nongovernment pilot programs aimed at prevention strategies particularly for women at risk for the development of SUDs (United Nations Office on Drugs and Crime 2004). In other regions of the country that have a high population of female sex workers and women who are considered "social outcasts," funding has been provided for a SUD treatment center for women that employs peer educators who are often HIV positive and have a history of a SUD (United Nations Office on Drugs and Crime 2004). A general lack of awareness of the prevalence of SUDs in women may interfere with the development of gender-sensitive prevention and treatment efforts in some countries. Thus, identifying ways to include women in epidemiological studies of SUDs may be the first step in garnering support for gender-sensitive treatment programs. In addition, education of treatment providers about gender differences in the etiology of SUDs may help overcome the attitude that women do not require specialized treatment options. It is also critical that standards and guidelines for treatment include measures that protect the confidentiality of victims of domestic violence, restore relationships with family and community members, and use a nonconfrontational approach to therapy. Treatment programs, whether mixed gender or women only, that pay special attention to psychiatric comorbidity, family and parenting issues, victimization, and gender-specific barriers to treatment are likely to be more successful for women.

127.5.2 Gender-Specific Barriers to Treatment

In the United States, women are less likely than men to enter treatment programs (Greenfield et al. 2007). Consistent with this finding, studies from countries that have collected gender-specific data demonstrate that women are consistently underrepresented in SUD treatment programs. For example, in Europe, the ratio of men to women in treatment for marijuana, cocaine, and amphetamine use is 4:1, which is significantly higher than the gender ratio of use for these substances (United Nations Office on Drugs and Crime 2012). Across substance use treatment centers in India, only 3 % of the 16,942 new patients were women. Men represent approximately 76–90 % of patients enrolled in substance use treatment programs across South Africa (Wechsberg et al. 2006; United Nations Office on Drugs and Crime 2002).

Globally, women with SUDs have less access treatment programs and harm reductions services than men with SUDs. For example, although 10 % of all substance users in Afghanistan have access to treatment, only 4 % of female drug users have access to treatment (United Nations Office on Drugs and Crime 2009). In eastern European countries, budgetary constraints and bureaucratic challenges have excluded incarcerated women from antiretroviral and opioid replacement treatments but have not excluded incarcerated men (Fair 2009; Pinkham et al. 2012).

Globally, there are a limited number of gender-based treatment programs. This is particular challenge for women who have been exposed to domestic violence, who may be more reluctant to attend group treatment programs that include men. In addition, there are few treatment programs for individuals with comorbid substance use and psychiatric disorders.

Sociocultural factors (e.g., shame, lack of spousal/family support) can also be significant barriers to women seeking treatment for SUDs. The social stigma attached to substance use in societies that value traditional roles for women as domestic caregivers can prevent women from seeking treatment. Women who drink alone may transition to alcohol dependence without their family's knowledge. In fact, one study found that in South Korea, women sought treatment only after the physical symptoms of drug withdrawal appeared (Lee and Kim 2000). In addition, women living in culturally conservative societies may not feel comfortable discussing sexual abuse and/or may not be knowledgeable of their own family history of SUDs. Relationship dynamics can also impact women's decision to seek treatment for SUDs. Women may be more reluctant to leave home for long-term treatment out of fear that separation from the family will lead to divorce and threaten family stability (Haj-Yahia 2000). In addition, women who are exposed to domestic violence exhibit self-destructive behaviors and are more reliant on their partners and thus less likely to engage in treatment and harm-reduction strategies (El-Bassel et al. 2000; Frye et al. 2001).

127.5.3 Special Issues: Pregnancy

Although global awareness of the adverse consequences associated with maternal substance use during pregnancy has increased, drug use during pregnancy remains a significant problem. For example, in the United States and Canada, 32 % of the 863 pregnant women who were surveyed reported occasional alcohol use, 16 % reported regular alcohol use, and 11 % reported heavy alcohol use (Edwards and Werler 2006). In utero exposure to alcohol is associated with fetal alcohol syndrome (FAS), characterized by irreversible neurological damage, developmental delay, facial malformations, and behavioral problems (Manning and Hoyme 2007). Another study of 1,632 mothers, 25 % reported using tobacco, 23 % alcohol, 6 % marijuana, and 1 % barbiturates during pregnancy (Arria et al. 2006). Screening for substance use in primary health-care and obstetric clinics is problematic since pregnant women face social stigma and legal problems which may prevent them from discussing substance use habits with health-care providers. In some countries, legislation and health-care policies are significant treatment barriers for pregnant women with SUDs. In the United States, laws that criminalize drug use during pregnancy in some states can prevent pregnant women from speaking openly with clinical care providers about their substance use (Paltrow 1999). In Russia and Ukraine, pregnant women with SUDs risk forced abortion and termination of parental rights (Eurasian Harm Reduction 2012; Canadian HIV/AIDS Legal Network and E.V.A 2012).

Pregnant women seeking substance abuse treatment often have additional health problems including HIV and other STDs, as well as psychiatric problems and abusive living situations. Thus, routine screening for trauma, victimization, and depression for this at-risk population is necessary (Tuten et al. 2004; Velez et al. 2006). A multidisciplinary approach to treatment that provides state-of-the-art treatment for SUDs integrated with psychosocial support and psychiatric, medical, prenatal, and gynecological care has been implemented in a number of countries, including Austria, Canada, the Czech Republic, and India (United Nations Office on Drugs and Crime 2004).

127.6 Conclusion

International research clearly indicates that gender-sensitive substance use policies and programs cannot ignore cultural influences. Large cross-national variation in gender differences in substance use disorders makes it clear that biological factors alone do not account for gender differences in substance use and addictions. Policies, education, and prevention and treatment efforts must take into account both the biological differences and the culturally defined gender roles that specify expected and tolerated drug use behavior in men and women. Cross-national research can help to explicate the complex interactions between biology, individual-level, and societal-level variables that influence alcohol consumption and drug use and allow us to design better-targeted prevention and intervention efforts for both genders worldwide.

Older People and Substance Misuse

128

Ilana B. Crome

Contents

Abstract

This chapter will outline the scale of the problem of substance misuse in older people, the burden of disease it incurs, morbidity and mortality, societal costs, and financial liability. Predictions are that over the next 20 years, there will be both an increase in the proportion of older people in the population and that older people will be using more alcohol, illicit substances, and prescription drug use compared with the past two decades. The nature and extent, the predictors and preventive potential, and the adaptations of successful treatment interventions will be outlined. Evidence is provided to demonstrate that the

detection, intervention, and development of care models that are likely to improve the health and well-being of older people with substance misuse should be instituted. This is an area of utmost relevance to all clinicians: old age psychiatrists, addiction specialists, geriatricians, nurses, psychologists, social workers, and their teams. Researchers in gerontology, sociology, and economics, as well as policy makers and commissioners, are likely to find the implications and gaps of interest.

128.1 Introduction

This topic is important because of the scale of the problem, the burden of disease it incurs, morbidity and mortality, societal costs, and financial liability (Crome et al. 2011). In the UK, people over the age of 65 years constitute approximately 18 % of the UK population: the prediction is that by 2020, this will rise to 25 %. This increase in the proportion of older people is reflected in other countries (Han et al. 2009; EMCDDA 2009).

There is accumulating evidence that older people are using more alcohol, illicit substances, and prescription drug use, over the past two decades. National surveys of alcohol, illicit drugs, presentations to accident and emergency units, presentations to specialist services, and hospital admissions for poisoning and drug- and alcohol-related mental and physical disorders demonstrate this upturn. The prediction in the USA and Europe is that this is likely to double in the next two decades both because of the expansion in the number of older people and the rise in substance use by older people. At present, in the UK, it is estimated that 13 % of men and 12 % of women still smoke cigarettes (Seymour and Booth 2010). Indeed, smoking-related disorders are still the largest cause of premature death (Department of Health 2006). Older people receive most prescriptions dispensed by NHS: 45 % of prescriptions dispensed by the NHS are for the over 65s. These are often as multiple medications and it is estimated that 1/10 receive at least one potentially inappropriate drug, though it can be even higher (Chrischilles et al. 1990; Gottlieb 2004; De Wilde et al. 2007; Culberson and Ziska 2008). Psychoactive medications with abuse potential are being used by one in four older people (Simoni and Yang 2006), which is four times greater in women especially those who are widowed, less educated, lower income, poor mental and physical health, and socially isolated. In the USA 60 % of patients attending Accident and Emergency Departments with adverse drug reactions are over the age of 65 years, 25 % of which are psychotropic medications (IOM 2012).

In the UK alcohol consumption above the "safe recommended" limits (for adults) occurs in 20 % of men and 10 % of women over the age of 65. In one decade, there has been a 25 % rise in the proportion of older men and a 300 % rise in the proportion of older women drinking above the recommended daily limits of alcohol (The Health and Social Care Centre 2011). Mortality due to alcohol-related causes has proliferated in parallel with the surge in alcohol consumption. However, the greatest increase in the death rate due to alcohol-related problems is to be found

in those aged 55–74. Furthermore, although presentations to specialist drug services have shown a decline in younger age groups, there is evidence that there is a growth in new presentations to specialist drug services the over 40-year-olds.

Seventeen percent of patients in drug treatment units are over 40 years old (Benyon et al. 2007; Crome et al. 2009; NTA 2010). This is consistent with national surveys which indicate that 5 % of over 45-year-olds used an illicit drug in the previous year and 0.7 % used a Class A drug. Thus, illicit drug use can no longer be considered a "young man's disease." It is estimated that in the USA, 14–20 % of older people have mental health and substance misuse problems (Crane 1998; Oslin et al. 1998; Byrne et al. 1999; Crane and Warnes 2001; Brennan et al. 2003; Moore et al. 2003; Whelan 2003; Blazer 2009; Okura et al. 2010; IOM 2012).

These statistics are of concern as tobacco, alcohol, and illicit drugs constitute the 2nd, 3rd, and 8th leading risk factors contributing to the European disease burden.

There are considerable methodological issues that have to be considered. The age range for older adults can range from 40 to >90 years old. As described above, for drug treatment services, 40 years old is in the higher age range (Sidhu et al. 2012). National surveys often do not include over 60- or 65-year-olds, and, if they do, may not break down those over 60 or 65 into separate cohorts, e.g., 65–69- and 70–74-year-olds. Community-based studies may miss out the heavier drinkers or substance misusers because they do not include those in residential and nursing homes (Blazer and Wu 2009). In the USA, for example, evidence suggests that 25 % of nursing home residents are prescribed a benzodiazepine, with 10 % misusing the drug through lack of vigilance over the potential for long-term dependence (Svarstad and Mount 2005). Older people may suffer serious harm from substance use without being dependent, and indeed the criteria for dependence, which were developed in the adult population, may not be appropriate, valid, and useful for research or clinical purposes. Measurement needs to be relevant and reliable and includes all substances, i.e., alcohol, tobacco, prescribed medications, over-the-counter medications, as well as illicit drugs.

128.2 Costs

The costs of addictive substances to the community are astronomical. The latest estimates which are conservative reveal that alcohol costs the UK approximately £21 billion per annum, of which £2.7 million are health costs, £7 million are crime related, and £6.4 billion are costs in the workplace. Drug-related costs are reported to be £15 million with the costs to the NHS being £0.5 billion, but drug-related deaths are estimated at £1 billion. Ninety percent of the costs are due to crime. Moreover, the wider costs to family, friends, and communities are not quantified (National Audit Office 2008).

There are some specific data on older people (National Information Centre 2011). Older people incur greater costs than younger people. In 2010/2011 the cost of alcohol-related inpatient admissions in England for 55–74-year-olds was more than ten times that for 16–24-year-old age group at £825.6 million compared

with £63.8 million. Eight times as many 55–74-year-olds were admitted as inpatients compared with 16–24-year-olds, i.e., 454,317 with 54,682. In addition, the costs of alcohol-related inpatient admission were £1,994 million or over three times greater than the costs of A&E admissions at £636 million. The cost of admission of older men (£1,278 million) is calculated at almost double that for older women (£715 million).

In short, older people, especially older men, are more costly due to the magnitude and type of admission.

128.3 Distinctive Issues in Older People

There are many myths about older people and about people who have substance problems. The main aim is to attempt to destigmatize and to demystify attitudes to older people with substance problems. With an enriched understanding of the nature and impact of substance problems on older people, this becomes more achievable. However, there has been sufficient knowledge to date which could reasonably drive appropriate management. Even if an older person continues to use substances in exactly the same way they did as an adult, the impact may differ (Crome and Bloor 2005a, b; Crome et al. 2012).

Elderly people take what is readily available (Crome 1984). Older people may mistake tablets for sweets and may also use household products or denture cleaners which may be caustic. Older people have intensified risks for the development of chronic complex physical and mental health problems (Brower et al. 1994). This, compounded with physiological changes intrinsic to the ageing process, makes them more vulnerable to the effects of substances. So, despite the fact that substance use decreases with age, substance use is more dangerous. Older people are more likely to suffer adverse physical effects as substances accumulate due to decreased metabolism. Brain sensitivity to substances may be increased, thus amplifying the consequences of substance use. Older people are prescribed more drugs and are prescribed multiple medications so drug interactions are more likely than in their younger counter parts. Older people may present with somatic symptoms, which may not be attributed to the substance problem, and which may precipitate inappropriate prescription, leading to overdose. Furthermore, acute and toxic confusional states are common and may lead to a muddle over medication. Older people may not comply with medical instructions so that their treatment may not be optimal: they may either take too little or too much, the latter leading to overdose. Older people often take analgesics, sedatives, and hypnotics – all medications with addictive potential – for insomnia, anxiety, and pain. They may not be aware of the complications of taking such medications in themselves, but of the interaction when taken in combination with other prescribed or over-the-counter medications. Medication for substance use and mental health problems may worsen physical health, and medication for physical health may worsen mental health and substance use. Cognitive and functional impairment may be attributed to "ageing" rather than substance use. There is also scope for mistakes due to cognitive

difficulties. Poor recall may result in practitioners not being informed of the medications and other substances patients are taking, and not probing any further. Thus, it may not be obvious that a patient has taken an "overdose," and the presence of physical disease may confuse the picture, and drug use can resemble the physical problems of old age. This does lead to tricky, even unsafe, situations.

128.4 Lifespan Perspective

We now know that addiction can be a lifelong problem (Schutte et al. 2003; Hser et al. 2001; Jacob et al. 2009). It is estimated that about one in ten people with addiction problems begins misusing substances before the age of 19. Traditionally, two trajectories have been identified: older people who have had a lifelong history of substance problems or those in whom problems began in their later years. The original "geriatric giants," iatrogenesis, immobility, intellectual deterioration, incontinence, and instability, can be generated by substance misuse in the older person since substances affect virtually every organ (BGS 2006, 2007; Mehta et al. 2006; Gupta and Warner 2008; Moos et al. 2009). Older people may not need to use excessive amounts – especially if substances are combined – to suffer adverse effects. Delirium and dementia are common as is depression, anxiety, adjustment reactions, complicated grief, bipolar affective disorder, post-traumatic stress disorder, schizophrenia, and personality disorder may present differently in the older person, but it is beyond the scope of this chapter. Suicidal plans and attempts should be elicited. Other features that may include neglect and squalor, hoarding, and fear of falling are some indicators of risk of substance misuse. Falls are the most common health risk for older people who are misusing alcohol due to the impact on muscle tone and balance, and to osteoporosis, which may lead to fractures.

Alcohol may interact with many of the drugs prescribed to older people, e.g., antihistamines, acid-lowering drugs, antiepileptic medications, and antibiotics.

A study of primary care attendees in the USA has drawn attention further to the level of complications related to alcohol use (Moore et al. 2011). They suffered from hypertension (30 %), depression (12 %), gout (8 %), diabetes (5 %), ulcer disease (4 %), liver condition (4 %), and pancreatitis (1 %). Sleeping problems were present in nearly 40 %, gastrointestinal symptoms in 24 %, memory problems in 23 %, feeling sad or blue in 17 %, and tripping and falling in 18 %. Medication prescription further highlighted the potential for mistakes and interactions: 32 % were on antihypertensives, 18 % on ulcer medications, 18 % on nonsteroidal anti-inflammatory drugs, 17 % on antiplatelet medications, 13 % on nonprescription drugs, 12 % on antidepressants, 10 % on sedatives, and 7 % on opioids.

In a study on health conditions among ageing heroin addicts (Hser et al. 2001), 108 survivors were followed up for 33 years. The mean age was 58.4 years and they had used heroin for 29.4 years. Their current use of other drugs was unsurprising: 84 % were smoking cigarettes, 18 % drank alcohol daily, 23 % were using heroin, 21 % were using marijuana, 11 % were using cocaine, and 6 % were using

amphetamines. As with the alcohol cohort described above, there were high levels of comorbidity: 51 % were hypertensive, 50 % were overweight, 50 % had abnormal liver function, 22 % had hyperlipidemia, 33 % had abnormal pulmonary function, and 13 % had elevated blood glucose. They also tested positive for hepatitis C (94 %), hepatitis B (86 %), TB (27 %), and syphilis (4 %). These were considered to be conservative estimates (Cainelli 2008).

128.5 Assessment

The assessment should cover mental and physical state, capabilities, and current support.

Treatment of substance misusers begins with the style of assessment. There are several overarching principles. Though self-evident, unfortunately there is a need to emphasize the importance of providing high-quality treatment to this group of patients because this is too often neglected. This means that compassion, dignity, integrity, and equality with treatment for physical health should inform the manner in which patients are assessed in the first instance. This group has many features that may make them feel especially undervalued, undermined, and with low self-esteem. Health, life circumstances, behavior, status, and personal qualities may all be threatened: being older, in poor mental and physical health, impoverished, in family conflict, socially isolated, involved in criminal activities, with cognitive dysfunction and impaired functional life skills, and perhaps even being an immigrant, a victim of abuse, or a refugee. It is essential that the practitioner should be nonjudgmental and non-confrontational as that is more likely to catalyze rapport and cooperation with the patient, family, carers, and other staff for the assessment and for the implementation of the management plan.

The details of core components in the assessment of substance misuse have been covered elsewhere in the book, but it is worth mentioning that some issues are central to the assessment of older people. As has been mentioned, the presenting problem could well mask the substance use. Substances can cause the complications directly or indirectly by aggravating age-related impairment. A forensic history of public order and acquisitive offenses may shed light on the background. These mainly revolve around social factors which may be pivotal in terms of information gathering and future management. Consent and capacity need assessment in the first instance. Social vulnerability, e.g., isolation, risk of falls, and financial abuse are not uncommon. Social function assessed by activities of daily living and the support by statutory, voluntary, and private care as well as informal social support from family, carers, and friends are essential for formulating the problems. Social pressures arising from substance-using "carers," open drug dealing, and debt are fundamental to appraisal. Ethnicity may inform some of the social behaviors described above.

Any change in pattern of sleep, appetite, and mood should be elicited. A structured approach to the past medical and psychiatric history including impact on occupational and social function, as well as response to treatment, is mandatory.

Details about the substance misuse in the patient and family history of substance misuse may provide pointers.

The social environment of the older person is a key consideration. This is directly relevant to the assessment of the substance problem and medical manifestations, but it has an important bearing on the management plan. Removal of substances of abuse from the home is vital.

A recent study in the USA (Lin et al. 2011) has reported on community-dwelling older adults with mental illness or substance use disorder. Older adults with substance abuse and mental illness had significantly greater risk of having a chronic physical illness ranging from 1.2 for hypertension to 9.9 for dementia. The risk of having a diagnosis of chronic obstructive pulmonary disease, hip or pelvic fracture, or dementia in community-dwelling older adults with co-occurring mental illness and substance use disorder was 1.7–2.8 times as high as in those with mental illness alone. Since when these disorders co-occurred substantially, greater medical comorbidity was found, indicating the need for integration of medical facilities with mental health and substance abuse.

128.6 Barriers to Detection

There are a multitude of explanations as to why older substance misusers are not identified.

Lack of training, too little time, and therapeutic nihilism are some of the factors mitigating against the identification and treatment of substance problems in older people. These barriers can be overcome. Training is a key consideration because if implemented systematically it does give the opportunity to change negative attitudes through improving knowledge and enhancing skills. The UK has embarked on the implementation of a national undergraduate curriculum, and postgraduate training is also being tackled jointly by the Royal Medical Colleges (RCPsych 2012; ICDP 2007). Thus, medical practitioners will become competent in the assessment and management of substance issue.

Substance problems will be regarded as a medical matter. Like any other medical problems, learning how to take a detailed history and having a high index of suspicion will ensure that underreporting of symptoms, misattribution of signs, and increased awareness of subtle presentations in older people will be properly diagnosed. Ageism further legitimizes stereotyping of older people and hinders achieving suitable treatment choices. Training is an essential component in defying stigma particularly in this age group.

Awareness of the nature, extent, risks, and complications is necessary to detect the contribution of the presenting problems to the clinical picture. The practitioner should have a protocol of items and issues relating to ascertaining when any problems may be substance related. Substance problems are protean in presentation and therefore may well mimic almost any physical or psychiatric illness. In the

older person, though, this may be atypical, and could easily be missed, it a systematic approach is not applied by the professional.

In general, any alteration or a change to erratic uncharacteristic behavior or development of symptoms can be a warning sign. Poor response to treatment for medical or psychiatric illness; requests for prescription drugs; evidence of storing or sharing medications; a past family or personal history of substance misuse; a legacy of personal, social, occupational deficits; and perhaps involvement in criminal activities can serve to alert the practitioner. Unexplained falls, changes in eating habits, weight loss, irritability, and agitation are some of the features.

However, there are very specific questions that need to be covered and in some detail. Clarification should be sought from family, carers, colleagues, other professionals, and of course the patients themselves. Meticulous assessment of all substances used over the lifetime, within the last month and week, will do much to provide a picture of the pattern of use including the impact on physical, mental, and social functioning. The need for treatment, the type of treatment, and its success are important features.

Although there are a host of instruments which can support the assessment, there is no one tool that is standardized for older substance misusers and which can detect how the presentation may relate to substance use.

Use of AUDIT or AUDIT-C (a shorter three-item version) and CAGE has been mooted (Saunders et al. 1993; Bush et al. 1998). The AUDIT is not specific to older adults and was outperformed by the MAST-G and the CAGE in a study of elderly male veterans (Morton et al. 1996), though more recently the 12-item AUDIT toll has been shown to be effective in the detection of older problem drinkers (Ryou et al. 2012). Buchsbaum et al. (1992) found that the CAGE could discriminate elderly patients with a history of drinking problems. A short version of the CAGE has been used in elderly, i.e., without the first item (C – have you ever tried to cut down), and has been shown to have improved detection on older people (Hinkin et al. 2001).

The SMAST-G (Short Michigan Alcohol Screening Tool – Geriatric Version) (Blow et al. 1992) was developed as the first short form alcoholism screening instrument for older adults. It is a ten-item tool and a score of 2 or more suggests an alcohol problem. It is useful to detect "at-risk" alcohol use as well as alcohol abuse and alcoholism (Naegle 2008). Moore et al. (2002a) also compared CAGE and SMAST-G and found that the SMAST-G identified older adults who were drinking at potentially harmful levels who had not been detected by the CAGE. A combination of both tools was recommended.

The Alcohol-Related Problems Survey (ARPS) and the Short ARPS (shARPS) were created to screen specifically for older adults. Moore et al. (2002a, b) tested these instruments which identify those at risk and found that they were more sensitive than the CAGE, AUDIT, and SMAST-G. Fink et al. (2002) have also demonstrated utility for the short version in elderly outpatients.

A more recent systematic review by Berks and McCormick (2008) has pointed to implementation problems with the ARPS and concludes that the AUDIT is more appropriate for hazardous and harmful drinking while CAGE is better for dependence.

There are fewer tools for the detection of drug misuse. The Drug Abuse Screening Tool is available in several versions with 10, 20, and 28 items, has been used in a variety of different groups, and has been shown to elicit drug abuse and dependence, though not specifically older people (Yudko et al. 2007). Gallagher et al. (2011) have developed a tool for the assessment of inappropriate prescribing which is of huge significance given the prevalence of prescribed medication in older people and the ensuing problems, and it has been suggested that this be used for screening (Lam and Cheung 2012).

Three important additional areas in which it might be prudent to use simple tests are for the assessment of nicotine dependence, cognition, and depression where the Fagerstrom test, the mini-mental state, and the Beck rating scales, respectively, may be handy. In addition to questioning, the "brown bag review" of prescription medication, over-the-counter medication, prescription herbs, vitamins, topical ointments, and dietary supplements may add to the picture of the patient's problems.

Recently Blazer has reported the DAPA-PC, the Drug and Alcohol Problem Assessment for Primary Care. It is a computerized screening system that quickly identifies substance problems in primary care, but it can be used by psychiatrists as well. It is self-administered and Internet based, and since it scores automatically, it generates the patient profile for medical reference and presents unique motivational messages and advice for the patient. It therefore has the advantage of saving clinicians' time, as patients can be screened in the waiting area. It is suggested that this kind of approach may lead to a more honest revelation by patients as compared with face to face assessments where patients may feel ashamed and shy. The point that the elderly will feel more and more comfortable about using technology of this kind is made. This is likely to have important ramifications for enhancing treatment interventions in the future.

128.7 Trials and Guidelines: Targeting Treatment Effectively

There is a need to be positive about where there is evidence and, while there are still uncertainties, embark on good practice (Mayo-Smith 1997; Crome and Bloor 2006; DOH 2007; Lingford-Hughes et al. 2012). There is opportunity to be proactive around factors of resilience that can drive forward improvement, so while taking account of vulnerabilities, not to give it undue and unhelpful focus. The overall theme very often is to conceptualize treatment of older substance misusers as that of the management of chronic disease (NCCMH 2007a, b, 2011; NICE 2007a, b, 2010; NCC-CC 2010). Guidelines are usually dictated by clinical trials. Unfortunately complex patients are excluded: those who are older, those who are substance misusers, and those with comorbidity. Combinations of treatments are rarely studied, and if they are, samples may not be representative of the complex group. There is much ongoing work, yet more to be done, to reverse the persistent exclusion – or discrimination – of older patients from clinical trials.

128.8 Pharmacological Treatments

Lack of evidence of safety in older people is a continuing issue. This chapter will not describe the use of pharmacological agents since this is dealt with in more detail in other chapters in this book. However, there are some relevant issues to consider. Clinical trials of the many agents that have been developed in the last couple of decades have not included older people. Older people may not exhibit withdrawal symptomatology or the severity of withdrawal with which younger people present. Thus, any pharmacological agent should be used with great caution and preferably initiated by specialists in geriatrics and addiction. Monitoring should be frequent, systematic, and regular depending on whether the patient is in hospital, in a nursing home, or in the community. Close scrutiny for adverse effects needs to be undertaken. Some medications may be contraindicated, e.g., bupropion for smoking cessation and nicotine replacement may be preferred. Benzodiazepines should be used sparingly due to accumulation, and this is especially the case for long-acting ones, e.g., lorazepam. It is also important to ensure the enough medication is given, e.g., confusional state due to withdrawal of alcohol, because the risk of fatality is a serious possibility.

Older people should not be denied pharmacological treatment for the management of withdrawal; for the maintenance of abstinence; for the prevention of complications, e.g., Wernicke-Korsakoff syndrome; and for relapse prevention. They should also be adequately assessed and treated for the mental and physical illnesses, since if this does not take place, treatment for the substance use disorder will be undermined and thought to be ineffective. For example, poor treatment for pain relief can exacerbate substance misuse and vice versa. Ineffective treatment for depression can render treatment for substance misuse unproductive. A multidisciplinary team approach is the most appropriate.

128.9 Psychological Treatments

As with the section above, details about the range of psychological treatments available are not detailed to any great extent as this is to be found in other sections of the book. However, the value of the treatments for alcohol, tobacco, and illicit and prescription drugs that have been evaluated in the older population will be described. This draws on a systematic and narrative review carried out in 2007 (Moy et al. 2011). As a result of a literature search, 16 studies were identified. These were carried out between 1984 and 2005, with 14 being published after 1990. Thirteen were undertaken in the USA, two in the UK, and one in Canada. Most (11) were on alcohol, three related to nicotine, one on opiate dependence, and one on prescription medications. The most common settings were five studies in primary care and four in outpatient programs.

The threshold for inclusion was over the age of 50 years, and most studies had a preponderance on male subjects, though one study was only on older women. The ethnicity of the reported studies was mainly Caucasian. Although the mean sample

size was 704 patients, the range was 24–3,622. Eight studies were randomized controlled trials and eight were cohort studies. Patient follow-up was 1 month–5 years and the mean was 18 months. However, less than half of the follow-ups were conducted after one or more years.

Baseline measures for alcohol varied widely, the most popular were the quantity/frequency (5), timeline follow back (4), and Addiction Severity Index (4). Others included the Gerontology Alcohol Project Drinking Profile, binge drinking episodes, weeks abstinent in previous 3 months, age of onset of alcohol use, diagnosis of alcohol abuse/dependence from the Diagnostic Interview Schedule, Composite International Diagnostic Interview – Substance Abuse Module, Quick Diagnostic Interview Schedule, lifetime use, relapse episodes, Drinker Inventory of Consequences, maximum alcohol use, and the Substance Abuse Inventory.

Psychological measures included Gerontology Alcohol Project personal stress inventory, state-trait anxiety, Beck Depression Inventory, Rotter's Locus of Control Scale, Brief Psychiatric Rating Scale, mental health, depressive symptoms, psychological distress, short form (SF-36) questionnaire, symptoms distress checklist short form (SCL-66), mood, and medical outcomes study short form health survey (MOS SF-12).

Outcome measures included mean number of drinks, number of binge episodes, excessive drinking, clinically significant drinking, alcohol consumption measures, Addiction Severity Index, abstinence measures, and quality of life.

Adherence to medication, attendance at therapy, formal aftercare, and informal aftercare were also assessed in some studies.

Interventions were very wide ranging and included the following:

For alcohol: brief interventions (including brief advice, motivational enhancement, or defined by the Medical Research Council or Project TrEAT; based on 12-step, cognitive behavioral; electic; rehabilitation; therapeutic community; general health promotion, ask, advise, assist, arrange; alcohol-specific modules, sessions on many different areas)

For drugs: methadone maintenance

For smoking: medications, e.g., nicotine replacement therapy, bupropion, and different interventions such as advice from GP/nurse, acupuncture, hypnosis, and advice from family and friends

For prescription drug misuse: peer support/education groups, education and counseling, and goal setting

It was acknowledged that the review had limitations which included a reliance on self-report in ten studies, a relatively low cutoff for "older" population, the use of instruments unvalidated in an older population, the representation of treatment-seeking individuals rather than those in need of treatment, treatment that was not designed specifically for older people in general, and the lack of equity in the programs that may downplay positive gains. There was also lack on randomization in half of the studies, selection bias, short follow-up period, small sample sizes, differing treatment populations, programs, settings, and providers, and the majority based in the USA.

However, there are considerable grounds for optimism and both older men and women should be encouraged to seek help for substance dependence (Satre et al. 2003, 2004a, b). Older adults who seek treatment have the capacity to change and do well when compared with younger patients and can be treated outside an age-specific program (Oslin et al. 2002). The number of patients who achieve their follow-up goal is at least as comparable to that of other populations (Dupree et al. 1984); physicians can help older adults who drink excessively (Fleming et al. 1999); patients in elder-specific programs improve across a variety of domains (Blow et al. 2000); older age should not be a barrier to addressing alcohol problems as there is potential for good outcomes and that patients may have achieved better outcomes in elder-specific programs (Lemke and Moos 2003a, b). It is recognized that information about long-term management requires more development (Oslin et al. 2005). These findings were similar to those on smoking, heroin dependence, and prescription drug misuse (Vetter and Ford 1990; Morgan et al. 1996; Brymer and Rusnell 2000; Firoz and Carlson 2004; Schroeder et al. 2006). Intervention by a nurse practitioner led to a decrease in smoking (Vetter and Ford 1990); older smokers benefitted as much as younger smokers (Morgan et al. 1996) and women found interventions helpful, especially light smokers (Schroeder et al. 2006). Firoz and Carlson (2004) dispelled the myth that older people would have worse outcomes than younger people and in fact, nearly twice the number of older people were rated as being "highly successful" compared with younger patients. Brymer and Rusnell (2000) found that patients responded positively to interventions in terms of reduction in substance use, fewer accident and emergency visits, reduced number of hospitalizations, and improved depression scores and activities of daily living. The funding implications were noted in the latter two studies.

The review concluded that older people do not achieve worse outcomes than their younger counterparts: in some cases they may even do better, even though treatments have been developed for younger people. This was considered a positive message which should raise awareness of the issues and the benefits of help. Of course, it is accepted that there are limitations as outlined above. Mainly the diversity of treatment options made it impossible to compare studies which were usually small. More studies on prescription drug misuse and smoking would be important given the projections in prevalence. Standardization of definitions of age and addiction, administration of common tools, description of psychological and pharmacological interventions, utilization of innovative treatment interventions, and delivery in line with best practice for older people would enhance the implementation of improved provision and allow research to evaluate interventions that are more generalizable. There is a reasonably solid basis on which to take such findings forward but most important to underline the fact that age should be no barrier to support.

More recently several studies have been published: Oslin et al. (2006), Lin et al. (2010), Moore et al. (2011), Gallagher et al. (2011), and Zbikowski et al. (2012) on alcohol in primary care, reduction of inappropriate prescribing, and smoking interventions, respectively. Oslin et al. (2006), in the PRISM-E study, compared enhanced specialty referral to integrated care in at-risk patients treated in

primary care. Drinking reduced in both groups at 6 months, and there was no difference between the groups. Thus, a model of care could not be recommended, as the interventions were both active. In another recent study, Lin et al. (2010) reported that 39 % of the older subjects randomized to an intervention comprising personalized risk reports, booklets on alcohol-related risks, and advice from physicians, followed by a health educator call, had reduced drinking within 2 weeks of receiving the initial intervention. Concern about risks, reading educational material, and the perception of physicians providing advice to reduce drinking were associated with early reductions in alcohol use in at-risk individuals. Schonfeld et al. (2010) examined the effectiveness of the Florida Brief Intervention and Treatment for Elders (BRITE) project. This multisite study showed that prescription drug use was the most prevalent substance use problem followed by alcohol, over-the-counter medications, and illicit substances. Those who had a brief intervention improved their alcohol misuse, medication misuse, and depression. Moore et al. (2011) undertook a randomized controlled trial in 631 primary care patients over the age of 55 years. They were given a booklet on healthy behaviors or a personalized report, a booklet on alcohol and ageing, a drink diary, advice, and telephone counseling. At 3 months the intervention group had fewer at-risk drinkers, fewer drinks in the past 7 days, less heavy drinking, and lower risk scores. Both groups demonstrated improvement and at 12 months there was no difference between them. Their conclusion was that a multifaceted intervention does not reduce the proportions of at-risk or heavy drinkers, but it does reduce the amount of drinking at 12 months. Zbikowski et al. (2012) reviewed 13 randomized controlled trials on smoking interventions and concluded that there was a significant intervention effect in 9 studies. Intensive multimodal treatments were more likely to be associated with improved longer-term outcomes, and of particular interest was the study by Hall et al. (2009) that showed the longer-term efficacy of extended CBT without NRT. A compelling trial by Gallagher et al. (2011), the Medication Appropriateness Index (MAI), and the Assessment of Underutilization (AOU) index were used to assess prescribing appropriateness, both at the time of discharge and for 6 months after discharge. Unnecessary polypharmacy, the use of drugs at incorrect doses, and potential drug-drug and drug-disease interactions were significantly lower in the intervention group at discharge. Underutilization of clinically indicated medications was also reduced. Significant improvements in prescribing appropriateness were sustained for 6 months after discharge.

128.10 Safe Limits

A degree of controversy has surrounded the debate about “safe limits” in older people. It should be noted that there is no such thing as a safe limit! Furthermore the recommended limits for adults are very likely not applicable to older people. The US NIAAA has recommended that for some older people one US drink (14 g of alcohol) a day and no more than seven US drinks per week are sufficient. More than three US drinks a day are considered highly likely to lead to harm. Older people

should be advised not to drink and drive, not to use machinery when they have been drinking, and not to swim after consuming drink. It is advisable to eat before drinking and to drink slowly. For those with comorbid conditions, and those on medications, it could be that no drink is the sensible advice (DOH 1995; RCP 1995; Crome et al. 2011).

128.11 Services: Programs and Models

In each country, the constellation of available, or potentially available, services will differ. Commissioners and providers are likely to establish that there are some consistent characteristics that need to be considered to provision. Services need to be "older person friendly." This includes making the referral process easy, ensuring that there are the facilities and information which older people require (DOH 2009; RCPsych 2009). This includes having staff trained in the needs of older people as well as addiction issues including the capability to counter the negativity and negative stereotypes about older people, information which is age specific in content with perhaps simple explanations if required and administered at the pace which is comfortable for older people. In other words, there needs to be a safe, suitable environment which takes account of the person's mobility, sensory, language, and literacy needs.

Older people now comprise the majority of hospital inpatients, so knowledge about the relationship of substance use to common presenting problems needs not only to be rooted in the main psychiatric specialties of old age psychiatry, liaison psychiatry, and addiction psychiatry but also in accident and emergency medicine, geriatrics, general medicine, general practice, and other health professionals, e.g., residential and nursing homes. In the UK, as in most developed countries, there are few models of service provision specifically for this group of patients. The developing world is even more impoverished.

Bartels et al. (2004) undertook a multisite study to determine whether mental health/substance abuse clinics in primary care were more effective than referral to specialist clinics. Seventy-one percent of patients engaged in integrated treatment compared with 49 % in the enhanced referral model. It concluded that older primary care patients were more likely to accept collaborative mental health treatment within primary care than in substance abuse/mental health clinics due to improved access. This has implications for service developments in a group that under use facilities.

The US National Academy of Sciences has produced a report which recommends how the workforce can be prepared to meet the needs of older people with mental health and substance use (IOM 2012). The range of practitioners from those with minimal education to specialists were considered. These included specialists such as general psychiatrists, psychologists, social workers, psychiatric nurses, and counselors; primary care teams including general physicians, general practitioners, nurses, and physician assistants; specialists in the care of older adults such as geriatricians and geriatric nurses, geriatric psychiatrists, gerontological nurses,

geropsychologists, and gerontological social workers; care workers who provide supportive services; peer support providers; and informal care givers, e.g., family, friends, and volunteers. However, their roles were often poorly defined.

It was suggested that as the "baby boom" generation had had higher mental health service use throughout their lives, it was likely that this would continue, although estimates on which to base accurate predictions were not available. However, it was concluded that the requirement for specialist providers was far in excess of that which was available and that this shortage meant that needs would have to be met by a whole range of providers. The report further highlighted the limited opportunities for recruitment to specialization in terms of financial incentives, support, and mentorship. Professional training was not mandatory, so that it was inconsistent, and where progress had been made, programs with promise were not disseminated or evaluated and were therefore at risk of collapse. Strengthening the roles and training of care workers, carers, and families was outlined.

The report further stated:

> A persuasive body of evidence, drawn from two decades of research, shows that two common MH/SU disorders among older adults—depression and at-risk drinking—are most effectively addressed when care is organized to include these essential ingredients: (1) systematic outreach and diagnosis; (2) patient and family education and self-management support; (3) provider accountability for outcomes; and (4) close follow-up and monitoring to prevent relapse. Moreover, these elements are best obtained when care is patient centered (integrating patient preferences, needs, and strengths), in a location easily accessed by patients (e.g., in primary care, senior centers, or patients' homes), and coordinated by trained personnel with access to specialty consultation. There is also evidence suggesting great promise in telehealth and web-based interventions for older adults with MH/SU conditions. Progress in these areas is not likely to be achieved, however, without practice redesign and change in Medicare payment rules. There is a fundamental mismatch between older adults' need for coordinated care and Medicare fee-for service reimbursement that precludes payment of trained care managers and psychiatry consultation. Finally, research on effective delivery of MH/SU care for certain older populations is urgently needed, especially for individuals residing in nursing homes and other residential settings, prisoners, rurally isolated elders, and older adults with severe mental illnesses.

A major hindrance in the implementation of training, treatment, and evaluation is the multiple agencies and departments within government, the voluntary sector, and private organizations that need to collaborate to agree to deliver education, services, and research. Many countries are facing severe reductions in budgets, and this further deters motivation to embark on so daunting a task, about which there is only partial awareness.

128.12 Training and Competencies

Despite recurrent policy recommendations on the need for training, in many countries undergraduate medical students do not have any systematic training in addiction. In the UK a national curriculum has been developed and implemented.

This ensures that every medical student has to be knowledgeable and skilled in tackling fundamental aspects of history taking, diagnosis, and management (ICDP 2007). However, it is recognized that this training needs to be reinforced and updated, so it is being extended to postgraduate medical practitioners so that they can be competent in the management of drug and alcohol problems (RCPsych 2012). A consensus approach between the 13 medical Colleges and Faculties outlines "core competencies which should be incorporated into the curricula for all doctors." It emphasizes three main components: behavior and attitudes, knowledge, and skills. Importantly, it stresses the need for feeling comfortable and confident when discussing addiction issues with patients, working in a supportive, nonjudgmental, and non-confrontational manner, and taking appropriate action with regard to their own or colleagues' misuse of substances. It describes the areas in which practitioners should be knowledgeable, e.g., the addictive potential of alcohol and drugs including prescribed and over-the-counter medications; the acute effects of intoxication, the chronic harms, and common presentations of problems related to substance use; the range of interventions available; recommended "safe" limits for alcohol; and the impact on the family and community as well as on the individual. Doctors across all specialties need to be competent in the screening, assessment, diagnosis, provision of brief interventions, and further management or referral of substance misuse patients. It notes that while 1.6 million people are alcohol dependent in the UK, only 6 % receive the treatment they need. While this is not specific to older people, the general principle is pertinent, given that the majority of patients are in the older age group. Specialist provision is dwarfed by the prevalence. Expansion in interprofessional training, mentorship, making the experience of working in this area a positive one, and financial arrangements to support training and service development is recommended (IOM 2012).

128.13 Future Prospects: A Matter of Principle

Some fundamental recommendations which can be implemented immediately encompass inclusion of older substance misusers in all relevant policy documents and in all clinical trials related to substance problems. Furthermore, older people with substance problems should be a focus of training in all medical and allied professionals throughout their professional career and should be a priority area for research. Research into the nature and extent, the predictors and preventive potential, and the adaptations of successful treatment and novel interventions is of high priority, though there is sufficient information to insist that, without delay, detection, intervention, and development of care models that are likely to improve the health and well-being of older people are instituted.

This is an area that should be of concern to all clinicians: old age psychiatrists, addiction specialists, geriatricians, nurses, psychologists, social workers, and their teams. It should be of interest to researchers in gerontology, sociology, and economics and to policy makers and commissioners. How we decide on

provision for this group of people is a measure of how we treat some of the most vulnerable and disenfranchised people in our communities.

Addiction and Lesbian, Gay, Bisexual and Transgender (LGBT) Issues

129

Steven Joseph Lee

Contents

Abstract

This chapter examines addiction issues particular to lesbian, gay, bisexual, and transgender (LGBT) people. This includes a description of the available epidemiological data on substance use and addiction in the LGBT community, as well as a discussion about unique psychosocial issues that LGBT people face that increase their risk of substance use, such as stigma, social rejection, discrimination, harassment, HIV, issues specific to adolescents and young adults, internalized homophobia, and transphobia. Because the vast majority of research on substance abuse in the LGBT community is from North America, examples of social settings and substances specific to this LGBT community are used to illustrate how specific drugs can develop a unique appeal to an LGBT community in response to the psychosocial environment and stressors that a specific LGBT community faces. Substances discussed include methylenedioxymethamphetamine (MDMA, ecstasy), methamphetamine, gamma-hydroxybutyrate (GHB), anabolic steroids, and cross-gender hormones. In other LGBT communities, different psychosocial

stressors lead to unique substance abuse patterns that must be understood to adequately treat addiction in those populations. General recommendations are made regarding the provision of clinically competent care for cases of LGBT addiction, and common clinical scenarios are discussed. The need for research on substance abuse patterns in LGBT populations is sternly emphasized in order to improve understanding of local patterns of substance abuse and to improve the provision of treatment to those populations.

129.1 Introduction

Addiction among lesbian, gay, bisexual, and transgender (LGBT) people requires special attention because patterns of substance use and abuse differ markedly between LGBT people and the general population. Studies examining LGBT addiction, which will be detailed below, indicate a higher prevalence of substance use disorders among LGBT people. Despite the increased risk of addiction, there is a relative lack of research studying the prevalence, causes, and consequences of LGBT addiction. In addition, training clinical training programs incorporate little to no education specific to LGBT people (Makadon 2006; Tesar 1998).

LGBT people face unique psychosocial stressors that lead to an increase in addictive substance use. Many of these people use drugs and alcohol as a way of coping with these stressors, which are largely related to homophobia and transphobia (transgender phobia). Examples include adolescents who are rejected by parents and become homeless, sometimes resorting to sex work in order to survive; people who lose their jobs or housing because of homophobia and have no legal recourse; people who are verbally harassed or physically assaulted because of their sexual orientation or gender identity; and people who hear repeated denigration of homosexuality in their religious places of worship. All of these examples can cause an immediate negative psychological response, but over time such events may also be insidiously incorporated into an individual's sense of self, resulting in the self-hatred of internalized homophobia.

LGBT people also have particular consequences of substance abuse. For example, methamphetamine use in North America has a much higher prevalence among gay men compared to the general population, and in this community it has a strong association with unprotected anal intercourse. As a result, gay men in North America have a significantly higher risk of infection with HIV or other sexually transmitted diseases (Lee 2006).

Clinicians must be familiar with LGBT-specific issues so that they can adequately understand and treat addiction in this population. However, because of the lack of clinical training in LGBT issues, most addiction specialists are not prepared to effectively treat LGBT addiction. In response to this need for improved LGBT treatment, LGBT-specific treatment programs have been developed. The goal of this chapter is to familiarize the general addiction clinician with the most relevant LGBT issues to improve the availability of competent clinical services to this population.

Unfortunately, the vast majority of date pertaining to drug use and addiction among the LGBT people is limited to North America. Because of the wide variation in cultures and local conditions in which people live, this chapter is not able to describe the issues and make specific treatment recommendations for the people of all countries. Rather, this chapter provides examples of challenges that some LGBT people face and how they may resort to substance use as an attempt to cope. At the conclusion of this chapter, consideration will be given to how the information in this chapter may be useful to clinicians from countries outside of North America.

129.2 LGBT Features

129.2.1 Epidemiology

Data on the prevalence of substance use and substance use disorders among LGBT people in North America vary widely, though most studies show higher rates when compared to either the general population or heterosexuals. Early studies had significant methodological problems, such as inconsistent definition of homosexuality, nonstandardized measures of substance use, small homogenous samples, lack of controls or comparison groups, and considerable sampling bias. For example, some studies obtained their study samples from gay bars – at one time the only place where gay men could be found because most hid their sexual orientation – which likely inflated the observed rate of alcoholism (Anderson 2009). Most studies and reports estimated an incidence of approximately 30 % among LGBT people, compared to 10–10 % for the general population (Cabaj 1996).

More recent research does not show such high prevalence, but continues to find an increased rate of drug and alcohol use and dependence among LGBT people (Cochran et al. 2003; Drabble et al. 2005; Fergusson et al. 2005; Hughes and Eliason 2002; McCabe et al. 2009; Meyer et al. 2003; Wilsnack et al. 2008). Cochran et al. (2004) found a moderate elevation of drug, particularly marijuana, use dependence in gay and bisexual men and women when compared to heterosexuals.

A more recent study by McCabe et al. (2009) examined US data with a large national sample of 34,653 from the 2004–2005 (Wave 2) National Epidemiologic Survey on Alcohol and Related Conditions (NESARC), finding that 16.8 % of gay-identified men met DSM-IV criteria for past-year alcohol dependence compared to 6.1 % of heterosexual-identified men, 0.6 % of gay-identified men met criteria for marijuana dependence compared to heterosexual-identified men, and 3.2 % of gay-identified men met criteria for other drug dependence compared to 0.5 % of heterosexual-identified men. Among females, 13.3 % of lesbian-identified women met criteria for past-year alcohol dependence compared to 2.5 % of heterosexual-identified women, 2.8 % of lesbian-identified women met criteria for past-year marijuana dependence compared to 0.2 % of heterosexual-identified women, and 5.7 % of lesbian-identified women met criteria for past-year other drug dependence compared to 0.4 % of heterosexual-identified women.

Other studies showed little difference between the patterns of alcohol use among gay and bisexual men compared to heterosexual men. However, other drug use was found to be higher among urban gay and bisexual men (Drabble et al. 2005; Stall et al. 2001). Several studies, however, found that lesbians had higher rates of heavy alcohol consumption and alcohol dependence, as well as more alcohol-related problems and a higher likelihood of prior substance abuse treatment compared to heterosexual women (Gruskin and Gordon 2006; Roberts et al. 2005; Drabble and Trocki 2005).

Overall, recent research has found that nonheterosexual orientation is associated with a higher risk of substance use and dependence. This higher risk should inform more targeted efforts in the development of intervention and primary prevention.

129.2.2 Psychosocial Issues Unique to LGBT Individuals

While rates of substance use disorders vary widely among studies, research data is consistent in showing that prevalence of substance use in the LGBT community is higher than the general population. Early on when homosexuality was considered a mental disorder, it was hypothesized that homosexuality itself was the cause of increased rates of alcoholism (Israelstam and Lambert 1983). However, this notion has never been proven and has long been discarded (Israelstam and Lambert 1986). Instead, research has found that LGBT people face unique stressors because of their minority status, such as harassment, discrimination, violence, and social rejection. All of these stressors are associated with higher rates of substance abuse, regardless of sexual orientation or gender identity. The following section will describe the particular stressors that LGBT face and how they relate to substance use as a maladaptive way of coping.

129.2.2.1 Stigma and Phobia Based on Sexual Orientation and Gender Identity

The most common problems that LGBT people face all stem from homophobia, heterosexism, and transphobia. A review of 24 separate studies looking at anti-gay experiences found that 80 % of respondents had been verbally harassed, 44 % of respondents had been threatened with violence because of their sexual orientation, 33 % had been followed or chased, 25 % had objects thrown at them, and 13 % had been spit upon (Berrill 1992). When individuals become the victims of such attacks, their sexual orientation itself becomes a source of pain and danger. As victims try to make sense of their attacks, many internalize the beliefs of their aggressors, and they believe that the attacks were justified punishments for being gay. This internalized self-hatred can lead to profound feelings of anxiety, helplessness, and depression (Garnets et al. 1990). Alcohol and drugs are common ways to attempt to deal with anxiety and depression. This is not a reaction specific to the LGBT population. Studies sampling the general population find that victimization, violence, trauma, and ostracism have all been associated with increased rates of substance use (Alegria et al. 2010; Johnson et al. 2010; Khoury et al. 2010).

Heterosexism pervades American society, and legally sanctioned discrimination is still common. At the time of this writing, anti-sodomy laws persist in over half the state of the United States, same-sex marriage is not legal in 44 states, and in most places there are no legal protections against discrimination based on sexual orientation. Under President Barak Obama, the ban on gays in the military was finally lifted, with heavy opposition by right-wing conservatives. In a telephone survey conducted by the San Francisco Examiner, 47 % of gays and lesbians reported some form of discrimination with jobs, housing, health care, or in other settings (San Francisco Examiner 1989).

Repeated discrimination causes a profound sense of victimization, and the lack of legal policies to protect LGBT people from discrimination leaves LGBT people feeling even more helpless. With no institutionalized protections, the message to LGBT people is that society as a whole rejects them. In contrast, heterosexuals who experience discrimination based on race, religion, or some other nonsexual orientation issues have legal protection and can take recourse. This deepens the sense of helplessness of LGBT people, and alcohol and drugs become a common way to cope with this ongoing pervasive stress. A study by the University of Michigan found that over two thirds of gay, lesbian, and bisexual adults surveyed had experienced discrimination based on sexual orientation, race, or gender. Those who reported all three types of discrimination were four times more likely to have a current substance use disorder compared to those who did not report discrimination (McCabe et al. 2010).

Through the process of "coming out" or making one's sexual orientation explicitly known to others, as well as fully acknowledging it to oneself, many LGBT people are able to overcome the negative impacts of heterosexism, homophobia, and transphobia. However, LGBT people who have not come out, continue to wish that they were heterosexual or to deny their true gender identity, or have little contact with the LGBT community are found to experience greater psychological distress (Bell and Weinberg 1978; Hammersmith and Weinberg 1973; Maylon 1982; Weinberg and Williams 1974).

Some people who still feel intense self-hatred may use mood-altering substances to numb or lessen feelings of fear, anxiety, or self-loathing. Certain substances disinhibit people, allowing them to act out the natural sexual urges that their internalized homophobia condemns. In both these situations, relief is only temporary, and during withdrawal from drugs or alcohol, the negative feelings can be intensified, increasing the likelihood that a person will use those substances again to experience relief.

129.2.2.2 HIV and AIDS

HIV continues to be a significant problem faced by the LGBT community. Dealing with HIV involves coping with multiple medical issues, as well as the stigma associated with HIV and AIDS. For most, the process is a difficult one, and psychiatric symptoms such as depression, anxiety, fatigue, sleep disturbances, and memory problems are common. One study of HIV-infected people in North Carolina found that 60 % of study subjects reported psychiatric symptoms

(Whetten et al. 2005). Another study found that 54 % of people living with HIV reported symptoms of depression in the past week (Eller et al. 2010).

The emotional stress caused by HIV puts HIV-positive people at increased risk of developing problems with substance abuse, as they may use substances to manage difficult emotional states. Sedating drugs such as alcohol, sedatives, and opiates decrease anxiety and emotional pain or assist with psychological attempts to deny one's problems. Stimulants such as cocaine and methamphetamine elevate depressed mood, distract one's attention from current problems, and combat certain symptoms of HIV infection, such as fatigue and decreased libido (Nakamura et al. 2009; Prestage et al. 2009). Methamphetamine in particular has become popular among some MSM with HIV. Some report that methamphetamine helps them overcome feelings of isolation through a sense of connectedness to other HIV-positive MSM who also use methamphetamine, making up an underground community of antiestablishment methamphetamine users. This rebellious counter-culture attitude of methamphetamine use gives some HIV-positive men a sense of empowerment that lessens feelings of helplessness. Indeed, substance use rates are elevated among people with HIV. In one study of HIV-positive MSM, 64 % reported alcohol use, 36 % reported marijuana, 27 % used nitrate inhalants ("poppers"), 13 % used cocaine, and 12 % used amphetamines/methamphetamine (Purcell et al. 2001).

In addition to the addictive and mood problems associated with substance use, several substances have been found to accelerate the disease progression of HIV. Frequent consumption of alcohol is associated with both increased viral load of HIV and decreased number of CD4 lymphocytes. The decline in immune function is the result of both decreased adherence to HIV medications and a direct effect of alcohol on immune cells (Baum et al. 2010). Stimulants such as cocaine, amphetamines, and methamphetamine accelerate the spread of HIV in certain immune cells that introduce HIV into the brain (Gaskill et al. 2009). Methamphetamine in particular has been shown in numerous studies to increase replication of HIV and accelerate brain damage caused by the virus (Nair et al. 2010; Marcondes et al. 2010).

Another concern about drugs of abuse and HIV is the increased risk to HIV-negative people of contracting HIV. All mood and consciousness-altering substances can affect sexual behavior and decisions about taking precautions to protect oneself from HIV infection. Several studies have demonstrated increased casual sex and decreased condom use associated with the use of alcohol, marijuana, and methamphetamine (Hasse et al. 2010; Hendershot et al. 2010; Townsend et al. 2010).

129.2.2.3 Ethnic Minority Status

Individuals who are "double minorities" – sexual minorities and ethnic minorities – face many challenges that are often not understood by others. In addition to the discrimination and stigma that each group deals with, there is additional stress from the conflict that arises between the two minority identities. Certain ethnic groups have particularly strong homophobic beliefs, with inflexible

ideas about gender behavior. The mainstream, predominantly Caucasian LGBT community, may be so culturally different from one's ethnic community that one often feels caught between the two worlds. Choosing one community over another can leave people with a guilty feeling that they have abandoned the other community, and those individuals are forced to deny a part of their identities. This intense psychological stress increases the likelihood that ethnic minority LGBT people will use drugs or alcohol. In one study of black gay men who use methamphetamine, the drug was identified by users as a coping tool for depression and anxiety; stigmatization from sexual identity, race, and or HIV status; and feelings of being excluded from both the black community and the white gay community (Halkitis 2009; Halkitis and Jerome 2008; Jerome 2007).

Various studies have found increased rates of drug and alcohol use among black and Hispanic men who have sex with men. A New York-based study found that African-American MSM reported a significantly higher number of drinks per occasion compared to other ethnicities (Irwin and Morgenstern 2005). In a study of gay men recruited from gyms, African-American men were almost twice as likely to report use of methamphetamine compared to white men (Halkitis et al. 2008). Studies of Hispanic gay men have similar findings. Methamphetamine use has been found to be higher in those Hispanic gay men who choose the mainstream gay community over their Hispanic communities and who have less language attachment to those communities (Fernandez 2005, 2007). A study of transgendered people of color in Washington, DC, found that 48 % of those surveyed reported a substance abuse problem (Xavier et al. 2005). There is an unfortunate lack of research examining the prevalence of substance abuse among ethnic minority lesbians.

Ethnic minority LGBT community organizations are important resources that address the difficulties that double minority individuals face. They offer experienced support, as well as reinforce the belief that one does not have to choose between one's ethnicity and sexual orientation or gender identity.

129.2.2.4 Youth and Coming Out

Adolescence is a developmental stage that is associated with experimentation and substance use. In addition to the usual difficulties of adolescence, LGBT youth have the additional challenge of trying to understand their sexual orientation and gender identities and dealing with stigma from largely heterosexist peers. Trying to cope with homophobic attacks, both physical and psychological, and risking rejection by peers, family, and teachers, LGBT teens often feel helpless and alone. This increased psychological stress during a time when teens are already experimenting with alcohol and drugs puts LGBT adolescents at significant risk of developing substance abuse problems. Alcohol and drug use early in life significantly influences substance use patterns later in life, and substance abuse among LGBT teens can lead to serious addictive problems in their adult years (Parks et al. 2007).

A study of students in Illinois found that the youth who identified as gay, lesbian, or bisexual and the youth who were questioning their sexual orientation were more likely to report high levels of bullying and victimization compared to the

heterosexual youth. Those who were questioning were found to have the highest levels of bullying compared to the heterosexual youth, as well as those with firmly established LGBT identities. High levels of bullying were found to correlate with higher levels of depression, suicidal thoughts, and substance use (Birkett et al. 2009).

Family acceptance is extremely important to the psychological well-being of adolescents. Unfortunately coming out threatens family acceptance for many LGBT youth. A San Francisco study looking at the effects of family rejection of sexual orientation and gender expression showed that gay, lesbian, and bisexual young adults who reported high levels of rejection during adolescence were 8.4 times more likely to have attempted suicide, 5.9 times more likely to report high levels of depression, and 3.4 times more likely to use illegal drugs, compared with gay, lesbian, and bisexual young adults who reported little or no rejection from their families (Ryan et al. 2009).

Homelessness is a tragic consequence for many LGBT youth who are rejected by their families. Homeless youth who are sexual and ethnic minorities are at increased risk of resorting to sex trade for survival (Walls and Bell 2010). In addition to physical danger, the sex trade exposes youth to drug use. Drugs are often used to enhance the psychological state required to do sex work, and drugs and alcohol are also used to cope with the stresses of resorting to sex work.

The behavior of role models significantly shapes attitudes that young LGBT people have about alcohol and drugs. For those newly coming out, bars and clubs are the first significant social contact that many youth have with the LGBT community. Drinking and club-drug use become normalized early, and for some individuals, drugs and alcohol become an integral part of their social and sexual behavior. This topic will be discussed further in the section on social venues as triggers for substance abuse.

LGBT adolescents encounter numerous life stresses that are associated with increased drug and alcohol use, and indeed, many research studies have found elevated rates of substance use among these teens (Birkett et al. 2009; Coker 2010; Ryan et al. 2009). Gay, lesbian, and bisexual youth report higher initial rates of substance use, and their use over time increases more rapidly than heterosexual youth (Marshal et al. 2009). One study found that gay, lesbian, and bisexual youth are 190 % more likely than heterosexual youth to use alcohol or drugs. In particular, bisexual youth are 340 % more likely, and females are 400 % more likely to use drugs or alcohol compared to heterosexual youth (Marshal et al. 2008).

Research indicates that there are concrete ways of addressing some of the causes of such high rates of substance use in LGBT youth. Schools have the ability to affect health outcomes and decrease drug and alcohol use in LGBT teens by creating positive climates for sexual minority youth and instituting policies that actively address bullying and homophobic teasing. In addition, schools, community programs, or other social services can decrease LGBT substance abuse by working with LGBT youth and their families to provide education and foster greater family acceptance.

129.2.2.5 Social Settings as Triggers for Substance Use

Historically, one of the earliest settings where LGBT people could meet socially was bars. Similar to the days of prohibition, gay bars were discreet underground places where LGBT people came secretly to find other LGBT people, whether for sexual encounters or for simple social connection. After the Stonewall riots, which broke out after the police raided a gay bar in New York City's Greenwich Village, gay bars became a community institution, no longer just providing a place to congregate, but also becoming a symbol of the gay community's right to exist.

Because of the importance that bars hold in the LGBT community and the lack of other social institutions that fulfill the community's needs, bars have become the focus of social life for many LGBT people. To frequent a gay, lesbian, or transgender bar was to be socially connected and to feel part of a community, when LGBT people otherwise felt isolated. For many people, drinking became associated with positive feelings of group membership. In addition, alcohol helped decrease the anxiety of coming to a secret place, hidden from heterosexual people. It helped with the anxiety of meeting new friends or sexual partners, and it helped to medicate difficult feelings around one's sexual orientation and gender identity. For many people, alcohol is present during their first social experiences in the LGBT community and first same-sex sexual encounters, and for some it becomes an integral part of these experiences in the future. A strong association is established between alcohol and most aspects of socializing, and the increased exposure to alcohol increases the risk of developing alcohol use disorders.

Circuit parties are a popular venue with some gay men that exposes them to extremely high levels of drug use. Circuit parties began as private house parties in the 1980s that grew in size to large-scale parties with thousands and sometimes over 10,000 people. These parties are sexually charged, with men dancing shirtless and with very little clothing. Sexually uninhibited behavior often occurs on the dance floor or in back rooms. For many gay men, who may travel thousands of miles to these events, circuit parties are a celebration of sexual liberation. In contrast to the social rules of a generally heterosexist society, circuit parties encourage openly gay sexual expression, and for many gay men, they are an important social ritual that helps to define their gay identity.

Club drugs [methylenedioxymethamphetamine ("ecstasy"), ketamine ("Special K"), gamma-hydroxybutyrate ("GHB"), and crystal methamphetamine] are commonplace at circuit parties. Many of these drugs enhance the experience of liberation, social bonding, and sexual disinhibition that partiers seek. In fact, drug use is the cultural norm at these events (Mattison et al. 2001; Lee et al. 2003; Ross et al. 2003; Weidel et al. 2008). A San Francisco survey of gay men who attended circuit parties found that 80 % of survey respondents used ecstasy, 66 % used ketamine, 43 % used crystal methamphetamine, 29 % used GHB, 14 % used sildenafil (Viagra), and 12 % used amyl nitrite ("poppers"). More than half of survey respondents in one study used four or more drugs at the same event (Colfax et al. 2001).

Club-drug use is an integral part of circuit parties, and for some gay men, circuit parties are their first exposure to these substances. While the initial motivation for attending circuit parties is usually social, drugs become so intertwined with the experience that they gradually become one of the predominant reasons people attend. A survey of 1,169 gay men who attended circuit parties found that while the majority of party goers were attracted to the social aspect of the parties, 13 % identified three or more of their motivations to be related to drugs and sex (Ross et al. 2003).

While the Internet is not a physical space, it is a virtual setting in which increasing numbers of LGBT people connect and communicate. People who live in remote areas or in communities with few LGBT members are able to contact and exchange ideas with others, and this new social setting decreases the sense of isolation felt by many people who otherwise would have little contact with other LGBT people. For those in urban or suburban areas, the Internet has become the new gay bar, serving as the place where many people go searching for companionship or sex. Gay men, lesbians, and bisexuals are more likely than heterosexuals to use Internet personal ads to meet others (Lever et al. 2008), and surveys estimate that 33–51 % of gay men have used the Internet to meet other men (Ogilvie et al. 2008; Bolding et al. 2005; Chiasson et al. 2007).

Although bypassing the bar and club scene seems like it would reduce alcohol and drug consumption, the Internet has become an active meeting place for gay men seeking methamphetamine-fueled sex. A culture and language has developed around Internet methamphetamine sex, with commonly used terms such as "PNP" (short for "party and play") and "chemistry-fueled sex," both referring to sex with methamphetamine. Many men report that they were first exposed to methamphetamine through sexual partners they met on the Internet.

One of the effects of methamphetamine is a dramatic increase in sexual desire and pleasure. During methamphetamine binges, some men have sex for hours to days, sometimes with multiple partners, with little to no sleep. The intense focus on sexual pleasure is so strong that some men decide against using condoms during anal sex (Mansergh et al. 2006; Mimiaga et al. 2010; Balan et al. 2009; Taylor et al. 2007), and methamphetamine is likely one of the major reasons for the increasing rate of new HIV infections among gay men each year. The Internet serves as a way of connecting methamphetamine users and providing them with easy access to drugs and sex. In fact, there has been a growth of underground member-only websites where members share videos of sex and injecting methamphetamine, and members openly discuss seeking drug-fueled sex. This ability of methamphetamine users to remain hidden from others through the use of the Internet has made it difficult for education and outreach services to reach them. Consequently, they do not access treatment services until much later, when their addiction is more severe. Recent research has been investigating online interventions to help MSM decrease their HIV-risk behavior (Rhodes et al. 2010; Chiasson et al. 2009). Similar online interventions need to be developed to reach the online community of gay male methamphetamine users.

129.2.3 Treatment and Obtaining Culturally Competent Care

129.2.3.1 LGBT-Specific Treatment Programs

The first addiction treatment center to offer services specifically for LGBT people was the Pride Institute in Minnesota, which opened its doors in 1986 (Ratner 1988). Since that time, a small number of programs have emerged that cater exclusively to LGBT clients. These programs usually have several LGBT clinicians and staff, and those who are not LGBT are screened for their sensitivity to LGBT people and issues. They are supportive environments where sexual orientation and gender identity are not stigmatized, and homophobia and transphobia do not pose treatment barriers to clients. If a person encounters homophobia or transphobia in the treatment setting, feelings of victimization and isolation make it difficult to experience the support from fellow clients and staff that are necessary for therapeutic change. LGBT programs have specialized knowledge about clinical issues common to LGBT substance abuse clients, such as stigmatization, victimization, coming out, histories of rejection by family of origin or peers, internalized homophobia, sexual addiction, same-sex domestic violence, and HIV. These clinical issues are often related to the development of substance abuse and addiction, and in these specialized programs, they can be explored in depth by experienced clinicians in a nonjudgmental environment.

After the Pride Institute opened in 1986, a handful of other private organizations opened to serve the LGBT community. Alternatives, located in Los Angeles, CA, offer inpatient rehabilitation, as well as intensive outpatient treatment. Smaller organizations, such as New Leaf Services in San Francisco and Montrose Counseling Center in Houston, TX, provide solely intensive outpatient services, with individual counseling and group therapy.

Some LGBT-focused health centers in metropolitan areas have expanded their programs to include chemical dependency treatment services. Examples include the Fenway Community Health Center in Boston, the Howard Brown Health Center in Chicago, the Whitman-Walker Clinic in Washington, DC, and Lyon-Martin Health Services in San Francisco, a facility specializing in the care of lesbian, bisexual, and transgendered women.

The demand for LGBT-focused addiction treatment centers remains high, and some LGBT community centers have developed addiction services to address their local community needs. An example is Center Care Recovery at the LGBT Community Center of New York, which has become a fully state-accredited addiction treatment program. The Los Angeles Gay and Lesbian Center offers outpatient individual and group counseling, with a particular focus on crystal methamphetamine.

Another way that LGBT services have grown is through the development of LGBT "tracks" or dedicated units within a general population treatment facility. An example is the LGBT Inpatient Treatment Program at Brattleboro Retreat, a historic facility dating back to 1834, with a pioneering philosophy of humane treatment of mentally ill patients. Smaller organizations have incorporated LGBT tracks into their programs, such as the Realization Center, an outpatient addiction treatment

facility in New York that offers clients in their general program the option of gay-focused support groups. Unfortunately, while many organizations may market themselves to the LGBT community, it is questionable whether they actually provide LGBT-specific services. In a 2004 study looking at substance abuse treatment programs in the United States and Puerto Rico, 11.8 % of the programs claimed to offer LGBT-specific services. However, of that 11.8 %, 70.8 % were no different from substance abuse treatment programs for the general population (Cochran et al. 2007).

Because of the small number of LGBT programs and the limited options available, many people wonder how essential LGBT-specific services are to recovery from chemical dependence. LGBT-focused programs are helpful options for people who are struggling with coming out and are not yet comfortable discussing their personal lives; people for whom inner conflict about one's sexual orientation or gender identity is a significant factor in their drug or alcohol use; trauma victims of homophobic or transphobic attacks; and people for whom drug-associated activities, such as compulsive sex with methamphetamine, are difficult to discuss in a general population setting. Otherwise, if a general treatment program is welcoming and supportive, it can be equally effective at helping someone achieve sobriety. A study of 162 - methamphetamine-using gay men looked at the outcome of those randomized to general treatment versus gay-specific treatment. While those who were in the gay-specific treatment showed a greater reduction in risky sexual practices, such as anal sex without using condoms, there was no difference in the rate of abstinence between the gay-specific and the nonspecific treatments (Shoptaw et al. 2005). While there are some clear benefits to LGBT-specific programs, such as greater comfort in discussing important life stresses, it is important to understand that significant benefit can be achieved at any program that is generally supportive.

129.2.3.2 Finding Clinically Competent Care

Clinical training in LGBT issues is generally lacking in all the mental health-related fields, including social work, psychology, and medicine (Hellman 1996; Makadon 2006; Tesar and Rovi 1998). A survey of 116 medical schools with departments of family medicine found that over half of the schools did not address homosexuality or bisexuality at all. For those that did, an average of 2.5 h total over the course of a 4-year program was devoted to addressing LGBT issues, mostly in the format of lectures on ethics and human sexuality (Tesar and Rovi 1998). The field of social work has been more active in advancing LGBT education. In 1991 the Council on Social Work Education established a requirement that content on sexual orientation be included in all accredited social work programs.

Educational requirements for certified drug counselors vary by state. In New York State, the Office of Alcoholism and Substance Abuse Services (OASAS) recognizes the importance of understanding specific community issues in working with substance abuse clients, and OASAS strongly recommends the inclusion of

racial and ethnic special needs to be in training curricula, yet there is no such recommendation for LGBT issues in education. This author is not aware of any state that requires LGBT content in drug counselor training programs.

A study of urban and rural drug counselors' attitudes about LGBT clients found that both groups had little formal education about LGBT issues, and more than half of counselors had negative or ambivalent attitudes toward LGBT clients. Many of the counselors lacked knowledge of basic social issues that impact LGBT drug and alcohol use, such as internalized homophobia, issues relating to family of origin and current family, and relevant legal issues. Although urban counselors had more contact with LGBT clients and underwent more LGBT-specific education than rural counselors, they did not report any more positive attitudes or knowledge of relevant LGBT issues compared to the rural counterparts (Eliason and Hughes 2004). More extensive education about LGBT issues and training around LGBT sensitivity is needed for clinicians at all levels to more effectively treat LGBT substance abuse clients.

129.2.3.3 Should My Care Provider Be LGBT?

There is significant debate as to whether LGBT clinicians are better suited to work with LGBT substance abuse clients. Heterosexual counselors and those with few LGBT friends have been found to have stronger negative biases against LGBT individuals compared to LGBT counselors (Cochran et al. 2007). A study of 126 gay, lesbian, and bisexual-identified people divided subjects into two groups: one group was read a vignette of a counselor that used heterosexist language; the second group heard the same vignette with the heterosexist language removed. Significantly more respondents responded positively to the vignette free of heterosexist language, and those respondents were much more likely to return to see the counselor, to disclose their sexual orientation, and to discuss personal information (Dorland and Fischer 2001). There is plentiful research examining the effect of similarities between therapist and client. One study looking at African-Americans found that those engaged in treatment with African-American therapists felt better understood and accepted, and they described a better rapport with their therapists, as well as an ability to be open in sessions (Jones 1978). There are similar findings for matching other ethnicities and gender. In addition to client comfort level, the LGBT therapist may have greater familiarity with client's experiences, such as growing up as a minority in a heterosexist society or experiencing unresolved internalized homophobia. The client can spend less time in therapy explaining these phenomena to an inexperienced therapist, and therapeutic work can begin more quickly. An LGBT therapist who is open about his or her sexual orientation or gender identity can also serve as a role model for the client.

Together with the advantages of LGBT therapists, there are many potential pitfalls. The most common difficulty is the therapist overidentifying with the client. Both therapist and client may assume that because they share some experiences, their reactions to those experiences are the same. The therapist may make incorrect assumptions about the client or may fail to explore a topic that was insignificant in

the therapist's personal experience but was traumatic to the client. Therapists may have difficulty keeping an open mind to reactions different from their own and may incorrectly perceive their own views in the clients, rather than being able to understand the clients as they really are. Lastly, a client who feels doubts and fears about being LGBT may be reluctant to fully disclose his or her negative beliefs to a therapist who is openly LGBT, and those fears may be more difficult to explore and resolve.

LGBT clinicians are not necessarily less inclined to heterosexist beliefs than heterosexual clinicians. Growing up in a heterosexist society, all people absorb some degree of heterosexist beliefs, even if only subtly or outside of conscious awareness. Researchers have described some lesbian, gay, and bisexual therapists as more homophobic than heterosexual therapists (McHenry and Johnson 1993), and because the homophobia may be less apparent or unexpected in those therapists, the therapist could have a greater impact in undermining the client's self-esteem and reinforcing negative beliefs about the self. While it remains unclear if the clinician's sexual orientation per se is important, heterosexual bias in any clinician makes a clear difference in clients' experiences.

There are many ways in which heterosexism can affect a client's treatment. For example, a clinician who believes that homosexuality is fundamentally wrong may assume that all of a client's problems stem from his or her sexual orientation, overlooking the other life issues that may be hurting the client's emotional life. The therapist might also fail to appreciate the degree to which societal heterosexism adversely affects the client and causes drug or alcohol use because the therapist believes that the heterosexism is justified and that the client must work to accept it. Clinicians who believe that homosexuality is shameful may encourage a client to remain secretive about his or her sexual orientation and may fail to help the client through the important life stage of coming out and developing a stronger and more positive self-image. This collusion with a client's internalized homophobia could worsen the internal conflict of a client who hates himself or herself, and this could result in worsening of alcohol and drug use.

Bisexual clients can experience unique difficulties from both heterosexual and gay or lesbian clinicians. Common assumptions about bisexuals are that they are unable to commit to relationships, they are unfulfilled unless they are simultaneously in relationships with both sexes, and they are in denial about being gay or lesbian (Dworkin 2001). Bisexuals suffer misunderstanding and discrimination from both heterosexuals and gay and lesbian people, and in some ways they can feel even more isolated and invalidated. An Australian study of 4,824 adults found that bisexuals scored highest on measures of anxiety and depression, compared to gay men, lesbians, and heterosexuals. Bisexuals reported more current adverse life events, greater childhood adversity, less positive support from family, and more negative support from friends (Jorm et al. 2002). Clinical assessments made with prejudices and incorrect assumptions may be inaccurate, and the actual life problems that underlie a bisexual person's substance use may not be recognized and properly addressed.

Transgender clients are perhaps the worst victims of phobic reactions by clinicians. Substance abuse counselors express even more negativity and feel they know even less about transgendered people than gay men, lesbians, and bisexuals (Eliason 2000). Some examples of transphobia include assuming that a transgendered person is mentally ill on the basis of his or her gender variance, recommending therapy to change a transgendered person's gender identity against that person's stated needs and goals, and withholding approval for gender reassignment treatments and procedures, such as hormones and surgery (Raj 2002). Transgendered people are also victims of physical and verbal abuse by staff in residential treatment settings, are often forced to wear clothes not consistent with their gender identity, and are forced to bathe and sleep in areas not of their gender identity (Transgender Substance Abuse Treatment Policy Group of the San Francisco Lesbian, Gay, Bisexual, and Transgender Substance Abuse Task Force 1995). For this group, transphobic treatment providers become an active part of the root cause of their substance abuse. It can be difficult, if not impossible, for a transgendered person to benefit from a clinician or treatment program unless transphobia is effectively addressed.

It is important to emphasize that any therapist, regardless of sexual orientation or gender identity, can have negative attitudes or reactions to LGBT clients. For example, a feminist lesbian doctor may react with feelings of anger or loathing at a male-to-female transgendered patient who has had breast augmentation surgery and dresses in highly seductive female clothing, feeling that the patient is perpetuating the sexist feminine ideals of a male-dominated culture. A gay male therapist whose partner died of AIDS may feel intense rage at a client who uses crystal methamphetamine and casually has unprotected sex with multiple partners when he goes on drug binges. It is important to remember that even LGBT clinicians may have strong reactions toward LGBT patients that can adversely affect their ability to view their clients objectively and treat them appropriately. It is crucial for all clinicians – heterosexual, gay, lesbian, bisexual, and transgendered – to fully examine their own beliefs and prevent them from affecting their clinical judgment.

129.2.3.4 Ideal Characteristics of Clinicians Working with the LGBT Client

A heterosexual clinician is not necessarily any less able to treat LGBT clients than a sexual minority clinician. As an analogy, consider a woman seeking an oncologist to treat her breast cancer. A good oncologist does not need to have had breast cancer herself to treat a breast cancer patient well. Rather, the patient will feel well cared for if the physician is knowledgeable, caring, empathic, and able to listen well to what the patient is saying. While having breast cancer certainly gives the physician a profound insight into the patient's experience, it does not guarantee that she is more knowledgeable or clinically sensitive. She might see her way of dealing with her own cancer as the only sensible coping method, which might make it more difficult to hear when the patient tells her that she needs to cope in a different way. Rather than focusing on finding a clinician who has had the exact same experiences, it is more productive to consider some general guidelines that should apply to all clinicians, regardless of sexual orientation or gender identity.

A good clinician should be reasonably free of homophobia, transphobia, and heterosexism. Because we all grow up in a heterosexist society, it is arguable that no individual is completely free of homophobia. However, a good clinician should have overcome most of these feelings and beliefs and should be aware of remaining homophobic, transphobic, and heterosexist ideas so that they do not interfere with treatment.

A good clinician should have an accepting and supportive attitude toward LGBT people. A crucial component of all clinical care is the positive regard for the client. Without this, the client cannot fully benefit from the treatment, and in substance abuse treatment, lack of positive regard can worsen a person's emotional life and substance use.

A good clinician should welcome and promote openness about sexual orientation and gender identity in the therapeutic setting. If a client is unable to disclose primary life issues to the clinician, then little therapeutic work can be accomplished. Additionally, welcoming openness about sexual orientation and gender identity fosters self-acceptance, which is a common difficulty for people with substance abuse issues.

While it is not essential that a clinician shares the same life experiences as the client, it is helpful for a clinician to be familiar with many of the issues commonly faced by LGBT people. Examples include the coming out process; dealing with heterosexism, homophobia, and transphobia; social isolation and stigma; and HIV and AIDS. Not all clinicians, even LGBT clinicians, will have an in-depth understanding of all of these concerns, but the clinician should be open-minded and willing to learn about unfamiliar issues and to understand them from the client's perspective.

Lastly, a good clinician should refrain from making assumptions of any kind and should actively listen for what the client identifies as his or her major life issues and goals, which may differ from the therapist's personal beliefs. The clinician should be able to actively listen to the needs identified by the client.

129.2.4 Selected Drugs with Particular Significance in the LGBT Community

While LGBT people are susceptible to abuse and dependence on all drugs and alcohol, there are a number of drugs that have particular appeal to members of the LGBT community, with a pattern of use distinct from the general population. Because the majority of research on substance abuse with LGBT people is from North America, this chapter is only able to describe drugs used in this community. Selected drugs used by the LGBT community in North America are described in the table below as an example of how the specific effects of different drugs can appeal to certain people who face specific psychosocial stressors. These are provided as an example to assist in the understanding of the use and misuse of drugs in other LGBT communities, who face their own unique psychosocial challenges (Table 129.1).

Table 129.1 Selected drugs used commonly in the North American LGBT community

Drug Mechanism of action	Specific population of users	Appeal unique to the population	Problems associated with misuse
Amyl nitrate Causes vasodilation, hypotension, and "head rush"	Gay men	Euphoria Eases discomfort of anal intercourse Intensifies orgasm Used in dance clubs and during sex	Nasal congestions Headache Severe hypotension in combination with PDE-5 inhibitors, can result in myocardial infarction Possible impairment of immune function
Ecstasy (Methylenedioxymethamphetamine, MDMA, "Molly") Increases presynaptic cytoplasmic levels of serotonin, dopamine, and norepinephrine in the CNS; induces their release into synaptic cleft. Increased levels of serotonin cause release of oxytocin	Gay men	Euphoria, dramatic increase in feeling of bonding with others, combating feelings of social alienation and isolation caused by homophobia Used at dance clubs, where it induces a feeling of belonging, connectedness, and community	Crash can involve severe depression, suicidal ideation, anxiety, panic attacks, and cognitive dysfunction. Other possible toxic effects include hypertension, hyperthermia, dehydration, hepatotoxicity, neurotoxicity, renal toxicity, and long-term cognitive impairment
GHB (gamma-hydroxybutyrate) GABA agonist; increases levels of serotonin and dopamine; mu opioid receptor agonist. Strong CNS depressant	Gay men	Decreases anxiety and inhibitions; dramatically increases libido; calm euphoria Overcomes sexual inhibitions due to internalized homophobia, allowing sexual gratification Used at dance parties and in combination with stimulants, especially methamphetamine Used in dance clubs and during sexual intercourse	Somnolence; respiratory depression; coma, especially when in combination with other CNS depressants; decreased sexual inhibitions can lead to sex without condoms and transmission of HIV and other sexually transmitted infections

(*continued*)

Table 129.1 (continued)

Drug Mechanism of action	Specific population of users	Appeal unique to the population	Problems associated with misuse
Methamphetamine (Meth, crystal, Tina, ice, crank, yaba) Increases presynaptic levels of dopamine and induces release of dopamine into the synaptic cleft in the CNS	Gay men	Dramatic increase in libido overcomes sexual inhibitions due to internalized homophobia, allowing sexual gratification Helps gay men with HIV to cope with their illness, reversing some of HIV symptoms, elevating mood and reversing depression during period of drug use	Extremely addictive, requiring more intensive treatment than other drugs. Sexually disinhibiting and commonly leads to anal intercourse without condoms, with transmission of HIV and other sexually transmitted infections. Crash can involve severe depression, suicidal ideation, anxiety, panic attacks, and hypersomnolence. Intoxication can cause anxiety, psychosis with paranoid ideation and tactile, visual, and auditory hallucinations. Frequent use leads to neurotoxicity of dopaminergic neurons, with resulting cognitive dysfunction and problems with behavioral inhibition due to decreased prefrontal cortical function. Other toxic effects include tachycardia, hypertension, myocardial infarction, arrhythmias, and stroke
Physique enhancing drugs: anabolic steroids Testosterone, stanozolol, oxandrolone, trenbolone enanthate, nandrolone decanoate; human growth hormone; human growth hormone-releasing peptide	Gay men	Increasing lean muscle mass, developing "hypermasculine" physiques that combat feelings of masculine inadequacy due to internalized homophobia	Psychological dependence on anabolic steroids to maintain positive self-esteem, with associated body dysmorphic disorder. Other side effects include excessive libido, aggression, irritability, explosive temper, testicular atrophy, gynecomastia, hypertension, hyperlipidemia, cardiomyopathy, hepatitis, polycythemia, and cellulitis at injection site

"Street hormones" Hormones purchased on the street for the purpose of cross-gender hormone treatment Includes testosterone, spironolactone, tamoxifen, synthetic estrogens, progesterone, and others	Transgendered people (both male and female)	Allows transgendered people who are disenfranchised and alienated from the general population's medical system to assist them in achieving a body more consistent with their internal gender identity. Cross-gender hormones are not considered drugs of abuse. However, street hormones are included here because their use without medical supervision can lead to multiple medical problems. Many transgendered people have been actively discriminated against or mistreated in the mainstream medical system, causing a general mistrust of the medical establishment by the transgendered community	Mood changes, including depression, irritability, aggression; nausea; edema; headache; hypertension; deep vein thrombosis and pulmonary embolism with smoking; hepatotoxicity; pancreatitis; endocrine dysfunction, including hypercortisolemia and hyperaldosteronism; deep tissue infections at injection sites; transmission of HIV, hepatitis B and C from sharing needles

129.3 Conclusion

This chapter provides an overview of the epidemiology of substance use disorders in the LGBT community in North America, as well as the particular psychosocial issues that increase the risk of substance abuse or dependence, as some of these individuals attempt to cope with these stressors by using the maladaptive tool of drugs and alcohol. Through data collected about this population over the past few decades, it becomes clear that it is neither sexual orientation nor gender identity per se that increases the risk of substance use disorders. Rather it is the social challenges that these individuals face, such as discrimination, harassment, assault, lack of social or legal protection, and lack of equality with mainstream society that cause anxiety, depression, internalized homophobia, and internalized transphobia.

Because this chapter presents information that is limited to North America, it may not accurately describe the situations that LGBT people face in other countries or the rates of substance use and abuse in those LGBT communities. It is important to acknowledge the many differing views of LGBT people, which may pose different challenges that LGBT individuals face in each country. Therefore, it is important for individual clinicians in each country to examine how their particular cultures view homosexuality and transgendered people, what the local laws are with regard to these people, and how these people may face social rejections, harassment, discrimination, assault, imprisonment, or even death sentences. Clinicians should listen to their LGBT patients with open minds to learn what their specific experiences are and use them as guides as to how to provide rational and compassionate care and treatment of addictive disorders.

Abstract

Doctors are at high risk for developing addictive behaviors due to their easy access to self-treatment and because they are usually reluctant to ask for help when they feel mentally or emotionally distressed. Alcohol dependence and sedatives and/or minor opioid dependences are the most prevalent substance use disorders (SUDs) among physicians. However, when doctors come to accept treatment in programs specifically designed for them (Physicians' Health Programs), they show better outcomes than the general population.

The aims of this chapter are (a) to provide a brief comprehensive review of addictions in physicians, (b) to analyze the barriers that prevent doctors with SUDs from seeking help, (c) to give some keys to enhance early detection of affected individuals, (d) to explain the different strategies developed by Physicians' Health Programs, and (e) to describe the treatment principles that should be considered when treating physicians with addictions.

130.1 Introduction

The concern for the high rates of alcoholism and drug addiction among physicians traces back to 1869, when physician-educators started to be concerned for students and fellow practitioners addicted to alcohol, cocaine, or morphine (Brewster 1991). In the last decades, growing evidence has shown that doctors and other health professionals are at high risk for developing addictions, mainly substance use disorders (SUDs) (Talbott and Martin 1986; Flaherty and Richman 1993; McLellan et al. 2008; Dupont et al. 2009).

Physician impairment refers to those situations where physicians are rendered unable to carry forward their professional responsibilities adequately due to a variety of health issues, including a medical disease, psychiatric problems, substance use disorders, or dual diagnosis (O'Connor and Spickard 1997). Physicians' impairment due to addictive behaviors may be episodic or steady, leading to psychosocial deterioration and, finally, becoming dangerous both to the physician's well-being and their patients' safety (O'Connor and Spickard 1997; Lusilla et al. 2008; Dupont and Skipper 2012).

The prevalence of addictions among doctors is said to be similar to that of the general population. Therefore, an estimated 10–14 % of physicians may become chemically dependent at some point in their careers (Flaherty and Richman 1993). Although physicians are less likely to experiment with illicit substances (such as marijuana, cocaine, and heroin), they are more prone to the use of alcohol and self-prescription of controlled medications such as benzodiazepine tranquilizers, minor opiates, and/or stimulants (Flaherty and Richman 1993; McGovern et al. 2000; Hughes et al. 1992; McLellan et al.2008; Skipper et al. 2009). Prescription substances are mainly used for self-treatment, whereas illicit substances and alcohol may be taken for recreational purposes mostly (Hughes et al. 1992), although the self-medication hypothesis cannot be disregarded.

Early diagnosis is critical because physicians are reluctant to ask for help when suffering from mental disorders (Stanton and Randal 2011), and their colleagues are often hesitant to intervene (Marshall 2008). Tendency to intellectualize psychiatric symptoms, greater stigma associated with mental disorders among doctors, and easy access to self-treatment with drugs, added to specific individual risk factors, may account for this increased risk (Firth-Cozens 1997; Hughes et al. 1992; Boisaubin and Levine 2001; Carinci and Christo 2009).

Doctors who delay seeking treatment frequently attempt to treat themselves (Hem et al. 2005a; Lusilla et al. 2008), potentially complicating their prognosis (Hughes et al. 1992), increasing the risk of developing comorbid conditions (Hem et al. 2005a), causing greater morbid-mortality (Lusilla et al. 2008), and usually leading to malpractice behaviors (Herrington and Jacobson 1982; Talbott and Martin 1987; McLellan et al. 2008; Skipper et al. 2009).

Dual diagnosis is a frequent condition associated with the risk of self-treatment. The combination of affective and alcohol disorders is the most common form of psychiatric comorbidity within physicians (Gastfriend 2005; Lusilla et al. 2008). Some Type II Personality Disorders, such as the Narcissistic and/or the Antisocial types, are often comorbid in physicians treated within specific programs for doctors once treatment has become compulsory (Angres et al. 2003). In nonpunitive programs (Lusilla et al. 2008), not only antisocial traits but avoidant and obsessive-compulsive ones are also present in doctors suffering from addictive disorders. However, specific occupational factors could play a role in the development of addictions in doctors: stressful situations, work-home time balance difficulties (with subsequent family stress), conflicts with patients, injury or accidents at work, life-and-death decisions, etc. (Marshall 2008; Carinci and Christo 2009).

Increased suicidal risk has also been associated with the presence of addictions and dual diagnosis in doctors (Center et al. 2003; Hem et al. 2005b; Lusilla et al. 2008). The typical physician at risk for suicide would be a man or a woman, around 50 years old, white, living alone, and suffering from one or more of the following conditions: depression, alcohol dependence, or any disabling medical condition (Center et al. 2003).

Therefore, addictions in physicians cause a serious concern due to their potential impact on patients' safety, the lives and careers of the impaired physicians, and the socioeconomic burden of the health-care system as a whole (Talbott and Martin 1986;

Boisaubin and Levine 2001; Dupont and Skipper 2012; Braquehais et al. 2012). However, if they come to accept treatment at programs specifically designed for them (such as Physicians' Health Programs, PHP), doctors with SUDs would have better outcomes and recovery rates in comparison to the general population (Herrington and Jacobson 1982; Carinci and Christo 2009; Dupont et al. 2009).

The majority of PHP are persecutory in nature, as their main aim is to protect population from the consequences of malpractice behaviors. Therefore, they look forward to warranting abstinence and mental stability but do not provide themselves clinical support and treatment for their patients. That is why some PHP, such as the Spanish program, were created to balance this secure approach with a clinical effort to prevent and treat conditions that may lead to malpractice issues.

The aims of this chapter are (a) to provide a brief comprehensive review of addictions in physicians; (b) to describe the usual barriers that prevent doctors with addictions from asking for help; (c) to give some keys to enhance early detection of affected individuals; (d) to explain the different strategies developed by specialized programs (PHP) in order to be able to deal with this problem, with a special focus on the new model for sick doctors developed in the Spanish PHP; and (e) to describe the main treatment principles that should be taken into account when treating physicians with addictions.

130.2 Addictions in Physicians

Boisaubin and Levine (2001) point out that medical students, like their peers outside medicine, may be fascinated by drugs and, during their early medical training, tend to overestimate their understanding of pharmacology and underestimate, or fail to comprehend, what addictions really mean. They may even continue to use drugs throughout medical school and into residency. Some physicians also begin using benzodiazepines and opiates during their residency training, when they first receive prescribing privileges. Most of them use those drugs to relief stresses generated during that time period (e.g., fatigue, early responsibilities, professional disillusionment, lack of emotional support, and less time to spend with friends and family).

College students may also use stimulants as "performance enhancers" or for pleasure (Arria and DuPont 2010). When comparing medical students to residents, Hughes et al. (1992) found that more residents reported lifetime usage of benzodiazepines (22.7 % versus 19.6 %) as well as barbiturates (8.5 % versus 7.3 %), but fewer of them reported cocaine use (29.2 % versus 32.5 %). With regard to alcohol use disorders, Flaherty and Richman (1993) found that 20.3 % of medical students met criteria for alcohol abuse or dependence in the 12 months prior to the interview.

Hughes et al. (1992), in a mailed survey to 9,600 physicians affiliated to the American Medical Association, reported that practicing physicians were as likely to have experimented with illicit substances in their lifetime as their age and gender

peers in society, but less likely to be current users of illicit drugs. Physicians' use of prescription substances (e.g., benzodiazepines, barbiturates, minor opiates, or amphetamines) was primarily related to self-treatment, while the higher prevalence of alcohol use could be related to their higher economic status. Schneider et al. (2007) also reported that Swiss primary care physicians tended to self-medicate with analgesics and tranquilizers.

In a nationwide, prospective, and longitudinal study following young Norwegian physicians from internship through the subsequent 9 years, Hem et al. (2005) found that physicians self-prescribed not only antibiotics (71–81 %) or contraceptives (24–25 %) but also analgesics (18–21 %) and hypnotics (9–12 %). Those suffering from mental disorders used mainly sedatives or hypnotics as a form of self-treatment.

With reference to medical speciality, the reported prevalence of alcohol use disorders and/or other addictive diseases in physicians is higher for psychiatrists (14.3 %) and emergency medicine physicians (12.4 %) compared to other specialities (Hughes et al. 1992). Psychiatrists are more likely to have used benzodiazepines (Hughes et al. 1992) and are also overrepresented in another study with alcoholic doctors (Bisell and Jones 1976). Hughes et al. (1992) also found that general practitioners and obstetric/gynecology physicians were more prone to use minor opiates, while anesthesiologists, emergency doctors, and chronic pain physicians used to self-prescribe major opiates. The trend was found to be similar within residents. Findings about anaesthesiologists have been also replicated in other studies (Garcia-Guasch et al. 2012). Although they are more likely to enroll US PHP because of opioid abuse, they have excellent outcomes similar to other physicians when they come to accept treatment at PHP (Skipper et al. 2009). In a recent study (Buhl et al. 2011), surgeons were found to be more likely than nonsurgeons to enroll in PHP because of alcohol-related problems but less likely to be admitted because of opioid use. They also had positive outcomes similar to those of nonsurgeons.

With regard to mandatory treatment, McLellan et al. (2008) reviewed the laboratory and medical records of 904 physicians admitted to 16 PHP in the United States (US). Five specialities represented more than 50 % of physicians: family medicine (20.0 %), internal medicine (13.1 %), anesthesiology (10.9 %), emergency medicine (7.1 %), and psychiatry (6.9 %). Alcohol use disorders and opioid abuse and dependence are the most frequent conditions among physicians compulsory referred to PHP programs (Brewster et al. 2008). In programs where physicians can also be admitted after self-referral, such as the Barcelona Substance Use Disorder Program, a higher prevalence for alcohol (83.3 %) and benzodiazepine (37.5 %) use disorders was found.

Smith (2008) underlined that most developed countries had shown a steady decline in physicians' smoking rates in the last decades. The lowest smoking prevalence rates (less than 10 %) have been consistently documented in the United States, Australia, and United Kingdom (Smith 2008; Smith and Leggat 2008). However, physicians in some developed countries and newly developing regions still appear to be smoking at high rates (Smith et al. 2008). In Catalonia, 24.5 % of working physicians continue smoking tobacco (Rohlfs et al. 2007).

130.3 Barriers to Ask for Help

Stanton and Randal (2011) identified some psychosocial factors that prevent physicians from asking help, increasing the risk of developing mental disorders: (a) doctors share a culture of unrealistic expectations, see themselves as super-people, and to show vulnerability has been identified with the risk of losing respect from peers and seniors; (b) these unrealistic expectations are associated with denial and minimization of need for self-care, personal vulnerability, and early signs of illness; (c) doctor colleagues, friends, and partners, whether recruited as doctor patients, doctor contacts, or treating psychiatrists, describe experiences of considerable difficulty in identifying concerns and speaking about them to other doctors; and (d) nondoctor personal contacts describe them as being unable to identify difficulties and speak about them.

Some other factors may increase this inability to develop healthy coping strategies (Firth-Cozens 1997; Rakatansky 2005): high self-criticism; low self-esteem; poor bonding to relatives; competitive, humiliating, and status-conscious work environment; and burnout symptoms related to high job demands.

Easy access to self-prescription may lead to tolerance and dependence of some licit drugs, while alcohol use may become a "socially accepted" strategy to deal with stressful situations. Once the addiction pattern is established, it gets even more difficult for the sick doctor to ask for help.

In fact, a high proportion of doctors show inadequate attitudes toward their general health care (Bruguera et al. 2001; Hem et al. 2005a). As some doctors with addictions do not ask for help, some direct or indirect signs (O'Connor and Spickard 1997; Boisaubin and Levine 2001) may help their colleagues identify their problem (see Table 130.1). In fact, it is the physician's ethical responsibility to

Table 130.1 Identifying physicians with SUDs

Indirect signs	Abnormal behavior
	Loss of reliability
	Unjustified absences from work
	Frequent medical complaints
	Abnormal prescription (tendency to self-prescription)
	Mood changes
	Isolation from colleagues
	Staff concerns of one colleague's behavior
	Citations for impaired driving
Direct signs	Smell of alcohol
	Somnolence
	Hyperactivity
	Disinhibition
	Ataxic gait
	Slurred speech
	Tremor
	Disheveled appearance
	Depressed mood

identify alcohol-impaired or drug-impaired physicians in order to help them return to optimal functioning and to safeguard the health of patients from the care of impaired physicians (O'Connor and Spickard 1997; Boisaubin and Levine 2001).

130.4 Treatment

130.4.1 Physicians' Health Programs

Specialized programs to help doctors who are dependent on substances seem to provide the best available measures for protecting patients and for recovering physicians' careers and well-being (Carinci and Christo 2009) (Table 130.2).

First PHP were developed in every US state since the late 1970s in order to identify and treat sick doctors who had a misconduct as a consequence of a mental disorder – mainly, addictions (Talbott and Martin 1986; Dupont et al. 2009; Dupont and Skipper 2012). The US Federation of Physician Health Programs (FSPHP) offers state programs (44 states are full members, as membership is voluntary), regional and national meetings, as well as electronic forums for issues concerning physicians' health (Dupont et al. 2009). US PHP contracts offer support and temporary safe haven for physicians who are typically in jeopardy or under pressure from others due to problems related to addictions. All US programs maintain a close relationship with the physician-as-patient state medical licensing boards. In fact, the boards often accept the care of the sick doctor instead of imposing disciplinary actions for them. Most contracts stipulate intense, ongoing treatment with substance monitoring, together with a close supervision plan (Dupont et al. 2009).

Table 130.2 Physicians' Health Programs (PHP)

Location	PHP
US	Physician Health Programs (44 states)
Canada	Physician Health Programs (4 provinces)
	Physician-Family Support Programs (4 provinces)
	Physician at Risk Program (1 province)
	Professional Assistance Program (1 province)
Australia	Doctors' Health Advisory Services-Support programs (6 states)
	Physician Health Program (1 state)
Europe	UK: Doctors for Doctors (BMA), Doctors Support Network, Practitioner Health Program (NHS), Sick Doctors Trust
	Switzerland: ReMed
	Norway: Research Studies (NMA) and Villa Sana Resource Center
	Spain: Physician Health Program (PAIME) and Evaluation Unit, Preventive Programs and Research Studies (Galatea Foundation)

BMA British Medical Association, *NMA* Norwegian Medical Association

Similar PHP were developed later in every Canadian province (Puddester 2004; Brewster et al. 2008). Other programs were developed in Australia (Jurd 2004) and the United Kingdom (Oxley 2004), trying to improve strategies to reach sick doctors and prevent those conditions, promoting healthy lifestyles among physicians, and offering counseling when needed. Norway, Austria, and Switzerland developed similar basic preventive and counseling services for doctors. Other European countries are receptive to these initiatives and plan to create similar programs in the future (e.g., in France some regions have created their own PHP).

On the other hand, cross-country collaboration is critical when promoting doctors' well-being. The American Medical Association (AMA), the Canadian Medical Association (CMA), and the British Medical Association (BMA) organize each year the International Conference on Physician Health to increase awareness on the topic and enhance networking activities. The European Association for Physician Health (EAPH) is a network of European groups and individuals concerned with doctors' health that regularly meet to (a) share the expertise and good practice on the treatment of doctors by doctors, (b) influence and encourage the development of health services for doctors, and (c) undertake joint research on the health and well-being of doctors.

Most programs include prevention strategies to increase awareness of the problem both among medical students and doctors as well as promoting their integral well-being. Promoting healthy coping strategies to deal with stressful situations and overcoming doctors' barriers to ask for help when they suffer mental disorders are the main objectives of prevention campaigns for this professional group.

In summary, national and international strategies are needed to sensitize medical students, residents, and doctors to the dangers of self-treatment with controlled prescription substances, to enhance functional coping strategies among physicians, and to develop specific PHP to treat doctors who finally develop addictive disorders.

130.4.2 Key Factors to Treat Doctors with SUDs

As already mentioned, physicians have a good response to addiction treatments when compared to the general population. Reports from several PHP report long follow-up abstinence rates for physicians to be around 70–80 % (Boisaubin and Levine 2001; Brewster et al. 2008; McLellan et al. 2008; Dupont et al. 2009).

Brewster et al. (2008), after monitoring 100 physicians with addictions treated at the Ontario PHP during 5 years, found that 71 % had no relapse and a total of 85 % successfully completed the program. Sixty-six percent had been compulsory referred by their College of Physicians, and 16 % had been sued for malpractice behaviors.

McLellan et al. (2008) retrospectively analyzed the laboratory and medical records of 904 physicians admitted to 16 PHP in the United States. At 5-year follow-up, 78.7 % were licensed and working. The typical program consisted of two stages: formal treatment (inpatient and outpatient treatment) followed by supervision after treatment. Most patients (78 %) entered inpatient treatment followed by outpatient treatment.

The rest of physicians (22 %) went directly to outpatient treatment. Those with good compliance and positive progress were eligible to return to work under supervision about 6 months after the start of treatment. Physicians were expected to attend Alcoholics Anonymous or other 12-step groups (92 %) during their recovery period. Urine testing was carried out four times a month early in care, tapering to one or two times a month throughout the monitoring period. The frequency of testing was contingent on the results of urine analysis and on the results of the supervision care plan. Urine testing was generally observed by the responsible staff (75 % of urine samples). The typical testing panel covered 20 substances (amphetamines, barbiturates, benzodiazepines, opiates, several opiates, cocaine, cannabinoids, and ethyl alcohol). Some cases needed to be tested using the hair (0.2 %), saliva (0.1 %), and breath (0.6 %).

US PHP programs complete the integral treatment group therapy and support group attendance at 12-step programs such as Alcoholics Anonymous, Narcotics Anonymous, and/or Caduceus (i.e., a program specifically designed for impaired doctors) (Carinci and Christo 2009).

In summary, results of follow-up studies support the need for and the efficacy of highly specialized programs for physicians with addiction problems (Boisaubin and Levine 2001; Carinci and Christo 2009; Dupont and Skipper 2012).

Some keys to success (Talbott and Martin 1986; Dupont et al. 2009; Dupont and Skipper 2012) when treating those doctors are (see Table 130.3):

1. Offering immediate and highly confidential intervention. Providing an adequate, easy-access, and confidential treatment as soon as the sick doctor seeks help is critical.
2. Evaluation and triage at the appropriate facility where a comprehensive case management is offered. Treatment at outpatient or inpatient facilities will depend on the severity of their addictive disorder.
3. The treatment staff should be trained to deal with the particular occupational components and with the most common defense mechanisms of the impaired physician.
4. Addictions must be conceptualized as mental disorders. Careful presentation of the diagnosis and the dynamics are critical to the acceptance of the "disease model" by physician-as-patients.

Table 130.3 A decalogue to treat doctors with SUDs

1. Immediate response and highly confidential treatment
2. Specialized treatment setting
3. SUD conceptualized as a mental disorder under a biopsychosocial paradigm
4. Specifically trained staff
5. Peer-group therapy
6. Uninterrupted and long follow-up program
7. Frequent random drug testing
8. Family involvement
9. Appropriate reentry into practice when maintained abstinence
10. Advocacy and relapse contingency plan

5. Peer-group therapies and mirror image techniques are useful in breaking through denial and overcoming the physicians' barriers to ask for help.
6. A non-interrupted, long follow-up program with extensively monitored and structured aftercare component is a key factor to foster physician recovery.
7. Random drug testing is a key component of adequate monitoring. Failure to call in for randomization is a prognostic indicator of imminent relapse.
8. Family involvement. Psychoeducation with families and significant others as well as family therapy when needed should be part of the patient-tailored treatment.
9. Appropriate reentry into practice when the impaired physician remains abstinent should be warranted. Supervision at work may become necessary in some cases.
10. Advocacy and a relapse contingency plan must be implemented when needed.

130.4.3 A New Model for Sick Doctors: The Spanish PAIME

In 1998, the Integral Care Program for Sick Doctors (PAIMM, in Catalan, and PAIME, in Spanish) was created in Barcelona (Spain) by the Regional Health Department of Catalonia (Spain) and the "Colegio Oficial de Médicos" of Barcelona (Bosch 2000), an institution similar to the Board of Trusties in Anglo-Saxon countries. Later on, it extended its activity to other "Colegios Oficiales de Médicos" all over Spain. The institutions called "Colegio de Médicos" act both as Board of Trusties and Medical Associations, thus being responsible for warranting safe medical practice in Spain.

The PAIME's main aim was to prevent and treat mental disorders in physicians and help them go back safely to their professional practice. The PAIME, in contrast with other international programs, was inspired by a new philosophy regarding the approach to the "sick doctor" phenomenon as it intended to become a highly confidential, non-persecutory, nonpunitive, voluntary, therapeutic, and recovery-oriented program. Treatment becomes mandatory only when there is a risk or evidence of malpractice behaviors.

In order to warrant confidentiality, a new name is given to each patient entering the program (e.g., all patients' last names are changed in order to warrant anonymity). Real identity data are only disclosed in circumstances where risk for the SD or others is involved (Table 130.4).

Table 130.4 The Spanish model (PAIME): a new approach to physicians' well-being

New philosophy	**Highly confidential**
	Only mandatory treatment when risk or evidence of malpractice
	Non-persecutory
	Voluntary access
	To promote rehabilitation ("regain good professionals")
	To enhance prevention

Therefore, the philosophy of the PAIME appeared in the international scenario as a new approach to doctors' mental health where the emphasis was put on enhancing voluntary help seeking among physicians suffering from mental disorders and promoting the return to their professional practice in good conditions. Their founders believed this approach would certainly help SD not feel punished or prosecuted when having mental disorders and, therefore, enhance help seeking among them (see Table 130.3).

All PAIME units in Spain have outpatient facilities where psychiatric and psychotherapeutic treatment is provided to all SD registered at their "Colegios de Médicos." PAIME units also warrant mandatory follow-up surveillance and treatment for those cases in which risk or evidence of malpractice issues can be involved. The PAIME unit in Barcelona, the Galatea Clinic, located in the mountains of the northern part of the city, has inpatient and outpatient facilities where psychiatric and psychotherapeutic treatments are provided to SD. It is the psychiatric hospitalization unit where SD from the rest of PAIME units in Spain are referred to if they need inpatient treatment (Table 130.5).

Since 2008, the Galatea Clinic offers a new highly structured, patient-tailored program in which a combination of psychopharmacological treatment and psychotherapy for doctors with SUDs is provided.

After a 1-month day-hospital daily intensive phase, all patients from Barcelona enter a 2-year follow-up stage where controlled, random drug screening, weekly motivational group therapy, and regular psychiatric and psychotherapeutic evaluations take place. Our psychotherapeutic approach combines both cognitive-behavioral techniques and motivational interventions as they have proven to be highly effective in alcohol and other SUD (Kilmas et al. 2013). A retrospective, longitudinal, cohort study was carried out over 2 years, from 1 February 2008 to 1 February 2010, of 153 medical records of physicians and nurses admitted to the

Table 130.5 Barcelona clinical unit (Galatea Clinic)

Highly structured intervention programs	Evaluation unit
	Substance use disorders program
	Mental disorders program
Treatment facilities	Psychiatric inpatient unit
	Outpatient facilities
	Day hospital
Treatment modalities	Psychopharmacological treatment
	Individual psychotherapy
	Group psychotherapy
	Family intervention
	Physical examination
	Neuropsychological assessment
Target patients	Residents
	Practicing physicians

program. During this 2-year period, only 15.7 % (54.2 % men and 45.8 % women) of all patients were readmitted after relapse. Of the readmitted patients, 54.2 % suffered from another mental disorder, mainly major depressive disorder (25 %).

The PAIME unit in Barcelona has treated up to 2,000 physicians so far, and the Galatea Clinic intends to promote their activity overseas, offering their expertise and specialized treatment to SD coming from all around the world. When the program started, more than a decade ago, most patients were referred for malpractice issues; nowadays, most patients are self-referred, and up to 85–90 % are able to go back to their professional practice in good conditions after their treatment process.

130.5 Conclusion

As SUDs in physicians may lead to serious consequences both for the physicians-as-patients and for their safe practice, most PHP only offer mandatory treatment to sick doctors. At the same time, although physicians are usually reluctant to ask for help, when they accept to be treated at confidential, highly structured, long-term programs, specifically designed for them, they have better outcomes, showing recovery rates higher than the general population. The Spanish Integral Care Program for Sick Doctors was created not only to warrant safe practice (through compulsory treatment when needed) but also to enhance voluntary help seeking among physicians. This new philosophy may be of greater help for addicted doctors instead of the standard mandatory treatments provided by other specialized programs.

Substance Use in Populations Displaced by Conflict

131

Nadine Ezard

Contents

Abstract

Around 45 million people are displaced by conflict; the majority have been displaced for around two decades. Conflict-displaced populations suffer excess mortality from communicable and noncommunicable diseases. Substance use is increasingly recognized as an important underlying behavior and determinant of these diseases and has been documented from a range of displaced populations: refugee and internally displaced, in and out of camps, and urban and rural settings, in Africa, Asia, Europe, and South America. The literature mentions a variety of substances, including alcohol, amphetamine-type stimulants, benzodiazepines, cannabis, and opiates. (Weak) data suggest an association between male gender, older age, multiple traumatic episodes, and increased substance use in displacement. Transitions in patterns of substance use appear to reflect a combination of pre-displacement patterns, host population patterns, and substance availability. Theoretical models suggest that psychological distress, social stressors, changes in social norms and networks, and growing

poverty and inequality may underlie these transitions. Harm related to substance use is well documented among non-displaced populations; documented problems specific to displaced populations include injection-related infection risks, mental health problems, suicide, and intimate partner violence. Conflict is a social determinant of health and an important influence on the distribution and patterns of substance-related harm globally. Interventions to reduce substance-related harm among populations displaced by conflict should be multilevel and multisectoral. Individual interventions target those who are already at risk of or experiencing harm; structural interventions address the underlying social determinants of substance-related harm. More study of intervention effectiveness is needed.

131.1 Introduction

The world's population is increasingly mobile, and conflict is an important cause of population mobility. In 2012 there were around 45 million people displaced by conflict (United Nations High Commissioner for Refugees 2013). The majority are from conflicts in Africa, Asia, and the Middle East and remain within those regions; two thirds are displaced within their own countries and not entitled to international legal protection afforded to refugees. Although many displaced people live in camps or collective settings, most are hosted among non-displaced populations, and more than half live in urban settings. New crises cause acute onset displacement, yet the majority of displaced people have been so for decades. Around two thirds of refugees are in so-called protracted situations of more than 5 years' duration, and the average length of stay in displacement is now around 20 years (Internal Displacement Monitoring Centre 2013; United Nations High Commissioner for Refugees 2013; World Bank 2011).

The high death rates among conflict-displaced populations are mostly due to noncombat-related causes, a mix of communicable and noncommunicable illness. Substance use is an important underlying behavioral determinant. The association between substance use – particularly alcohol – and chronic illness, depression, and other mental health problems is well documented, as is the link with infections such as tuberculosis and HIV. Displaced settings provide contexts in which substance use may be promoted and in which substance-related harm may flourish. Economic, psychosocial, and cultural aspects of displaced contexts can promote newer and more hazardous patterns of substance use. Displacement causes a speeding up of the urbanization process and shifts to urban – and potentially more harmful – patterns of use.

This chapter will review the literature on substance use among populations displaced by conflict and the relationship between conflict-induced displacement and changing patterns of substance use. (This chapter is concerned with groups of displaced people, be they within or across international borders. It does not directly address onward migration or third-country resettlement, which

introduces different contextual factors.) It will then explore the literature on substance-related harm among populations displaced by conflict. By conceptualizing conflict as a social determinant of health, the chapter will conclude with an intervention framework for minimizing substance-related harm among these populations.

131.2 Key Concepts

- **Armed conflict:** According to international humanitarian law, war opposing two or more States is termed international armed conflict, and war between governmental forces and nongovernmental armed groups, or between these groups alone, is called non-international armed conflict (International Committee of the Red Cross 2008).
- **Internally displaced persons:** By convention, where persons are displaced within state borders due to armed conflict, they are termed internally displaced persons (IDPs) (United Nations Office for the Coordination of Humanitarian Affairs 2004).
- **Interventions:** Interventions are actions taken to prevent the onset, continuation, or deterioration of an adverse health outcome (often termed, respectively, primary, secondary, and tertiary prevention) and to promote positive health outcomes. Interventions can include services, programs, laws, regulations, and policies and may include the unintended health consequences of non-health sector policies and programs. Interventions can be classified as individual interventions, targeting individuals and their families, or structural, targeting the social environment.
- **Refugees:** According to international refugee law, people fleeing conflict and displaced across international borders by armed conflict are termed refugees. The legal definition of a refugee is someone who, "owing to a well-founded fear of being persecuted for reasons of race, religion, nationality, membership of a particular social group or political opinion, is outside the country of his nationality, and is unable to, or owing to such fear, is unwilling to avail himself of the protection of that country" (United Nations 1951: Article 1(A)2; 1967).
- **Social context:** Substance use patterns, problems, and solutions are all embedded in their social context, a term used to describe the cultural, social, and structural environment that shapes human behavior and health outcomes of behavior.
- **Social determinants of health:** Social determinants of health include living conditions across the life course – such as education, environment, and access to health care – and the underlying economic and political structures determining the distribution of resources and power (Commission on the Social Determinants of Health 2008).

- **Substance use:** The phrase "substance use" means ingestion of a medicinal, industrial, or plant-based psychoactive chemical with the aim of changing consciousness, mood, behavior, or thought processes. For the purposes of this chapter, tobacco products and nicotine are excluded. Substance use covers the spectrum of behavior from beneficial and nonproblematic to hazardous and harmful.

131.3 Substance Use in Displacement

Use of a number of different substances has been reported from displaced populations, depending on the local context and substance availability. Globally, alcohol use is the most prominent, its use documented from a range of settings, including camps in Croatia (Kozarić-Kovačić et al. 2000), Uganda, and the Thai-Burma border (Ezard et al. 2012) and among urban displaced in Colombia (Roberts et al. 2011). Khat use is very prevalent among the most conflict-affected areas of Somalia among combatants and civilians (Odenwald et al. 2007; Hansen 2010). Opiate and cannabis use is common among displaced populations in Pakistan and Iran (Ezard et al. 2011). Documented use of other classes includes amphetamine-type stimulants, cannabis, glue, and other inhalants.

Patterns of use also vary widely. These patterns can be characterized as an extension of pre-displacement patterns, transition to host patterns, or a mix of the two (Ezard et al. 2011). For example, frequent high-volume use of home-brewed alcohol has been documented among some men living in long-term conflict-displaced settings in northern Kenya, Uganda, and Thailand (see Box 131.1 for a case example). Refugees from Somalia in Ethiopia describe a transition in patterns of khat use from celebratory and weekend use to daily use (Hansen 2010). These patterns of use are considered an exaggeration and modification of pre-displacement use patterns.

On the other hand, new-onset use, mirroring that of the host population, can occur. This is the pattern observed among some Afghan refugees in Iran, who have adopted the use of Iranian *kerack* (a concentrated form of heroin) and *crystal* (a predominantly methamphetamine preparation). Transition to injection use of opiates among Afghan refugees in Iran, Pakistan, and Turkmenistan has been well documented; this practice was diffused into on return and is now normalized in Afghanistan (Todd et al. 2012). Figure 131.1 shows a diagrammatic schema for understanding changing patterns of use in displacement.

How and why these transitions occur is complex and poorly understood. There are a number of contributory elements, which act at both individual and social levels. Individual trauma experiences, for example, have been hypothesized to promote substance use. Among combatants, conflict exposure has been shown to result in increased substance use. Among conflict-displaced civilian populations, there is some (weak) evidence that multiple trauma exposure promotes substance use (Ezard 2012). It is not clear how much of this substance use is new-onset

Box 131.1. Case Study: Alcohol Use in Mae La Refugee Camp, Thailand, 2009

Armed conflict in Burma has displaced more than two million people into neighboring Thailand since independence from the UK in 1948. An assessment of alcohol use was conducted in Mae La refugee camp in 2009. More than 150,000 refugees lived in nine camps along Thailand's western border, in addition to 500,000 people displaced internally within Burma and several million migrant workers in Thailand. Mae La was the largest of the camps, established in 1984, with a population of around 45,000. The majority of the population was Karen, an ethnic minority in both Thailand and Burma, of Buddhist and Christian religions. The Karen people had been engaged in armed resistance against the Burmese state for a number of decades. Employment and education opportunities were limited, and the population was largely dependent on external aid. There was high population turnover and an active program of third-country resettlement.

A range of substances was used in the camp including opium, heroin, *ya ba* (Thai for "crazy medicine," a tablet form of methamphetamine mixed with caffeine), cannabis, benzodiazepines, other pharmaceuticals, and, among young people, glue sniffing. Alcohol caused the most public health and social concerns for the population, implicated in episodes of insecurity, gender-based violence, physical assault, and suicide. Around a quarter of men and no women of reproductive age screened positive for risky drinking. Prevalence of risky drinking was likely to be lower than many countries of resettlement and the host country, Thailand.

Beer, wine, and whisky could be obtained at nearby bars and shops, although not officially permitted to be sold in the camp. The most popular form of alcohol, however, was cheap, locally brewed rice liquor, despite its illicit status in Thailand. It was preferred only for reasons of affordability – no one claimed to enjoy the taste and many expressed fears around contaminants and a belief that production had moved away from traditional methods. "Auu! . . . you see they make with shoes as well as battery acid and other things which are not clean" said Naw W, a 34-year-old woman and long-term resident interviewed as part of the study (the names presented here are pseudonyms).

Alcohol had been used for many years in Karen culture for the purposes of socialization, and it was often referred to in Karen as "happy water." According to Saw S, a 42-year-old man who had been living in Mae La for 17 years, this meant "it is like we drink alcohol in order to make us happy . . . I have a lot of friends sometimes we buy a bottle of alcohol and drink together with friends."

Its use was subject to strong social controls. Saw S went on to explain that "[I] come back to eat after drinking, but I do not continue to have more. I just drink it in moderation." Small amounts of alcohol were considered "good to eat rice" (improve appetite) and "like medicine" (improve health). Intoxication, however, was proscribed. As Saw E, a 43-year-old man and long-term resident, explained: "[if alcohol is drunk] within limits, it is like medicine.

If it is over the limit, it is dangerous." One of these dangers was being loose tongued and indiscreet, described frequently as "the theft of the buffalo is revealed."

Use by women was also proscribed, and abstinence associated with femininity. Naw P, a 22-year-old woman who had been in Mae La since the age of 17, explained that "[men drink] because they get tired; they keep drinking until they are drunk in the street. Women also get tired! Drinking alcohol to freshen up that is just giving in to your desires." Saw Y, a 24-year-old man, thought that there were fewer women than men who drink because "women can control themselves if they get upset. Usually, men have no self-control," and Saw V, a 20-year-old man, thought that one reason women don't drink is because "they are afraid that the neighbors will gossip about them."

Nevertheless, there was a dominant belief that the pressures of displacement and refugee camp life were starting to erode these strong controls, and drinking norms were changing. Alcohol use was shifting from celebratory and occasional towards every day and high volume, at least by some people. A number of rationales were given to explain this. For example, Say, a 19-year-old man, described using alcohol as a form of self-medication to deal with distressing emotions; "I drink so that I don't need to think so much" he explained. Others described alcohol use to manage social stressors. Saw Y, a 24-year-old man explained, "Mae La residents have only alcohol. If they go out, the Thai will catch them. Here, it's like being in a farm. It is surrounded by a fence; they can't go out, so if they get upset, there's only alcohol to get release." He went on to list the constrained options for many people and the hopelessness that this engendered, "so they just drink alcohol."

For some, disruption to existing social hierarchies resulted in changes in controls on alcohol use behaviors. According to Saw P, a 56-year-old man who had been in out of the camp since it was established,

> now the UN also control as well as the Thai authorities so people do not know to who to listen to and parents have less power to take control over their children . . . Alcohol drinking is not unusual for the Karen people, the Karen people drink alcohol based on their custom such as weddings, funerals and so on . . . they drink alcohol in these situations but had no problems with alcohol drinking. But now people are creating problems and fighting due to alcohol drinking so it is frightening the lives of the people in the camp . . . but now more and more people are coming into the camp with different ethnic backgrounds and different characteristics and more fighting, more drugs, and more problems happen in the camp.

As a result of these social changes, alcohol use was becoming more prominent and more dangerous.

In addition, there was a belief that increased economic resources derived from third-country remittances enabled participation in the host country alcohol market. This promoted commercial alcohol consumption. Indeed the camp was not isolated from marketing efforts of alcohol companies in Thailand, one of the fastest growing alcohol markets in the world.

For example, sponsorship of the camp football team by a well-known beer manufacturer was evident.

Together these economic, cultural, and social transitions contributed to changes in alcohol use behaviors and norms and increased the potential of alcohol-related harm. Risky alcohol use was common among men but not women and warrants targeted early intervention. Nevertheless, the population may have been partially protected from rapid rises in problem alcohol use observed in the host country, Thailand.

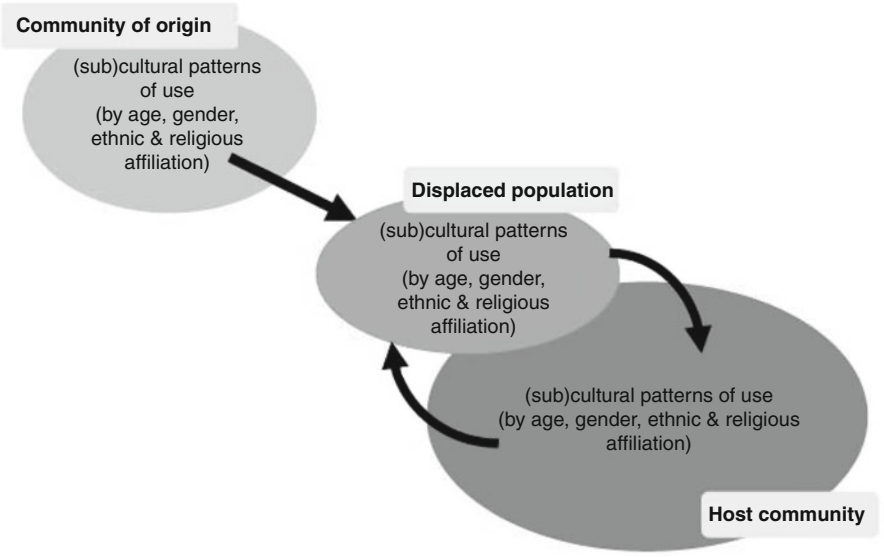

Fig. 131.1 Changing patterns of substance use in displacement (Source: Ezard et al. 2011)

following trauma or how much is increased use among those with preexisting substance use disorders. The relationship between formally diagnosed post-traumatic stress disorder and substance use is complex and is mediated by gender and pre-displacement substance use disorders (Kozarić-Kovačić et al. 2000). It may be expected that other mood disorders which are highly prevalent among conflict-displaced populations, such as depression and anxiety, may be associated with substance use as seen in non-displaced populations. Perhaps most importantly, a history of substance use disorder pre-displacement is likely to predispose an individual to substance use disorder following displacement. Individual socioeconomic determinants are also important. For example, homelessness, unemployment, and a lack of education are prevalent among opiate using Afghan refugees

in Pakistan (and more prevalent than among the non-displaced hosts) (Zafar et al. 2003).

Substance use patterns vary by gender – in general men use psychoactive substances more frequently and in greater amounts than women. For example, Roberts and colleagues showed that being older, male, and a history of exposure to multiple war-related traumatic events increased the odds of drinking alcohol at risky levels among displaced populations studied in northern Uganda (Roberts et al. 2011). One study from the Thai-Burma border suggested that women in a long-term refugee camp drank very little alcohol, whereas around a quarter of men drank at risky levels (Ezard et al. 2012). Nevertheless, women are not always excluded from participating in substance use. Afghan women in Pakistan reported commonly using opiates in one study (Ezard et al. 2011). An important proportion of women screened positive for alcohol dependence in a study from a Croatian IDP camp, a setting in which the prevalence of adult alcohol dependence was extremely high: 8 % of women and 61 % of men (Kozarić-Kovačić et al. 2000).

Supply factors will also influence observed patterns of substance use. Opiates, for example, are widely available and used among Afghani refugees, although believed to be less than among the host populations (Ezard et al. 2011). Grains supplied in food rations have been used to manufacture alcohol in long-standing displaced settings, such as refugee camps in Kenya and Thailand. Similarly transition to urban patterns of frequent heavy drinking – such as seen among some displaced populations – is believed to be stimulated by the more ready availability of alcohol (Room et al. 2002).

Economic drivers underlie these observed transitions. Alcohol brewing and sale is an important source of income in settings where other livelihood options are constrained – such as in among IDPs in camps in northern Uganda and refugees in Kakuma camp, Kenya (Ezard et al. 2011). Arguably this may contribute to the availability – and use – of alcohol. Transition to injection routes of administration such as observed among Afghan refugees in exile (Todd et al. 2007) is also partly driven by the microeconomy. Injection is more efficient, with greater psychoactive effect for the same amount of substance, and less easily detectable than smoking, important in a setting where the substance is illegal and the user may not be legally permitted in the country or subject to harassment from the authorities.

Various theoretical models can be applied to explain why substance use may be popular among populations displaced by conflict. The self-medication hypothesis (Khantzian 1985) proposes that psychoactive substances are used to relieve individual suffering, particularly among groups of people who are powerless and poor (Singer 2008). This hypothesis is shared by a number of displaced persons and observers. For example, research conducted among refugees from Sudan in Kenya explores the use of alcohol by refugees to manage thoughts of past trauma and the stress of confinement, hopelessness, and powerlessness (Ezard et al. 2011). Similarly research from refugees from Somaliland in Ethiopia describes increased khat use to moderate guilt and emotional trauma (Hansen 2010).

Alternatively, the social stress model suggests that disruption to relationships between people and social networks may induce fear and anxiety and promote substance use (Rhodes and Jason 1990). It is likely that these social changes represent more than just psychological stress. Displacement can disrupt tight family and community networks and social hierarchies and replace them with new, expanded, and unstable networks, removing preexisting social controls on substance use. Qualitative research conducted with refugees from Burma living in a long-standing refugee camp in Thailand explores how changing social structures influence changes in substance use (Ezard et al. 2012) (see Box 131.1). Altered norms emerge, accompanied by transition to potentially more harmful patterns of substance use (Friedman et al. 2006). Social norms are likely to be at least as important as social stressors in mediating substance use (Galea et al. 2007).

131.4 Harm Related to Substance Use in Displacement

A public health perspective focuses on the harm related to substance use rather than the substance use per se. Harm can include impacts on individual health or social functioning. The harm related to substance use is well documented: alcohol alone is associated with dozens of illnesses and is responsible for 4 % of global mortality (Rehm et al. 2009). In addition, a number of health and social problems associated with substance use have been documented to be of particular concern among conflict-displaced populations. These include communicable and noncommunicable diseases, violence, and economic impacts.

For example, higher HIV seropositivity and lower tuberculosis treatment success has been documented among people who inject drugs compared with people who do not inject drugs in a conflict-displaced population in India (Rodger et al. 2002). HIV risk behaviors – unsafe sexual and injecting practice – were more common among refugees than host populations in Pakistan (Zafar et al. 2003). A similar pattern was observed among displaced refugees returning to Afghanistan (Todd et al. 2007). Transition to injection may introduce HIV into communities. Molecular evidence from Afghanistan suggests a nascent epidemic of IDU-associated HIV infection in Herat, with a similar strain of HIV observed in Iran, where the majority of opiate injectors began injecting while refugees (Sanders-Buell et al. 2010).

Compounding the health risks of alcohol consumption, the livelihood imperative to generate income from alcohol production may promote the addition of harmful chemicals. Qualitative research from Mae La refugee camp in Thailand explored community perceptions that artisanal alcohol production process may be dangerous as a result of the introduction of poisonous additives (see Box 131.1). Similar observations have been made in long-standing camps in African contexts. Nevertheless, although deaths have been reported from contaminants such as methanol or herbicides in poorly produced alcohol, it is the amount of ethanol and pattern of consumption that pose the greatest threat to public health globally (Lachenmeier and Rehm 2009).

Other health problems include mental illness, which can be a cause or consequences of substance use. Among some displaced populations, substance use has made an important contribution to completed suicides. For example, alcohol has been implicated in the majority of suicides among war displaced in northern Uganda (Kinyanda et al. 2009).

Substance use has been implicated in other forms of violence. Intimate partner violence is common among women in conflict-displaced settings and is linked with substance use. In one long-standing refugee camp in Ethiopia, women whose male partners drank alcohol had twice the odds of experiencing intimate partner violence within the previous 12 months than those who did not (Feseha et al. 2012). Similarly in long-standing IDP camps in northern Uganda, women whose husbands use alcohol were 50 % more likely to report intimate partner violence (Annan and Brier 2010). This connection has been made for other substances too – for example, violence against women was linked with their male partners seeking money for cannabis in a qualitative study in Pakistan (Ezard et al. 2011).

Substance use has been observed to have important economic impacts at the individual, household, and community level. These aspects have not been explored in depth. Household expenditure can be considerable – in refugee camps along the Thai-Burma border, 80 % of households spent money on substances (Cardno Agrisystems 2009). Theft, family conflict, poverty, and child neglect among families with opium-dependent household members increased when the population was displaced away from traditional opium-growing areas in Laos (Westermeyer 1982). Collectively, transitions in substance use may contribute to the changing economic environment. Returning refugees to Somalia from Ethiopia promotes an increasingly thriving market, supported by third-country remittances (Hansen 2010). In turn, khat trade is believed to contribute to prolonging the conflict.

131.5 Intervention Framework

The literature review presented above suggests how conflict may drive changes in social conditions, which in turn may promote transitions in substance use and development of substance-related harm. Public health has long been concerned with understanding links between the context in which people live and the distribution of health outcomes. These social determinants include living conditions across the life course – such as education, environment, and access to health care – and the underlying economic and political structures determining the distribution of resources and power (Commission on the Social Determinants of Health 2008).

Conflict can be considered to be a social determinant of health. In most conflicts, the causes of mortality are indirect and noncombat related. For example, in conflict-affected Darfur, Sudan, close to 90 % of excess civilian deaths between 2003 and 2008 were due to nonviolent causes (Degomme and Guha-Sapir 2010). Conflict limits access to livelihoods, clean water, and healthy food, causes displacement and overcrowding, and disrupts health services. As a result, death rates increase, deaths that are not directly conflict related (Coghlan et al. 2006).

Not only is conflict itself a social determinant of health, social determinants of health *within* conflict-affected populations will influence the magnitude, prevalence, and distribution of substance-related harm within those populations. Aspects of material wealth, such as access to health care or differential policing patterns, make the poor more likely experience harm from substance use than the rich may experience from the same pattern of use. Health problems are compounded by limited access to good nutrition and social resources, which is frequently the case with displaced populations. Income inequality will contribute to differential development of substance-related problems – on the one hand access to cash can increase access to substances, and on the other hand limited access to services and resources will increase the likelihood of harm from substance use.

It follows, therefore, that effective intervention for substance-related harm in populations displaced by conflict requires action on the social determinants of harm. Drawing from the HIV literature, actions aimed at addressing these social determinants are increasingly termed structural interventions. Structural interventions do not aim to change individual behaviors per se; instead they aim to change the distribution of risk, health, and illness in the population. Structural interventions can be single or combination processes, policies, or programs and may have an important public health impact on multiple endpoints (not limited to substance-related harm). Growing evidence suggests that individually directed interventions have only modest impacts on risk behavior in the absence of population and policy interventions to support their effective introduction. Individual interventions target individuals (and their families) already at risk or experiencing harm; structural interventions include whole populations and have greater population impact. Figure 131.2 demonstrates this concept.

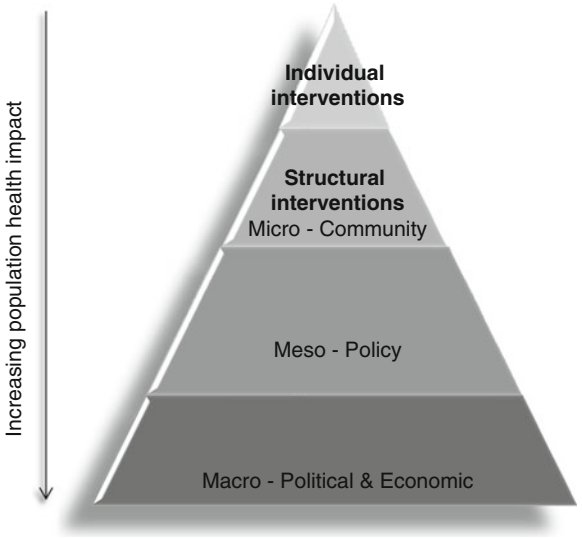

Fig. 131.2 Population intervention framework for reducing substance-related harm (Source: informed by Friedan 2010)

Experience of interventions to reduce substance-related harm among populations displaced by conflict is limited. This schema can provide a theoretical basis for identifying and organizing interventions and for evaluating their effectiveness. While changing the conditions of conflict may be beyond health professionals, the model may be useful to develop interventions within populations displaced by conflict.

Examples of individual-level interventions include biomedical interventions such as thiamine provision for heavy alcohol users and treatment of withdrawal and dependence syndromes. Other interventions include ensuring ready access to early intervention for substance-related health consequences such as hypertension, tuberculosis, sexually transmitted infections, and injuries. There is some experience in the implementation of behavioral interventions, such as screening and brief intervention aiming to decrease volume and frequency of drinking (Ezard et al. 2010). Substance use may also be incorporated into mental health programs to detect and treat depression-like illness and other locally identified mental health problems. Social interventions, such as women's safe houses, have already been introduced in some settings. Advocacy for inclusion of displaced populations into host population services may be relevant.

Individual-level interventions with evidence of effectiveness from non-displaced settings may be adapted for conflict settings. Yet it remains unclear whether these contexts are so vastly different in salient ways as to limit effectiveness. The question of how much evidence of effectiveness is necessary comes into relief. The gold standard of evidence-based interventions may not be realistic in settings of high population mobility, competing health and other priorities, resource constraints, and with complex ethical dimensions. At a minimum, interventions should be theory based and show positive outcomes on monitoring or evaluation.

Structural interventions can be divided into micro-, meso-, and macro-levels. Microlevel examples include community-based interventions to mobilize and empower marginalized and affected populations. Experience of engaging community support as therapeutic intervention for substance use problems has been described in post-conflict settings such as Kosovo (Agani et al. 2010). Effective community mobilization strategies have also been developed to address stigma around problem substance use to promote demand for services.

Community strategies like those described above are aimed at supporting individual behavior change. Others may be indicated for changing prevailing norms and attitudes, such as towards excessive drinking or violence (Jewkes et al. 2002). Efforts to modify drinking culture have met with mixed success elsewhere and need to be further investigated in displaced populations.

Experience is growing with community-based alternative income strategies for illegal drug production and for artisanal alcohol (with mixed success). The aims of these initiatives need to be clearly defined. One study from displaced camps in northern Uganda showed no relationship between women's alcohol brewing and their husband's alcohol use, or women's alcohol brewing and experience of intimate partner violence, despite a relationship between women's experience of

intimate partner violence and their husband's alcohol use (Annan and Brier 2010). In this context, then, the aim of micro-finance initiatives is not to directly decrease alcohol-related intimate partner violence. Instead, the aim is to indirectly decrease intimate partner violence through gender-based empowerment and improved livelihoods by building skills and increasing income. Indeed, there is some evidence from South Africa for micro-finance initiatives decreasing both HIV transmission and intimate partner violence (Pronyk et al. 2006).

Meso-structural interventions targeting the policy environment include limiting hours of sale, restricting age of purchase, controlling marketing, increasing taxation, and imposing minimum pricing strategies (Casswell and Thamarangsi 2009). However, these strategies apply to licit commercial markets with strong regulatory and enforcement capacity and may have limited application in conflict-affected settings. Interventions to improve the quality of artisanal alcohol such as brewer education and micro-financial incentives may be trialled in settings where the commercialization of homebrew is prominent (Kanteres et al. 2009).

Other policy interventions include equity-based initiatives by service providers. These efforts include ensuring good gender policy among interventionists, human rights-based programming, and inclusive participatory approaches to service delivery and management. Gender equity policy may address early childhood development, access to education, and high-quality childcare. A health equity approach incorporates collective and community needs, not only those of individuals. The focus is not on identifying and targeting marginalized groups so much as developing systems and processes that are socially inclusive. Socially inclusive processes of service delivery should incorporate the marginalized and avoid reinforcing existing inequalities (rather than focusing on identifying and exclusively targeting the most vulnerable).

Macrostructural changes to the political and economic context may have a profound influence on substance-related harm; acting at this level may be challenging for people working in the health sector. Actions can include drug law and economic reforms. Cross-sectoral alliances with environmental, human rights, and governance-focused groups may be directions for action, such as advocacy for refugee and migrant groups and engagement with processes governing global migration.

Structural interventions, characterized by multiple components and multiple endpoints, are complex to evaluate. Evaluation is even more challenging when attempts are made to include difficult-to-measure endpoints such as "hopefulness." Nevertheless, the effectiveness of these interventions must be assessed and the results disseminated. These types of interventions may not readily lend themselves to existing methods for assessing effectiveness and demand new approaches. Gupta and colleagues suggest a "realistic evaluation" approach, which relies heavily on qualitative process assessment as well as evidence from elements along the hypothesized causal chain (Gupta et al. 2008). Common endpoints with other interventions, such as violence prevention, should be recognized, as should consequences for substance use of other interventions.

131.6 Conclusion

Substance use among populations displaced by conflict is an important area of public health endeavor. Effectively intervening to minimize harm related to substance use requires an understanding of the social context in which substance use occurs. This chapter has described how conflict can shape transitions in substance use and development of substance-related harm. By highlighting the social determinants of substance-related harm in these populations, interventions can be identified that address these determinants. Effectively minimizing harm from substance use among conflict-displaced populations requires a combination of individual, micro-, meso-, and macrostructural interventions.

evidence suggests that while many young people experience distress in the immediate aftermath of a disaster, a majority recover within a year and maintain a pattern of adequate functioning. A minority reveal clinically meaningful levels of PTSD, substance abuse, or post-disaster increases in substance use. Objective and subjective disaster exposure has been linked with psychological symptoms and increases in substance use. Further, substance use among disaster survivors is associated with impaired behavior and poor performance in school. Parents, school personnel, and health professionals are encouraged to be vigilant and monitor disaster survivors for signs of enduring distress, substance abuse, and impaired functioning. Possible pathways to development of comorbid PTSD and substance abuse are reviewed and promising integrated treatment programs are identified. Multisystemic models of intervention are likely well suited to address the various dimensions of disaster impact and recovery among youth most adversely affected. However, the need for controlled clinical trials involving these and other promising interventions for disaster-impacted youth is apparent.

132.1 Introduction

There is evidence that individuals exposed to major disasters experience a range of psychological and stress-related physical problems including PTSD, other anxiety reactions, depression, grief, suicidal ideation, and substance abuse (Shore et al. 1986; Goenjian et al. 1995; Staab et al. 1996; Vernberg et al. 1996; North et al. 1999; Bolton et al. 2000; Hoven et al. 2003; Rehner et al. 2000; Nandi et al. 2005; Roussos et al. 2005; Chen and Wu 2006; Kar and Bastia 2006; Vehid et al. 2006; Mortensen et al. 2009; van der Velden and Kleber 2009; Bonanno et al. 2010). It is easy to assume that most individuals who experience disaster will require treatment. However, careful evaluation of the nature and extent of disaster-related impact is necessary to develop and appropriately allocate treatment resources. A disaster's impact depends not only on degree of exposure to disaster-related events but also on a variety of individual, family, and community risk and protective factors. In fact, the majority of exposed individuals demonstrate resilience after experiencing potentially traumatic events, reporting only temporary distress while sustaining a pattern of healthy functioning. Studies of both adults and children typically reveal that fewer than 30 % demonstrate persistent symptom elevation (Bonanno 2005).

Multiple risk and protective factors have been identified as potentially significant in distinguishing individuals likely to be adversely impacted from those likely to adapt favorably. Among these factors are demographic characteristics including age, gender, ethnic minority status, and level of education; degree of exposure to potentially traumatic events; the number and nature of secondary stressors experienced in the disaster aftermath; social and material resources as well as loss of such resources post-disaster; personal and family history of psychiatric disturbance; and person-focused variables including neuroticism, hardiness, and self-enhancement (Green et al. 1991; Norris 1992; Garrison et al. 1993; Thompson et al. 1993; Bokszczanin 2007; Bonanno et al. 2010). Results of these studies are not consistent.

However, youth and old age, relatively high subjective or objective impact of disaster, lack of a support system, and pre-disaster psychological difficulties are all associated with post-disaster problems (e.g., PTS, substance use). A substantial amount of research on psychosocial consequences of disaster exposure has focused on adults, and considerable emphasis has been placed on PTSD as an outcome. Much less attention has been devoted to effects on youth and other outcomes such as alcohol and other drug use.

This chapter will examine studies involving adolescents and young adults exposed to disasters and will review evidence for a range of disaster effects with an emphasis on substance use. Implications for treatment will also be addressed. At the outset, it is important to note the challenges of conducting careful research on effects of disasters. Because disasters are infrequent and unpredictable, pre-disaster measurements of potentially critical personal and social contextual predictors of disaster outcomes are typically unavailable. Recall bias and inaccurate memory of disaster-linked past events and behaviors may limit the value of post-disaster assessments. Collecting data in the immediate wake of a disaster is challenging limited availability of individuals most severely impacted may contribute to biased samples. Institutional review boards are often burdened with achieving a delicate balance between expediting data collection to support evidence-based response and guarding against the approval of multiple redundant studies and protecting the human subjects who have already experienced excessive stress (Fleischman et al. 2006). Furthermore, disasters vary widely in nature and severity and involve different types of damage and rates of mortality. Findings based on data from communities that experienced severe earthquakes may not apply to those that experienced floods or fires. Similarly, impact of disaster on use of substances ranging from alcohol and cigarettes to harder, illegal drugs such as cocaine may be contingent on pre-disaster substance use, access to substances post-disasters, or other factors which may lead to inconsistent findings in disaster-related studies. Yet another challenge to the generalizability of study findings involving disasters is the fact that these events often occur in communities that have distinct socioeconomic characteristics that influence availability of resources necessary for recovery. Members of a wealthy community in the suburb of a major metropolitan area may experience and respond to disaster differently than members of a poor rural community. With these challenges in mind, we review studies in which disaster exposure among youth is examined in association with substance use and related outcomes.

132.2 Disasters and Youth: Substance Use and Related Outcomes

132.2.1 Linking Disaster Exposure, Substance Use, and Associated Problems

After conducting several electronic literature searches up through June 1, 2013 (PubMed, OVID, Medinfo, PsycINFO, and first 100 pages of Google Scholar), we

were only able to locate six well-designed studies that examined relationships between disaster exposure and substance use among adolescents and young adults.

Chemtob et al. (2009) examined associations between exposure to the World Trade Center (WTC) attacks on September 11, 2001, and levels of substance use, psychiatric symptoms, functional impairment, and mental health service utilization 18 months post-9/11 among a convenience sample of 1,040 middle and high school students whose schools varied in proximity to the WTC. Subjects were from diverse ethnic backgrounds (33 % Asian, 13 % African-American, 19 % Hispanic, 17 % Caucasian, and 18 % multiracial and others), and 55 % were female. Objective and subjective indices of disaster exposure included (a) death of known individuals, (b) proximity of school to attack site, (c) worry about personal safety, (d) worry about safety of others, and (e) parental impairment. Criterion and control measures included self-reports of increased substance use, PTSD symptoms, depression, functional impairment reflected in difficulty getting along with friends and family, schoolwork difficulties, poor grades, behavioral problems at school, difficulty with teachers, pre-9/11 and post-9/11 mental health service utilization, and desire for mental health assistance with 9/11 reactions.

Approximately 10 % of participants reported increased substance use post-9/11 with smaller proportions revealing impairment in friendships, family, and school performance. PTSD diagnosis, while infrequent, was strongly associated with impairment in these areas. Logistic regression was used to evaluate associations between risk factors and both disorder symptoms and functional impairment. Indices of trauma exposure including worry about others' safety, loss, parental impairment, and proximity to the WTC were linked with likelihood of reporting increases in substance use. Participants with one exposure risk factor were more than 5 times more likely to report an increase in substance use than those with no exposure risk factors, those with two were more than 8 times more likely, and those with three or more risk factors were nearly 19 times more likely. Increased substance use was linked with functional impairment in behavior at school, in schoolwork, and in grades. Adolescents who had revealed increased substance use were more likely than those who had not to demonstrate functional impairment in behavior at school (6.7 % compared to 3 %), in schoolwork (18.1 % compared to 7.8 %), and in grades (38.2 % compared to 0 %). All students whose grades declined reported increased substance use. Further, those who reported increased substance abuse were nearly twice as likely to want mental health services 1½ years after the attack but were not more likely to receive them. Finally, those reporting increased substance use, PTSD, or depression were not more likely to have received mental health services before 9/11 than those without these characteristics. Compared to those who had not increased substance use, adolescents who had increased substance use were more than twice as likely to want mental health services 18 months after 9/11, but they had about the same likelihood of receiving such services (11.2 % vs. 13.8 %). Youth who had increased substance use without experiencing PTSD or depression were even less likely to receive services.

Rohrbach et al. (2009) explored relationships among exposure to Hurricane Rita, post-traumatic stress (PTS) symptoms, and changes in adolescent substance use

from 13 months pre-disaster to 7 and 19 months post-disaster. Subjects were 280 high school students recruited from ten schools in southwestern Louisiana that participated in a national dissemination trial of substance use prevention and lived in areas where storm effects caused widespread electrical outages, human causalities, and destruction to property. Nearly 68 % of participants were female and a similar proportion was white. Surveys were administered 13 months prior to the hurricane and 7 and 19 months after the hurricane. At each assessment, use of cigarettes, alcohol, and marijuana over the past 30 days was evaluated. PTS symptoms were assessed at 7 months post-hurricane. Researchers used measures that distinguished between objective hurricane exposure (e.g., hurt in hurricane, property damaged, had to move) and subjective exposure (e.g., experienced fear, thought life was in danger). Post-hurricane negative life events that might have occurred to the individual (e.g., relationship breakup) or to the individual's family (e.g., problems with money) were assessed at 7 months post-hurricane.

Although the majority of participants (>75 %) reported nonuse of cigarettes and marijuana both at baseline and follow-up, a minority (8–15 %) reported change from nonuse to use at follow-up. Forty-seven percent reported nonuse of alcohol at baseline and follow-up; however, about a quarter changed from nonuse at baseline to use at follow-up. Objective hurricane exposure assessed at 7 months post-hurricane was associated with increased cigarette use from baseline to 7 and 19 months and with increased marijuana use from baseline to 19 months. Post-hurricane negative life event exposure was linked with increases in all three substances at 7 months and with increased cigarette and marijuana use at 19 months. Although PTS severity was linked with alcohol and marijuana use at 7 months and with marijuana use at 19 months, most participants reported few such symptoms and these relationships were not significant when other predictors (e.g., storm exposure and negative events) were controlled.

Cepeda et al. (2010) investigated demographic variables, criminal history, lifetime trauma exposure, and hurricane impact variables in relation to changes in substance use among economically disadvantaged drug users who were evacuated from New Orleans due to Hurricane Katrina in August 2005. Data were gathered from July 2006 to January 2007 using semi-structured interviews with 200 evacuees participating in an ongoing drug abuse study in Houston. Participants were 18–65 years old with a mean age of 32. Ninety-eight percent of the sample was African-American and 60 % was male. Ninety percent of participants reported that their home was demolished or uninhabitable and 63 % reported they left New Orleans after the hurricane. Prior to the hurricane, tobacco, alcohol, and marijuana were each used by about 70 % of the sample. Tranquilizers, barbiturates, or sedatives were used by 31 % of the sample, ecstasy and crack were each used by 25 %, and cocaine was used by 19 %.

Of particular interest in this study is a comparison of changes in substance use among younger evacuees (18–28) and older evacuees (29–58). In addition to age, demographic variables included gender, education, marital and parental status, and income before the hurricane. Hurricane impact variables included time of evacuation (before or after the hurricane), a disaster-related exposure score, and a resource

loss score. Profiles of change in substance use were based on self-reported frequency of use during the 30 days before the hurricane and the 30 days before the interview. Substance use change profiles reflected increased or decreased use of alcohol and/or tobacco (AT) and increased or decreased use of illicit drugs (ID; barbiturates, cocaine, crack, ecstasy, marijuana, sedatives, and tranquilizers). Overall, increases in tobacco use, alcohol, and marijuana were reported by about 30 % of the sample. Twenty-three percent increased use of ecstasy, 14 % increased use of tranquilizers, barbiturates, or sedatives, 12 % increased use of crack, and 8 % increased use of cocaine. Larger proportions reported decreased use of all substances except for tobacco. Seventy-two percent of the sample decreased cocaine use; 65 % decreased tranquilizer, barbiturate, or sedative use; 57 % decreased crack use; 36 % decreased ecstasy use; 35 % decreased alcohol use; 27 % decreased marijuana use; and 16 % decreased tobacco use.

Chi-square tests were used to identify significant associations between predictor variables and increases and decreases in AT and ID use. Factors with significant associations ($p < 0.10$) were included in follow-up multivariate logistic regression analyses to identify the same changes in profiles of use identified earlier. Multivariate analyses revealed that younger evacuees were more likely than older evacuees to increase use of alcohol and tobacco (52 % vs. 36 %) and less likely to decrease use of both alcohol and tobacco (29 % vs. 43 %) and illicit drugs (40 % vs. 55 %) in the 11–17 months following the disaster. Also of interest, women were more likely than men to increase use of AT (54 % vs. 38 %). Evacuees with more education were more likely to increase use of AT (52 % vs. 39 %), as were evacuees who left New Orleans before Katrina compared to those who left after the hurricane (54 % vs. 38 %). Individuals who reported high resource loss were more likely than those who reported moderate resource loss to increase use of ID (56 % vs. 40 %). Perhaps surprisingly, evacuees with a criminal history were more likely than those with no such history to decrease use of ID (55 % vs. 41 %). Individuals with a moderate total score on disaster-related exposure were more likely than those with a high score to decrease use of AT (57 % vs. 31 %) but less likely to decrease use of ID (32 % vs. 52 %).

Overstreet et al. (2010) examined relationships between initial hurricane impact, "secondary stressors" thought to be important in post-disaster environments, and crime exposure in relation to PTSD symptoms among high school students exposed to Hurricane Katrina. Both direct and moderating influences of substance use were also evaluated. Of the 261 participants included in the analysis, 54 % were considered to be economically disadvantaged, 55 % were female, 41 % identified as black, and 50 % identified as white.

Surveys were distributed by homeroom teachers and completed by 76 % of students. Four items from a 12-item measure of various Katrina-related disruptions were used to create two predictor variables: initial impact and crime exposure. These items were as follows: "How many schools have you attended since August 29, 2005?," "How many times have you moved since August 29, 2005?," "Did one of your parents lose his or her job because of the disaster?," and "Have you or members of your family been the victim of crime?" Level of exposure to secondary

stressors was assessed using eight items reflecting the current status of hurricane-related disruptions (e.g., "Has it been hard to see your friends since the evacuation?"). Three of these were drawn from an existing measure of hurricane-related disruptions (e.g., ongoing damage to one's home, parental job loss, difficulty seeing friends). PTSD symptoms were assessed using selected items from the adolescent version of the Los Angeles Symptom Checklist (LASC). Substance use was assessed using two items from the LASC, dichotomized to reflect nonuse or some use. Ninety-two percent of participants experienced at least one secondary stressor, with nearly half experiencing three or more. The most common secondary stressors involved disruptions in contact with friends. Twenty-six percent of participants scored in the clinically elevated range of PTSD symptoms. This proportion is similar to those found in other post-disaster studies. Females reported significantly more PTSD symptoms than males but similar levels of secondary stressors. Fourteen percent of participants reported substance use, consistent with previous post-disaster studies. There were no gender differences in substance use.

Analysis of bivariate relationships revealed significant associations between gender, secondary stressors, as well as problem substance use and both an overall index of PTSD symptoms and specific measures of reexperiencing, avoidance/numbing, and hyperarousal. Secondary stressor exposure was significantly associated with problem substance use; however, initial hurricane impact was not. Hierarchical regression analysis was used to determine if gender, initial hurricane impact, crime exposure, secondary stressor levels, problem substance use, and a variable reflecting the interaction of secondary stressors and substance use contributed to prediction of overall PTSD symptoms. Gender and crime exposure entered in the first block contributed significantly to prediction of PTSD symptoms. Females and those with higher levels of crime exposure experienced more symptoms. Initial hurricane impact did not predict PTSD symptom level. Secondary stressors and problem substance use, entered in the second block, contributed significantly, with problem substance use contributing most to prediction. The secondary stressor moderating influence of substance use was examined in the final block but it did not contribute significantly to prediction of PTSD symptoms.

Rowe et al. (2010) studied hurricane impact variables, individual, and family factors in relation to substance involvement and post-traumatic stress symptoms in a group of adolescents exposed to Hurricane Katrina. Eighty adolescents and their parents were interviewed at substance abuse treatment intake between 16 and 46 months after the hurricane. The majority of participants were male (87 %) and between 13 and 17 years of age. Sixty-two percent were white, 31 % African-American, and 4 % Hispanic. Pre-disaster predictors included demographics, adolescent and parent substance abuse, and pre-disaster trauma exposure. Hurricane impact variables included initial loss/disruption and perceived life threat. Post-disaster variables included family psychopathology, family cohesion, parental monitoring, and adolescent delinquency. Participant scores on the adolescent self-report and parent reports of adolescent symptoms reflected mild PTS symptom severity on average. Substance use scores were also within a mild range of severity on average. Hierarchical regression analysis revealed that greater hurricane-related

loss/disruption, lower family cohesion, and greater adolescent delinquency were linked with greater adolescent-reported symptoms of post-traumatic stress. Parental psychopathology, lower family cohesion, and less parental monitoring were associated with parental reports of adolescent PTS. Adolescent substance use involvement was associated with lower parental monitoring, higher adolescent delinquency, and higher family income. Hurricane-related variables were not significantly related to adolescent substance involvement.

Parslow and Jorm (2006) explored the experience of traumatic events, immediate disaster-related emotional response, and fire-related PTSD symptoms of reexperiencing and hyperarousal in association with changes in tobacco consumption in a sample of 2063 young adults living in a region of Australia impacted by a major bushfire in 2003. Participants were between 20 and 24 years of age at the time of the initial evaluation, which took place several years prior to the disaster (1999–2000). The follow-up evaluation was conducted 4 years later (2003–2004), a few months after the fire occurred. A majority (62 %) lived or worked in an area that was put on alert and about half reported that friends or relatives had experienced fire-related damage. Smaller proportions reported forced evacuation from home or own workplace (11 %), possessions damaged (3.9 %), personal injury (1.9 %), or death or injury of a personal friend or relative (4.7 %). Nearly 14 % reported personal involvement in fighting bushfires threatening home or neighborhood, and nearly one fifth reported other work involving bushfires and their effects. Five percent of the sample fit criteria for PTSD with the majority reporting no PTSD symptoms in the week prior to evaluation. Over the 4 years of the study, 13 % of participants increased tobacco use. Those reporting more traumatic events experienced during the disaster were slightly more likely to report increased consumption of tobacco (OR: 1.12, 95 % CI: 1.03–1.21). This relationship applied only to those who reported some tobacco use at the initial assessment. A higher proportion with PTSD hyperarousal symptoms reported increased tobacco use (31.1 % vs. 24.9 %; $p = 0.018$). This relationship was no longer significant after controlling the number of traumatic events experienced.

132.2.2 Treatment Implications and Recommendations: When and With Whom to Intervene

Evidence from the studies reviewed suggests that a minority of adolescents and young adults exposed to disasters reveal clinically meaningful levels of PTSD, substance use, or post-disaster increases in levels of substance use. However, consistent with the adult literature, there is evidence that higher levels of objective and subjective disaster exposure are linked with greater psychological symptoms and increases in substance use (Green et al. 1994; Parslow and Jorm 2006; Chemtob et al. 2009; Rohrbach et al. 2009; Cepeda et al. 2010; Rowe et al. 2010). Further, increased substance use has been linked with functional impairment in behavior and

performance in school (Chemtob et al. 2009). Although most young people are expected to experience distress in the immediate aftermath of a disaster, the majority recover within a year and maintain a pattern of adequate functioning (La Greca et al. 1996; Chen and Wu 2006; Bonanno et al. 2010). That said, school personnel and health professionals should be vigilant and monitor disaster survivors for signs of enduring distress, substance abuse, and impaired school functioning (Chemtob et al. 2009; Rohrbach et al. 2009). It has been argued that school-based monitoring and treatment resources should be made available to facilitate assessment and intervention when needed (Chemtob et al. 2002, 2009; Joshi and O'Donnell 2003; Taylor and Chemtob 2004).

Vernberg (2002) distinguished post-disaster interventions on the basis of phase of recovery. While a number of interventions have been designed for implementation in the immediate aftermath of disasters or terrorism, there is little evidence that psychological interventions in this time frame effectively reduce immediate distress or improve longer-term outcomes (La Greca 2008; La Greca and Silverman 2009). La Greca and Silverman (2009) suggest best practices include having adults provide comfort and reassurance; encourage expression of concerns, fears, and apprehensions; and assist youth in returning to normal activities and routines. During this phase, adult caretakers might be assisted in identifying acute stress reactions that require evaluation and treatment.

In the next phase, short-term recovery (from the first few weeks to the first year post-disaster), La Greca and Silverman (2009) recommend a focus on building coping skills for dealing with emotional reactions and predictable stressors in the disaster aftermath, reestablishing supportive social relationships, and continuing to encourage a return to normal roles and routines. A number of psychoeducational resources have been developed to accomplish these objectives (La Greca et al. 1994, 2001; Prinstein et al. 1996; Gurwitch et al. 2005). Although promising, little is known about the effectiveness of these informational approaches. As in the initial phase, there is a need to identify youth with moderate to severe symptoms who may need careful evaluation and treatment.

Although most youth recover during the first year after exposure to traumatic events, a significant minority experience chronic stress reactions (La Greca et al. 1996, 2002). Current interventions typically target persistent or chronic youth PTSD reactions, and cognitive behavioral therapy (CBT) is the treatment approach about which most is known (Brady and Back 2012). CBT is thought to promote habituation by targeting stimulus–response associations and correcting distorted cognitions. Prolonged exposure approaches involve psychoeducation, breathing retraining, imaginal exposure to trauma memory, and in vivo exposure to trauma reminders (Rachman 1980; Deblinger et al. 2001; Vernberg 2002; Cohen et al. 2004, 2005; La Greca and Silverman 2009). These interventions have been effective in treatment of abuse victims and may reduce PTSD symptoms in youth (Deblinger et al. 2001; La Greca et al. 2002; Cohen et al. 2004, 2005). It should be noted that some research has shown that unnecessary reexposure may trigger substance abuse and other problems (Brady et al. 2013).

132.2.3 Understanding and Addressing Comorbid Substance Abuse and PTSD

There are likely multiple pathways to development of comorbid PTSD and substance abuse among youth exposed to disasters, but few studies have examined this issue. It is often assumed that PTSD emerges initially and substance use and abuse follow reflecting efforts to cope with post-traumatic symptoms. The link between traumatic event exposure and substance abuse is argued to be mediated by PTSD and/or other psychiatric symptoms (Souza and Spates 2008). A number of the studies reviewed earlier identified a relationship between disaster event exposure and both PTSD symptoms and substance abuse (Parslow and Jorm 2006; Chemtob et al. 2009; Rohrbach et al. 2009). Although none of these studies included formal mediation analysis, conditions for mediation did not appear to be met. In Rohrbach et al. (2009) and Parslow and Jorm (2006), associations between PTS symptom severity and substance abuse increases were no longer significant when indices of disaster exposure were controlled. Rowe et al. (2010) found that among adolescents exposed to Hurricane Katrina prior to entry into substance abuse treatment, degree of loss and disruption associated with the hurricane exposure, while linked with PTSD symptom elevation, was not associated with level of substance involvement. This study employed a cross-sectional design and could not illuminate potential causal linkages among event exposure, PTS, and substance use.

Other PTSD vulnerability factors (e.g., minority ethnic status, female gender, lack of education, and younger age) have been argued to moderate the relationship between exposure and substance use initiation or increase in use. Unfortunately, few studies involving youth have examined the contribution of these potentially important factors. Cepeda et al. (2010) found that among economically disadvantaged drug users, younger evacuees from New Orleans during Hurricane Katrina were more likely to increase use of alcohol and tobacco and less likely to decrease use of alcohol, tobacco, and illicit drugs than older evacuees. They also found elevated risk among females and among those with more education.

While little research has addressed pathways leading to PTSD–SA comorbidity among youth exposed to disasters, further exploration in this area may be important in identifying streams of influence necessary to address when developing treatments (Souza and Spates 2008). In the adult literature, it has frequently been assumed that PTSD is a major risk factor for development of substance use. PTSD-related intrusive thoughts, negative emotions, and hyperarousal symptoms have been linked with increased craving for substances following presentation of trauma-related stimuli (Marlatt and Gordon 1985; Sharkansky et al. 1999; Souza and Spates 2008). There is some evidence that substance abusers are more vulnerable to developing PTSD after trauma exposure and the effects of some substances (i.e., cocaine) may exacerbate PTSD symptoms (Sharkansky et al. 1999). Further, negative impact of high SA risk situations may complicate the substance user's ability to cope with the symptoms of PTSD (Souza and Spates 2008). Those with co-occurring PTSD and substance abuse demonstrate higher levels of interpersonal

conflict, less self-efficacy, and more limited ability to cope with psychological distress compared with those showing only substance abuse (Ouimette et al. 1999; Sharkansky et al. 1999). Indeed, the co-occurrence of substance abuse and PTSD may be linked with the severity of symptom presentation of both conditions and may complicate treatment of each. Although clinical folklore favors initial treatment of substance problems followed by attention to PTSD issues, increasing emphasis has been placed on integrated treatment models that address PTSD issues relatively early in treatment (Souza and Spates 2008). There are likely multiple pathways to development of comorbid PTSD–SA among youth exposed to disasters, but few studies have examined this issue. A randomized, controlled study comparing outcomes of adolescent females with comorbid PTSD and substance abuse treated with *Seeking Safety* to those who underwent "treatment as usual" found that the group treated with *Seeking Safety* had significantly better outcomes in several areas, including some trauma-related symptoms and substance use (Najavits et al. 2006). This approach has not yet been studied in disaster-involved youth.

132.2.4 Broadening the Perspective: Multisystemic Approaches

Bonanno et al. (2010) emphasize that disasters have an enduring negative psychological impact on a minority of individuals exposed, that exposure outcomes vary considerably and depend on a combination of risk and resilience factors, and that effects on families, neighborhoods, and communities are important to consider because disasters can damage these critical social units. Youth are at risk for a range of negative outcomes under conditions of individual, family, and community disorganization (Hawkins et al. 1992; Newcomb and Felix-Ortiz 1992; Rowe and Liddle 2008). The loss of or disruption to crucial community structures may have particular impact on youth already at elevated risk (Rowe and Liddle 2008). Typical service structures available for working with young disaster victims, their families, and communities are often not well equipped to address complex co-occurring psychiatric conditions (e.g., PTSD–SA), as well as disruption to already high-risk families, neighborhoods, and communities (Rowe and Liddle 2008). Multisystemic models of intervention seem particularly well suited to deal with the multiple dimensions of disaster impact and recovery among those severely affected. However, little research has addressed the efficacy of such models in disaster-impacted communities.

Hawkins et al. (1992) have developed both assessment and intervention programs that enable evaluation of the particular needs of individuals, schools, and communities and argue for tailoring intervention efforts on the basis of careful needs assessment. Another promising model, Multidimensional Family Therapy (MDFT; Liddle 2002), is being evaluated in a randomized trial with clinically referred substance-abusing teens in a New Orleans area community impacted by Hurricane Katrina (Rowe and Liddle 2008). Bonanno et al. (2010) emphasize that it is important to improve and mobilize essential community resources following a massive disaster (Norris et al. 2002; Somasundaram et al. 2003;

Hobfoll et al. 2007). However, when large-scale resources are suddenly imported, care must also be taken not to harm to the post-disaster community's fragile cohesiveness and sense of efficacy (Kaniasty 2012).

132.3 Conclusion

The studies reviewed may suggest at least three programmatic directions specifically relevant to youth. First, some type of family treatment may be important to increasing monitoring of youth and family cohesion and to dampen potential impact of a disaster on PTS and substance use. Knowing youths' whereabouts and providing grounding in a meaningful home lifestyle are imperative when the environment has become suddenly and dramatically disorganized. The treatments suggested above (e.g., MDFT) may assist in that regard. One may speculate that provision of family-based substance abuse prevention programming such as the Strengthening Families Program (SFP) or Family Matters (FM) might also provide a protective impact prior to the experience of disaster (Sussman 2013). In fact, use of prevention programming may benefit outcomes by lessening the need for post-disaster treatment that may elicit negative side effects (e.g., sensitization to the disaster, demoralization; Wagner et al. 2009).

Second, evaluating mental health and substance abuse treatment needs of, and providing needed treatment to, high-risk youth as soon as possible post-disaster is indicated. Lack of personal and social resources (e.g., adequate coping skills and social support) has been a reality for survivors of many disasters and impedes recovery from PTS and drug misuse (Wagner et al. 2009). The need for controlled clinical trials of treatments for youth presenting with SA and/or PTSD is obvious. The Multidimensional Family Therapy study of Hurricane Katrina-exposed, substance-abusing youth is an important effort in this area (Rowe and Liddle 2008).

Finally, providing instrumental environmental resources (e.g., insurance, medical care, employment, and housing) and capacity to create an organized, restructured, restorative environment as soon as possible (to reduce post-disaster crime or other secondary trauma exposure) is needed to embed youth within a safe community context in which family support could be maximal and individual resilience might be reinforced (Wagner et al. 2009).

The conclusions and recommendations found in the chapter are only suggestive because of (a) the paucity of work in this arena, (b) the existence of retrospective report confounds in most studies (all but the Rohrbach et al. study), and (c) numerous variations across these few available studies (e.g., types of disaster, age of youth, SES of context). However, we believe in erring on the side of caution and carefully evaluating and addressing the needs of those most vulnerable and most seriously impacted. Most studies on youth have been conducted in highly developed locations. In less-developed locales (e.g., post-disaster circumstances in Haiti), providing needed assistance may require more extreme measures just to stave off starvation. Clearly, more research is needed to assess both the amount and nature of assistance that can be most beneficial to youth post-disaster.

Children, Adolescents and Young Adults: An Introduction

133

Ilana B. Crome and Robert Milin

Abstract

One of the major challenges that young people face is the risk of initiating substance use, which is especially high at this age. It is a vital area of study because if we can effectively intervene early, we will prevent chronicity as well as the potential development of other mental disorders and even premature death, with its impact on families and community. It is vital because an understanding of the mechanism of development in young people may provide pointers to understanding the nature of addiction. Promising interventions for adolescents who misuse substances have been identified and we should build on findings to date to further enhance methods to improve treatment outcome, accessibility, implementation, and relapse prevention through the integration of research findings into treatment.

Little seems to engender so much disquiet as young people who use drugs. This is for many obvious, and sometimes not so obvious, reasons. There is fear, concern, and worry. This can be justified, since one of the major challenges that young people face is the risk of initiating substance use, which is especially high at this age. This may result in a plethora of unwanted acute and chronic social,

psychological, and physical consequences and may occasionally be life-threatening. The risk of self-harm and suicide is of concern to clinicians for every patient they assess.

Intervention improves outcomes; thus, it is right that substance use in adolescence is an area of significant individual and public health concern. It is also likely that the earlier the intervention, the more chance there may be of a successful outcome.

So, while there is every reason for parents and the communities in which we live to feel apprehensive, we have attempted to focus on a few key areas in this domain, where promising advances over the last decade have elucidated our understanding and treatment of young people with substance use problems.

We have been fortunate that our colleagues from across the globe have agreed to contribute to this vital topic. It is vital because the majority of people who experience lifelong substance use problems have started in their teenage years. In some, their mothers and fathers will have suffered too. Therefore, this young cohort gives us clues about the degree to which substance problems may be inherited genetically and the product of environment.

It is a vital area of study because if we can effectively intervene early, we will prevent chronicity as well as the potential development of other mental disorders and even premature death, with its impact on families and community. It is vital because an understanding of the mechanism of development in young people may provide pointers to understanding the nature of addiction.

Thus, we have chosen topics that are important and controversial, and authors have critically analyzed the material which they have presented:

The overview chapter by Milin and Walker which focuses on enhancing comprehension of adolescent substance use disorders (SUD) in addressing the following areas, epidemiology, vulnerability and developmental course, comorbidity, assessment, treatment, and outcomes, provides us with a valuable synopsis of the current state of knowledge on adolescent SUD.

Schlosberg and Shoval remind us that suicide is the second or third leading cause of death among adolescents in the industrialized world. They present data which substantiates that the connection between suicide and substance abuse in adolescents is very strong and poses substance use disorders as a major risk factor for emergent suicidal behaviors. They highlight the role of salient moderating factors such as comorbid psychiatric pathologies, age, gender, and sexual minorities.

Dr. Brook and colleagues have demonstrated that adolescent substance use is best understood as determined by a multitude of risk factors in different developmental contexts (i.e., individual, micro-and macro-contextual). However, it also describes how the developmental pathways to adolescent substance use can be modified by protective factors, including an attachment between parents and children, which have the ability to mitigate the impact of risk factors on adolescent substance use and abuse. Of particular importance, they draw attention as to how this knowledge can optimize preventive strategies and note the importance of cultural and developmental relevance and appropriateness in prevention.

Dr. Chang has placed a spotlight on the paradox that the treatment of ADHD in this population is often with medications with a risk of diversion and hence abuse.

He reviews clinical trials so as to understand the relative benefits versus risks because of their clinical relevance. A review of the literature in these areas leads then to an effort to translate research findings into relevant clinical practice that maximizes benefits but minimize risks.

Drs. Velez and Janssen alert us to the fact that it has been established that in utero exposure to psychoactive substances is one of the major preventable causes of disorders of fetal and infant/child growth and neurodevelopment. The effects of these neurodevelopmental alterations can appear at any time of the individual's life and can affect a variety of domains including developmental, behavioral, cognitive, and adaptive functioning. Moreover, maternal chronic substance use can compromise the maternal neural circuitries that subserve executive functioning and the regulation of stress response and consequently the ability to appropriately parent children. It is fascinating that the expression of the teratogenic effects of perinatal exposure to substances can be exacerbated by a toxic or unstable prenatal and/or postnatal environment and ameliorated by a nurturing and stable one.

Drs. Aklin and Chambers have provided an absorbing examination of the integration of translational science into adolescent addiction which has the potential to greatly improve treatment outcomes and relapse prevention. Areas of research that focus on potential behavioral and neurobehavioral targets have direct implications for treatment efficacy and build on the current treatments that have been successful. This is of great public health importance, given the clear relationship between initiating treatment, remaining in treatment, long-term abstinence, and relapse. Developmentally appropriate, targeted treatments are likely to be more efficient and potent, require less staff time, lead to less relapse, and ultimately reduce the burden on providers.

What are the striking commonalities that emerge? The first is that substance use is mainstream – it is not exceptional any longer. It has percolated through to younger age groups and can be understood through the developmental lens of adolescence and young adulthood.

A second thread is that substance misuse in young people is not just the responsibility of direct face-to-face interaction with medical professionals when a young person has an identifiable clinical "problem." It is a public health issue in that some of the precursors are socially determined and ramifications have impact on the community beyond the individual themselves.

Another common feature is that of engagement of a young person who is often vulnerable, even marginalized. There are a host of factors which may limit the degree to which a young person – and their family – might be willing to become engaged. This may depend as much on features of the intervention program as the individual and family seeking treatment. The inclusion of ongoing screening for substance use in adolescents as part of primary care may facilitate the necessary discussion of substance use and misuse.

A further notion which cuts across all contributions to this section is that of the need for coordination since teenagers who misuse substances will require involvement of multiple systems. This will include holistic and systematic and often repeated assessment. It will include coordination of health services such as primary

health care, specialist mental health, substance misuse, and general medical services. It will include coordination with other providers such as educational, criminal justice, and child welfare services. Young people with combined mental and substance use disorders exhibit greater severity of clinical symptoms, functional impairment, poorer response to treatment, and service utilization.

An additional unifying observation is that account needs to be taken of the total psychosocial environment of the adolescent at the point of assessment through to intervention and that this needs to be a continuous process due to the rapidly changing nature of adolescent substance use which can be unpredictable. Furthermore, there is agreement that effective preventive and treatment interventions must be developmentally, as well as culturally, appropriate and should be tailored to the individual's developmental stage and cultural context. Importantly, treatment itself can be preventive in terms for further deterioration.

Greater specificity in treatment choice which is explicitly tailored to the individual resonates throughout. For, although the research base has expanded enormously over the last decade, this itself leads to the conclusion that understanding is still at a relatively early stage! Broadly, psychosocial family-based interventions and developmentally appropriate CBT with MET as part of outpatient interventions have been demonstrated to provide the most consistent gains. There is accumulating evidence that supports the benefit of adolescent SUD treatment programs across different settings, including residential, short-term residential/inpatient, partial hospitalization/day treatment and outpatients, as well as some promising findings with respect to aftercare. This is encouraging. However, we are still not in a position to select which treatment modality might be more suited and effective for a particular patient. Indeed, contributors consider that involvement of the family and community is pivotal in the implementation of change.

Principally, there is a consensus for a need for larger studies with regard to the place of extended or maintenance pharmacological therapies for young people with substance use problems, especially in those with comorbid mental health problems. This represents the majority of adolescent substance misusers in residential/inpatient facilities: there are substantial implications for initial engagement, quite apart from retention in treatment, with the young person who has combined disorders. Rapid entry to treatment enhances retention.

Despite this, while effectiveness of treatment has improved, service utilization has remained relatively stable. It is also the case that, in many countries, the development of service provision has not matched need. Why is this? What are the barriers? Introduction and implementation of novel interventions can be problematic: staff are not always susceptible to change. Although the most severely afflicted young people may be treated in inpatient units, at least initially, the possibility of supporting teenagers in their communities might meet with greater success. Weighty barriers remain such as stigma, safety, transportation, family commitment, and need resolution. Mutual aid is another growing area especially if continuing care is required to sustain recovery. In keeping with this, all authors emphasize that appreciation be given to the developmental stage of the young person and their cultural background.

That the use of new technologies may support investigations is emerged as a key consideration from further biological research to the delivery of interventions. Some intriguing suggestions and pointers for the future have been described such as targeting impulsivity, risk-taking propensity, and delay discounting or choice preference. Neurobiological development of reward function is being investigated by neuroimaging studies and is a current research focus, and this may assist in the expansion of tailor-made therapies to enhance outcomes and prevent relapse. Having a greater appreciation of the specific characteristics of reward-related behavior may lead to enrichment of the socio-behavioral model by encouraging and training young people to implement coping skills by curbing self-control and impulsivity. Research on decision making, risk reduction, and behavioral control may lead to implementation of more powerful targeted interventions. While all authors agreed that there has been a wealth of research over the last couple of decades, it is essential that this is ongoing and expanded. We are aware of certain gaps, for example, the developing world, which appears to be on the cusp of the emergence of serious substance problems in its youth, has not been adequately represented.

As Dr. Chang noted in his discussion on ADHD and addiction, "Contributions from epidemiology, genetics, neuroimaging, psychopharmacology, and of course long term clinical follow up (are needed) to understand that SUD is a significant complication of the lack of adequate treatment of ADHD, often dating from early childhood," though current treatment for ADHD may not reduce this risk. He also pointed to "a bidirectional influence, especially with the use of tobacco and alcohol during pregnancy increasing the risk for development of ADHD in the fetus." This insight that the research contributions themselves need to be multidisciplinary are echoed throughout.

All authors agreed that promising interventions for adolescents who misuse substances have been identified and that we should build on findings to date to further enhance methods to improve treatment outcome, accessibility, implementation, and relapse prevention through the integration of research findings into treatment.

To conclude, as Drs. Aklin and Chambers have aptly stated:

This is of great public health importance, given the clear relationship between initiating, remaining in treatment, long-term abstinence and relapse. Developmentally appropriate, targeted treatments are likely to be more efficient and potent, require less staff time, lead to less relapse, and ultimately, reduce the burden on providers.

Adolescent and Substance Abuse

Contents

Abstract

Substance use disorder (SUD) in adolescence is a serious mental health and social problem with its significant association with morbidity and mortality. Substance abuse has progressed from the more antisocial, risk-taking, and marginal groups of the population to the mainstream of society and dramatically to younger populations, reinforcing and expanding the boundaries of at-risk populations for SUD. Research in the area of adolescent substance use has expanded significantly over time, and while many studies have contributed to the growth of knowledge in this area, ongoing study remains important. Substance use may be seen through a developmental perspective progressing across adolescence into young adulthood. We have included the most recent studies and

research findings on adolescent substance use and related disorders in this chapter. The chapter will focus on enhancing knowledge and comprehension of adolescent substance abuse in addressing the following areas: epidemiology, vulnerability and developmental course, comorbidity, assessment, treatment, and outcomes. The transitional period of adolescence presents itself as an especially critical and vulnerable time for the onset of substance use disorder (SUD) with its impact on normal development, future SUD, and for society as a whole. Adolescence is a period of major risk for the onset of SUD. Treatment approaches must be tailored to developmental patterns of substance use and include comprehensive assessment and a holistic approach. High rates of comorbid mental disorders among adolescents with SUD further emphasize the need for psychiatric care. An integrated approach to treatment for youth with SUD and comorbid mental disorders is paramount to effective intervention.

134.1 Introduction

The goal of this overview chapter is to present the current knowledge and discuss the balance of evidence to enhance the understanding, significance, and treatment of adolescents with substance use disorder (SUD). Research in the area of adolescent substance use has expanded significantly over time. While many studies have contributed to the growth of knowledge in this area, further research and study remains important. As such, we have included the most recent research and findings on adolescent substance use and related disorders in this chapter.

As preadolescent substance use is uncommon, the focus of this chapter is on the adolescent population, an age group that faces major developmental and psychosocial challenges including substance use. Substance use may result in serious mental health and social impairments with a significant association with morbidity and mortality. The onset of substance use disorder is particularly high during adolescence. Substance use has essentially become part of mainstream adolescent development and, over time, has become increasingly common among younger populations. Adolescence may be appropriately defined as a time of major risk in the development and onset of SUD.

134.2 Youth Substance Misuse

134.2.1 Epidemiology

The Monitoring the Future survey (Johnston et al. 2013) has been annually measuring the prevalence rates of substance use in adolescents attending school across the United States (US) in a nationally representative sample for more than three decades. Substance use (alcohol and illicit drugs) in general across the grades has shown a steady and measurable decline for some time led by a decline in alcohol use, though with some exceptions. The rate of binge drinking

has remained a concern at 24 % in 2012 for grade 12 students. Marijuana, in contrast, has shown a significant increase in use over the last several years affecting the rate of illicit drug use, whereas illicit drug use other than marijuana has more or less held steady or declined. The rise in marijuana use appears to mirror the lessening attitudes toward the perceived risk of harm associated with its use. The annual prevalence rates for 2012 of any illicit drug use in grades 8, 10, and 12 stand at 7.7 %, 18.6 %, and 25.2 %, respectively, which remain relatively high. Substance use overall shows a marked increase in prevalence from grade 8 to grade 12. By far, the two most common substances used by adolescents are alcohol and marijuana, with current rates for senior high school (grade 12) students of 41.5 % and 22.9 %, respectively in 2012. Marijuana has been the most common substance of daily use among adolescents by far for more than a decade, currently standing at 6.5 %. Prescription drug misuse among high school seniors remains a concern at approximately 27.7 % per annum. Included in this group are narcotic analgesics (vicodin and oxycontin), stimulants (Adderall and Ritalin) used for treatment of attention-deficit/hyperactivity disorder (ADHD), and sedatives/tranquilizers.

Prevalence rates of substance use do not provide one with comparable rates of SUD in general and especially in adolescents (American Academy of Child and Adolescent Psychiatry 2005). Substance experimentation among adolescents is highly prevalent, though the vast majority of these adolescents do not develop an SUD, even with some of these adolescents engaging in more regular use for a period of time, though the latter does increase the likelihood of developing an SUD (American Academy of Child and Adolescent Psychiatry 2005; Brown et al. 2008; Gilvarry 2000). These patterns of substance use, as it would relate to alcohol and marijuana use seen in adolescents, appear for some to be within normative behavior and part of the maturation process of adolescence, but for others may lead to significant SUD (Brown et al. 2008; Shedler and Block 1990).

The US National Comorbidity Survey-Adolescent Supplement (Merikangas et al. 2010) has recently provided us with the first general estimates of lifetime prevalence rates of SUD in this population. SUD at 11.4 % and mood disorders at 11.2 % represent the two most common categories of mental disorders with severe impairment in adolescents. It is important to recognize that the prevalence of drug use disorders at 8.9 % exceeds that of alcohol use disorders at 6.4 % contrary to adult prevalence rates for SUD. SUD was found to be somewhat more common in boys at 12.5 % than girls at 10.2 %. The median age of onset for SUD was 15 years, with a steep increase in incidence thereafter.

SUD prevalence rates have been reported in a US community sample examining higher-risk groups of adolescents receiving public sector services including those receiving mental health services. The overall past year prevalence rate for SUD was found to be 24 % across all five public sectors (Aarons et al. 2010). This rate is being more than two times greater than the recently reported prevalence of SUD in the general adolescent population.

Despite the overall relative decline of substance use in adolescents, the prevalence remains high and is the greatest with older adolescents. Emerging areas of

concern include a defined minority of adolescents who engage in polysubstance use which may carry a greater burden of related problems (Conway et al. 2013) and the rising misuse of prescription pain relievers by adolescents with evidence of significant dependence liability (Wu et al. 2008). One can also surmise that cannabis is the most telling and common substance of dependence in adolescents with alcohol being the predominant substance of abuse (Young et al. 2002; Dennis et al. 2002). The prevalence of substance use and SUD in adolescents remains a major public health issue with drug use disorders being more prevalent than alcohol use.

134.2.2 Development and Course

Levels of substance use have been found to increase from early adolescence to early adulthood (mid-1920s) and decline thereafter. Girls may exhibit higher levels of substance use than boys during early adolescence, whereas over time boys exhibit greater rates of change, resulting in high levels of substance use from mid-adolescence through young adulthood (Chen and Jacobson 2012). Adolescence is a time of major risk for the onset of SUD that shows a developmental trajectory (Palmer et al. 2009). The peak age of onset for SUD, both alcohol and drug use disorders, is in late adolescence/early adulthood, between the ages of 18 and 20 (Brown et al. 2008; Compton et al. 2007).

Adolescence, as seen from a developmental perspective, represents a time of convergence of significant neurobiological, cognitive, behavioral, emotional, and social changes with continuity of risk from earlier developmental stages, providing a unique period of heightened vulnerability and susceptibility for SUD (Brown et al. 2008; Schepis et al. 2008; Casey and Jones 2010). Brown and colleagues (2008) reflect on these interrelated developmental factors, the changes that occur during adolescence, and its influence on individual alcohol use trajectories and risk for problem drinking. The authors' narrative highlights the growing evidence that adolescents are particularly vulnerable to the adverse effects of heavy alcohol use both in the biological and social domains and that the consequences of drinking appear to differ between adolescents and adults. They also identify that problem drinking has the potential to redirect the normative course of adolescent development in a manner that increases the risk not only of alcohol use disorders but also of mental health and social problems.

Schepis and coauthors (2008) in their review of the neurobiological processes involved in the etiology of adolescent SUD emphasize the significance of maturational changes of the central nervous system that occur in adolescence, the foremost of these being synaptic pruning, myelination, and neurotransmitter system modification. In general, adolescents appear to have greater neurobiological bases for risk-taking behavior with attenuated suppressive and regulatory controls on behavior. The authors surmise that the abnormal neurological markers of those at risk for the development of SUD may best correspond to disinhibition and/or negative affect. Adolescents appear more vulnerable to the effects of many substances that are most likely mediated by increased neuroplasticity and the effects of stress. It is likely that

substance-induced neurobiological changes enhance drug use behaviors. These attributes reinforce the progression to SUD in adolescents.

A great number of risk factors have been identified in the prediction of SUD in adolescence/young adulthood. These risk factors may be conceptualized into four domains: (a) culture and society (e.g., laws and availability of substances), (b) interpersonal (e.g., peers and family including attitudes), (c) psychobehavioral (e.g., early/persistent behavioral problems, poor school performance, rebelliousness, early onset of substance use, personality characteristics such as temperament and affect), and (d) biogenetic (e.g., inherited susceptibility and psychophysiological vulnerability to the effects of substances) (Gilvarry 2000; Compton et al. 2007; Hawkins et al. 1992).

It appears that social factors, especially peer influence, are the strongest determinants of initiation of substance use, whereas psychological factors and the self-reinforcing effects of a substance are more closely associated with the progression to SUD (Newcomb 1995).

There is not much evidence to assist in distinguishing the relative importance of risk factors and their specificity in the development of adolescent SUD. It is the number of risk factors, rather than any one factor, that is predictive of SUD. Many of these risk factors are shared with those related to the onset of other mental disorders in adolescents (Gilvarry 2000; Newcomb 1995).

Protective factors are those that reduce the likelihood and level of substance use. Multiple protective factors have been identified including a positive temperament (absence of depression)/self-acceptance, intellectual ability/academic performance, supportive family/home environment, caring relationship with at least one adult, external support system (e.g., religion/church) that encourages prosocial values, and law abidance/avoidance of delinquent peer friendships (Gilvarry 2000; Newcomb 1995; Fergusson and Lynskey 1996). Again, it is not one particular protective factor but, rather, the number of protective factors that has the greatest influence on reducing the likelihood of developing SUD in adolescence. As such it has been shown that those adolescents with five or more protective factors are over 20 times less likely to develop cannabis abuse than the general sample. Protective factors also appear to have a moderating influence on the risk for drug use involvement with high protective indices being found to have the strongest effect on those at high risk for greater drug involvement (Newcomb and Felix-Ortiz 1992). One factor that has been identified above others as protective of substance use is having early academic success (Upadhyaya 2008).

The early initiation of substance use in adolescence predicts a considerably greater likelihood of developing later SUD with a more rapid progression to substance dependence, being of particular relevance for cannabis and alcohol. These findings are most robust for initiation of substance use by age 15 or younger; thereafter, other variables may come into play (Substance Abuse and Mental Health Services Administration 2009; Anthony and Petronis 1995; Chen et al. 2005; DeWit et al. 2000; Copeland et al. 2009). Adolescent SUD has been found to be a strong homotypic predictor (a disorder predicting itself over time) of young adult SUD (Copeland et al. 2009). A pattern of regular weekly use of cannabis in

adolescence appears to be a threshold marker for the risk of cannabis dependence in young adulthood (Coffey et al. 2003).

A widely held concept reasons that there are developmental stages in the progression of substance use through adolescence into young adulthood (Kandel 1975). The sequence of stages defines a temporal relationship progressing from legal to illegal and softer to harder drug use, with each stage acting as a potential "gateway" to the initiation of the next stage (Kandel 1975; Kandel et al. 1992). The use of one substance increases the likelihood of initiation of the second substance. For example, very few individuals who have tried cocaine and heroin have not already tried marijuana, the majority having previously used alcohol or cigarettes. However, the use of one substance does not invariably lead to the use of other substances. Many youth will stop at a specific stage and do not progress further or may return to an earlier stage of substance use (Kandel 1975). It is relatively common to carry over substance use from one stage to the next. Adolescents who engage in the use of multiple substances increase their risk of developing an SUD into young adulthood (Palmer et al. 2009).

The causal application of the gateway hypothesis is more open to debate and specifically as it relates to cannabis use and other drugs (Degenhardt et al. 2010). However, a strong association has been established for cannabis use and the use of other illicit drugs (Kandel 2003). Further to this, regular or heavy cannabis use has been significantly associated with other illicit drug use and abuse/dependence. The relationship is especially strong during adolescence and declines with age. These findings add support to the potential causal role of cannabis use on the development of other illicit drug use disorders, though the actual causal mechanisms, whether direct or indirect, remain unclear (Fergusson et al. 2006a, b). Adolescents may show a greater likelihood of developing drug dependence (cannabis) than adults across levels of use (Chen et al. 1997).

Substance abuse, expressly cannabis, in adolescence is clearly associated with significant developmental impairment and negative consequences in multiple life domains including behavioral, psychosocial, and academic/vocational (Brown et al. 2008; Macleod et al. 2004; Newcomb 1997; Scholes-Balog et al. 2013; Horwood et al. 2010).

In summary, the onset of SUD in adolescence with its biopsychosocial determinants is a serious mental health problem, with a serious impact on developmental tasks and a strong link to future SUD.

134.2.3 Comorbid Disorders

The association of SUD with other mental disorders is well established. In clinical and treatment studies of adolescent SUD, elevated rates of comorbid mental health disorders have been found across clinical settings with prevalence rates ranging from 55 % to 80 % (Clark et al. 1997; Dennis et al. 2004; Sterling and Weisner 2005; Stowell and Estroff 1992). Prevalence rates of comorbid disorders are significantly greater than community control samples of non-SUD adolescents.

Adolescent SUD patients often present with more than one comorbid disorder. Clinical studies, however, may suffer from Berkson's bias where it is probable that an adolescent with a particular disorder such as SUD who is seeking treatment will have a greater likelihood of a second disorder, thus confounding the ability to generalize results. Only a handful of studies have examined the comorbidity of adolescent SUD in general community samples. Two such studies have found similar elevated rates of comorbidity as seen in clinical studies. Comorbidity rates were two to three times greater in adolescents with SUD than those without SUD for anxiety, mood, or disruptive behavior disorders (DBD). In comparison to adult studies, comorbidity rates of mental disorders are similar for lifetime SUD and may be higher for current SUD in adolescents (Kandel et al. 1999; Rohde et al. 1996). These higher rates of psychiatric comorbidity in adolescents with SUD are most likely reflective of the number of DBD diagnoses made in adolescents that are either not applicable to or not routinely assessed for in adults. There is some evidence to support that comorbidity of mental disorders increases with progression of SUD and severity of substance use (Grella et al. 2001; Tims et al. 2002). The genders share far greater similarities than any meaningful differences with respect to comorbidity characteristics, especially when gender differences seen in the general population of such disorders as conduct disorder (CD) and major depressive disorder (MDD) are taken into account (Dennis et al. 2004; Armstrong and Costello 2002).

Prospective studies suggest that early and more frequent substance use through adolescence is associated with, and may predict, later mental disorders in particular depressive disorders in young adulthood (Brook et al. 2002, 1998; Hayatbakhsh et al. 2007). Analysis of retrospective epidemiologic data has found the age of onset of DBD and anxiety disorders to precede the onset of substance dependence (Glantz et al. 2009).

The most common comorbid mental disorders seen in community studies of adolescent SUD are that of DBD, in particular CD, with these disorders showing a prevalence range of 25–50 % and a median of four times greater likelihood of co-occurrence with SUD than without. The next most common comorbid disorder is that of depressive disorders with a prevalence range of 20–30 % and a median of over twice the likelihood of co-occurrence (Armstrong and Costello 2002). These findings are relatively consistent with clinical studies, though there is a fair degree of variability in prevalence rates between studies of clinical population samples. On the other hand, SUD is a common comorbid disorder in clinical studies of youth that present with serious emotional problems or mental disorders (Deas 2006; Greenbaum et al. 1991; Grilo et al. 1995; Kramer et al. 2003).

In this section of comorbidity, we will take a closer look at selected aspects of the relationship of the more prominent comorbid mental disorders and SUD.

134.2.3.1 Conduct Disorder

CD and SUD are strongly associated, with CD typically preceding the onset of SUD (Costello et al. 2003; Grilo et al. 1996; Sung et al. 2004). CD imparts an increased risk for the initiation of substance use by age 15 and is a powerful prediction of

SUD by age 18 (Hopfer et al. 2013; Elkins et al. 2007). As well, the severity of CD has been found to predict the severity of SUD. This relationship, however, appears to be reciprocal with each condition heightening the expression of the other. In such a manner, early-onset substance use has been associated with later criminality, and if substance use or drug dealing is reduced, there is a subsequent decrease in criminality (Stein et al. 2008).

Adolescents who present with CD may rapidly progress from substance use initiation through abuse to dependence, moving from one stage to the next in a matter of months (Reebye et al. 1995), whereas early conduct problems have not been directly linked to the onset of SUD in adulthood (Milin et al. 1991). Also, juvenile offenders with comorbid SUD have shown greater additional psychopathology than those without SUD (Milin et al. 1991).

134.2.3.2 Attention-Deficit/Hyperactivity Disorder

ADHD has been found to be a common comorbid disorder in clinical studies of adolescents with SUD, with large outpatient clinical studies reporting a range of 17–38 %; however, similar findings have not been found in community samples (Dennis et al. 2004; Sterling and Weisner 2005; Armstrong and Costello 2002; Disney et al. 1999).

There has been considerable debate in the extant literature as to whether ADHD is an independent risk factor for the development of SUD in youth or whether the association is indirect and mediated by the presence of co-occurring CD or oppositional defiant disorder (ODD) (Brook et al. 2010; August et al. 2006; Barkley et al. 2004; Biederman et al. 1997). What is now clearer on the balance of evidence is that childhood ADHD is a risk factor for the development of SUD in young adulthood, independent of co-occurring ODD/CD with the dimension of hyperactivity/impulsivity being of particular significance. However, the addition of ODD/CD and severity of ADHD further increases the risk for SUD in youth (Elkins et al. 2007; Wilens et al. 2011; Charach et al. 2011; Molina and Pelham 2003). Adolescents with ADHD have shown an earlier age of onset of SUD, a more rapid progression of SUD, and a greater severity of SUD (Biederman et al. 1997; Horner and Scheibe 1997).

Considerable evidence exists as supported by a recent meta-analysis that treatment of childhood ADHD with stimulant medication does not increase the risk of SUD in adolescence or young adulthood (Mannuzza et al. 2008; Biederman et al. 2008; Wilens et al. 2003, 2008; Barkley et al. 2003; Molina et al. 2013; Humphreys et al. 2013). There has also been a certain degree of evidence to suggest that stimulant treatment of ADHD may even reduce the risk of developing SUD in adolescence, though the effect appears to wane into young adulthood (Biederman et al. 2008; Wilens et al. 2003, 2008; Katusic et al. 2005). However, more recent research findings have not been supportive of a protective stimulant treatment effect for the risk of adolescent or later SUD (Molina et al. 2013; Humphreys et al. 2013).

The relationship between ADHD and SUD remains complex in adolescence, and with the addition of CD, this grouping of disorders may represent a worse prognosis for the persistence of antisocial behaviors and substance abuse.

134.2.3.3 Depressive Disorders

Depressive disorders frequently co-occur with adolescent SUD and are the second most common comorbid disorder. The association of depressive and substance use disorder in adolescents is more frequent than one would expect and has been more widely studied than other comorbidities. It is also noteworthy that adolescents with a history of MDD show an elevated rate of SUD than those without a history of depression (Substance Abuse and Mental Health Services Administration 2009; Rao et al. 1999). Rao and Chen (2008) in a comprehensive review of this topic proposed that common genetic, environmental, and neurobiological factors may possibly mediate the relationship between depressive and substance use disorder in adolescents, constituting a basis for their linkage. The authors recognized the limitations of the neurobiological findings and, by design, the selectivity of various risk mechanisms examined.

In clinical studies of adolescents with SUD, the onset of MDD most often follows the onset of SUD (secondary MDD). Secondary MDD is considerably more common than MDD preceding the onset of SUD (primary MDD) (Bukstein et al. 1992; Deykin et al. 1992). In the majority of cases, irrespective of whether it is primary or secondary, comorbid MDD in adolescents has not been found to spontaneously remit with abstinence and/or early treatment (excluding pharmacotherapy) by the third week. As would be expected, comorbid MDD has been found to be more prevalent in girls with adolescent SUD than in boys, with the girls showing an earlier age of onset of depression (Deykin et al. 1992). Adolescents with SUD and comorbid depressive symptoms on admission to residential treatment have shown poor substance use outcome (Subramaniam et al. 2007).

Adolescents with depression are more likely to develop an SUD, showing an earlier onset and a greater severity of substance abuse. Comorbid SUD in adolescents with depression appears to have a negative impact on the phenomenology and course of illness with greater behavioral and CD problems, longer duration of depressive episodes, and increased psychosocial (school, family, and legal) impairment (Rao et al. 1999; Rao and Chen 2008; Subramaniam et al. 2007; King et al. 1996, 1993). A greater severity of substance use in adolescents with treatment-resistant MDD (without comorbid SUD) has been associated with increased severity of depression and comorbid ODD and CD. Adolescents with low substance-related impairment at the end of treatment for depression showed the best response (Goldstein et al. 2009). Alternatively, achieving a positive response in the treatment of adolescents with MDD has been shown to reduce the risk of subsequent drug use disorders but not alcohol use disorders (Curry et al. 2012).

SUD in adolescents has been linked to an increase in suicidal behaviors including ideation, attempts (frequency, recurrence, and seriousness), and completed suicide. However, the risk for suicide is most significant when comorbid with MDD (Crumley 1990; Brent et al. 1993; Esposito-Smythers and Spirito 2004).

The comorbidity of substance use and depressive disorders appears to be interactive and has at least an additive, if not a synergistic effect on the burden of illness of these disorders, with significant morbidity and mortality.

134.2.3.4 Psychotic and Bipolar Disorders

Few studies report an incidence of comorbid psychotic and bipolar disorders in the adolescent SUD population. This absence of reporting is quite likely a reflection of the severity of the illnesses, with those adolescents who experience the onset of these disorders being more likely to present to psychiatric services for assessment irrespective of whether they have an SUD or not. In that comorbid psychotic and bipolar disorders are not commonly or reliably reported in the adolescent SUD population, only a few selected comments will be made in this chapter.

A strong association has been found for comorbid SUD with first-episode psychosis (FEP) and bipolar disorder (BD) in adolescents/young adults. The presence of comorbid SUD has been associated with a more debilitating course of illness, poorer clinical and treatment outcomes, as well as greater functional impairment in patients with FEP and BD (including evidence in first-episode mania and adolescents) than without comorbid SUD. SUD has been linked to an earlier age of onset of schizophrenia and BD with its significant negative clinical implication on prognosis. In the majority of cases, SUD typically precedes the onset of psychosis/schizophrenia, whereas the onset of BD may often precede that of SUD. The most common SUD is that of cannabis in FEP and first-episode/early-onset BD (Milin et al. 2010).

Cannabis use has been found to be an independent risk factor for the development of psychosis/schizophrenia in young adulthood with a two- to threefold increase in risk. The risk for this outcome increases in a dose-dependent manner and is greater with the onset of use in adolescence and especially in vulnerable individuals. Cannabis-induced psychotic disorder has been found to be a cogent marker in the vulnerability for developing a primary psychotic disorder. In essence, adolescents and young adults should be counseled that cannabis use may increase their likelihood of developing a clinically relevant psychotic disorder/schizophrenia-related disorder (Milin et al. 2010; Moore et al. 2004; Large et al. 2011).

134.2.3.5 Other Comorbid Disorders

There is considerably less extant literature on the relationship of other comorbid disorders in adolescents with SUD. Elevated rates of anxiety disorders, including social and generalized anxiety disorders and posttraumatic stress disorder (PTSD), have been noted in clinical studies (Sterling and Weisner 2005; Crumley 1990; Brent et al. 1993; Esposito-Smythers and Spirito 2004; Giaconia et al. 2000). From these studies, social anxiety disorders (SAD) and PTSD have been identified as the most clinically relevant of the anxiety disorders. SAD precede the onset of SUD and inherently may have an impact in SUD treatment that is oriented toward group therapy. Those with SAD may best be served initially through individual cognitive behavior-oriented SUD treatment.

The relevance of PTSD in this population is significant, given the high rate of physical and sexual abuse (57 % of girls and 31 % of boys) identified in a clinical sample across treatment settings (residential, inpatient, and out-/day patient programs) (Rounds-Bryant et al. 1998). In a cross-sectional community sample of

adolescents, a strong association was found for the comorbidity of SUD and PTSD with a significant impact on psychosocial impairment. The findings suggested multiple pathways leading to comorbid SUD and PTSD (Abrantes et al. 2003).

No consistent association has been found in adolescents for comorbid SUD and eating disorders (ED). There is some clinical evidence to suggest a possible relationship of SUD with bulimia (Von Ranson et al. 2002).

134.2.4 Assessment of Adolescent Substance Use Disorder

It is recommended by both the American Academies of Child and Adolescent Psychiatry and Pediatrics that screening for substance use and SUD in adolescents be part of standard clinical care (American Academy of Child and Adolescent Psychiatry 2005; Committee on Substance Abuse 2011). It has also been asserted that the goal is to apply universal screening for substance use, brief intervention, and/or referral to treatment (SBIRT) for every adolescent on an ongoing basis as part of routine healthcare, employing developmentally appropriate tools and strategies (Committee on Substance Abuse 2011). However, further study of long-term effectiveness of SBIRT in the adolescent population is required (Pilowsky and Wu 2013). Despite the importance of screening adolescents for substance use, most physicians/pediatricians feel uncomfortable screening for drug and alcohol use, and even fewer feel comfortable completing a comprehensive assessment or referring adolescents for drug and alcohol treatment (Van Hook et al. 2007). Reasons for failure to screen adolescents for substance use and abuse include the lack of training and familiarity with screening tools, time to complete the assessment, need to triage competing medical problems, unfamiliarity with treatment options and resources, and issues with confidentiality and disclosure due to parents who will not leave the room (Van Hook et al. 2007).

Screening tools are brief self-reports or interviews often used as the initial step in assessing for adolescent substance use and related problems. The outcome of screening may determine the need for further evaluation and a more comprehensive assessment. The next step would entail a comprehensive assessment that examines the severity and course of substance use and related problems (frequency, quantity, duration, number of substances used and circumstances, etc., problem-related consequences of substance use and treatment needs in multiple life domains (Winters and Kaminer 2008)). The appropriateness of the instrument is dependent upon the setting and the purpose of the assessment (Samet et al. 2007). Winters and Kaminer (2008) identified and reviewed several preferred measures for screening and assessing adolescent SUD in clinical populations. Their selection of instruments was comprised of two screening tools, the CRAFFT and the Personal Experience Screening Questionnaire, and three comprehensive assessment instruments, the Global Appraisal of Individual Needs (GAIN), the Teen Severity Addiction Index, and the Personal Experience Inventory. These instruments were guided by a combination of robust psychometrics and user-friendliness. The features they examined included the strength of psychometric properties, simplicity of

scoring, efficient length of administrations, and the degree of user training required. The measures were also found suitable for periodic use in reevaluation of treatment outcome. The authors recommend that clinicians working with youth should receive training in at least one screening and one comprehensive assessment instrument, ideally during their formal years of education (Winters and Kaminer 2008). The CRAFFT has been identified as the best studied screening tool for substance use and related problems in adolescents with evidence to support its use in medical settings (Pilowsky and Wu 2013).

Urine drug testing is an objective measure to screen for recent drug use in a time-limited manner. However, a positive urine screen is not diagnostic of an SUD and does not provide information on substance-related problems. Echoing the findings from studies investigating the concordance between objective, self-, and collateral reports of substance use in adolescents (Winters et al. 2008; Burleson and Kaminer 2006), Winters and Kaminer (Winters and Kaminer 2008) advocate that the use of self-report and collateral information may be the most reliable measure in many instances of assessing adolescent substance use and disorders. Nevertheless, urine drug analysis may be beneficial when screening those who fear the consequences of reported substance use and abuse or those who are concerned about confidentiality and therefore may not respond validly. As well, it may be helpful as a tool in providing clinical feedback to the adolescent in treatment and in assessing clinical response to treatment.

The significance of screening and assessing for SUD in adolescents using multiple sources is brought to bear by findings from a study of adolescents seeking mental health treatment (Kramer et al. 2003). SUD prevalence was found to be approximately 17 % on a self-report structured measure, whereas clinicians identified less than half (45 %) of these adolescents with SUD. The researchers suggested that the gap between the need and access to SUD treatment services may have contributed to poorer outcomes for youth with comorbid SUD. They also noted the important clinical consideration that clinicians should continue to screen/assess for SUD throughout treatment in that confidence to disclose this behavior may be enhanced with the establishment of a therapeutic relationship with the adolescent patient and family.

In summary, there is convincing evidence that all adolescents seeking treatment for essentially any condition should, at minimum and in an ongoing manner, receive screening for substance use and as warranted more comprehensive assessment for SUD. Assessment should include diverse sources where possible and cover multiple life domains leading to identifying the appropriate treatment resources to meet the needs of the adolescent.

134.2.5 Treatment

Treatment of adolescent SUD starts for all intents and purposes with the process of a biopsychosocial/multidimensional assessment (Ahuja et al. 2013). The American Society of Addiction Medicine Patient Placement Criteria (ASAM-PPC) for the treatment of substance-related disorders (American Society of Addiction

Medicine 2001) sets forth consensus criteria and guidelines for adolescents with many distinguishing features from that of adults. The six dimensions identified for assessment include (a) intoxication and withdrawal potential; (b) medical conditions and complications; (c) emotional, behavioral, and cognitive condition (includes stages of development) and complications; (d) readiness for change; (e) relapse, continued use, or problem potential; and (f) recovery environment.

The evaluation of key clinical domains within dimension (c) is intended to help guide the clinician with treatment planning and toward matching the adolescent patients to the appropriate level of care. ASAM-PPC has become a standard in the addiction field in the United States. Unfortunately, only preliminary work has been done in the study and operationalization of the adolescent PPC (Fishman 2008).

An area often previously overlooked in adolescents is the presence of substance withdrawal and its impact. Recent studies support that cannabis withdrawal is common and of clinical significance in adolescents with cannabis dependence (Milin et al 2008; Cornelius et al 2008).

The treatment of adolescent SUD may occur at one of several levels of care, across a range of settings reflecting the intensity of treatment and level of supervision/restriction of environment (American Academy of Child and Adolescent Psychiatry 2005). These treatment settings mainly encompass outpatient, partial hospitalization/day treatment, and inpatient or residential care. There continues to be a significant gap between adolescents who need treatment for SUD and those who receive treatment in a specialty facility. It is likely that two major factors play a role in this marked deficit of treatment: they did not seek treatment or they were unable to access treatment for various reasons (Substance Abuse and Mental Health Services Administration 2009).

As of date, there has been a proposed shift away from large-scale outcome-based performance measurements as they may be impractical where outcomes may be reflective of case mix, and between program differences may be small, for identifying quality of care indicators for adolescent SUD treatment programs (Morral et al. 2006). Along these lines, Brannigan and colleagues (2004) identified several key elements of effective adolescent drug treatment through literature review and expert panel consensus. The key elements identified were (a) assessment and treatment matching, (b) comprehensive integrated treatment approach, (c) family involvement, (d) developmentally appropriate program in treatment, (e) engaging and retaining teens in treatment, (f) qualified staff, (g) gender and cultural competence, (h) continuing care, and (i) treatment outcomes. However, no weighting was assigned to these key elements. In a subsequent survey of highly regarded adolescent SUD treatment programs across a range of settings in the United States, most were found to be insufficiently undertaking the key elements of effective adolescent SUD treatment in their programs. The elements with the poorest quality performance were assessment and treatment matching, engaging and retaining teens in treatment, gender and cultural competence, and treatment outcomes. The authors concluded that there is a considerable need to expand the awareness of effective elements in treating adolescent SUD and that this will heighten program improvement and also serve as a measurement of progress in the field.

In reviews of studies on adolescent SUD treatment outcomes, it can be derived that treatment is better than no treatment (American Academy of Child and Adolescent Psychiatry 2005). The largest follow-up study to date of over 1,000 adolescent patients, SUD treatment outcomes across different treatment modalities [outpatient, short-term inpatient, and residential care] showed significant improvements in the domains of substance use, psychological adjustment, school performance, and criminal behavior at 1 year posttreatment than in the year prior to treatment. Also, a longer duration of treatment was associated with reduced rates of substance use and a decrease in arrests following treatment. These findings are similar to those in adult SUD treatment evaluation research as well as the finding that different treatment modalities appear to reflect different levels of problem severity (Hser et al. 2001).

134.2.5.1 Psychosocial Treatments

Waldron and Turner (Waldron and Turner 2008) undertook a comprehensive review and meta-analysis of psychosocial outpatient treatment modalities for adolescent SUD with the purpose of establishing evidence-based practice guidelines. They identified three approaches to be considered as well-established interventions: the first two being family-based approaches, multidimensional family therapy (MDFT) and functional family therapy, and the third being group cognitive behavioral therapy (CBT). The authors also found other family models, including multisystemic therapy, brief strategic family therapy, and behavioral family therapy, as most likely efficacious, pending further exploration by independent researchers. Both Adolescent Community Reinforcement Approach (ACRA) and other individual CBT models appear promising but require further research. They also concluded that none of the treatment approaches emerged as being superior over another. Subsequent to this meta-analysis of psychosocial outpatient treatments for adolescent SUD, further studies have supported the benefit of individual CBT (Cornelius et al. 2009; Riggs et al. 2011). Also, findings for the effectiveness of MDFT have been replicated in a RCT of adolescents in Western Europe, showing a reduction of the rate of cannabis dependence (Rigter et al. 2013). In a comparative analysis of outpatient treatment effectiveness for adolescent substance abuse, psychoeducational therapy did not fare well as compared to other treatments (Tanner-Smith et al. 2013).

Waldron and Turner (2008) also identified Winters and colleagues' evaluative study of the Minnesota Model 12-step approach for treatment of adolescent SUD as promising, with favorable substance use outcomes, and worthy of further research to establish the effectiveness of this treatment approach. The Minnesota Model has been reported to be the most widely used approach in the United States for the treatment of severe SUD/substance dependence in adolescents which is typically conducted in a short-term (28-day) admission to a specialized inpatient hospital or residential care setting. An intensive day treatment program was also included as part of Winters and colleagues' study which showed similar treatment outcome findings to short-term residential care (Winters et al. 2000).

To date, the largest randomized adolescent SUD treatment study has been the Cannabis Youth Treatment (CYT) study (Dennis et al. 2004). This multisite

comparative study ($N = 600$) was comprised of two interrelated randomized trials of five short-term psychosocial treatment interventions for outpatient adolescents with cannabis use disorders. Comorbidity was common with 33 % of the adolescents having internalizing disorders and 60 % presenting with externalizing disorders. All interventions were designed to be developmentally appropriate. The study included an extended period of naturalistic follow-up of more than 8 months posttreatment, with study completion at 12 months postrandomization to treatment. All five CYT interventions, including brief psychotherapy of five sessions in total, were found to be effective, demonstrated by significant improvements in the days of abstinence by an average of 24 % and the percent of adolescents in recovery (no substance use or abuse/dependence problems) averaging 24 % across the 12-month duration of the study. Clinical outcomes were similar across treatment sites and interventions, with no significant differences between conditions on these outcome measures. Despite the findings of clinical improvements, more than 50 % of adolescents went in and out of recovery or relapse one or more times posttreatment. The majority were still reporting substance use or related problems at 12 months. These results lead the authors to suggest a need to consider the potential role of continuing care for a significant segment of adolescents entering outpatient treatment for SUD.

134.2.5.2 Treatment Outcome Parameters

A substantive concern has been the high rates of attrition reported in adolescent SUD treatment that ranges from 20 % to greater than 50 % across program types (Chung and Maisto 2006; Monti et al. 2001). This high rate of treatment dropout is greater than that seen in adults and is likely related to the adolescents' typically low motivation for treatment and the absence of perceiving their substance use as a problem. The CYT study (Tims et al. 2002) reported that only 20 % of adolescents who entered treatment viewed their substance use as a problem. There has been no thorough examination of motivation as a moderator of treatment outcome in adolescents. However, along this line of thinking, several psychosocial interventions for adolescent SUD have specifically incorporated individual motivational enhancement therapy (MET) as part of treatment (Waldron and Turner 2008). Recent studies have demonstrated in several modes of treatment that formation of early therapeutic alliance predicts the likelihood that adolescents will stay in treatment and that they will have better clinical outcomes on measures of drug use as well as internalizing and externalizing behaviors (Waldron and Turner 2008; Diamond et al. 2006).

Most adolescent SUD treatment programs advocate a primary goal of achieving and maintaining substance abstinence. The maintenance of abstinence has been linked to positive long-term psychosocial functioning in treated youth (Brown et al. 2001). Reviews of adolescent treatment outcome studies identify relatively low rates of continuous abstinence following treatment with over 50 % of adolescents showing relapse of substance use by 3 months posttreatment (Chung and Maisto 2006; Williams and Chang 2000). In comparison to adults, the rates and timing of relapse to any substance use posttreatment appear to be similar. However, the most

common context for initial relapse differs between adolescents and adults. Adolescents most commonly report a social situation or peer influence such as socializing with pretreatment friends as context for initial relapse, whereas adults most commonly report negative intra- or interpersonal states (Chung and Maisto 2006).

Follow-up treatment studies that examine the patterns of substance use suggest fluctuations in use and problems with an overall reduction of clinical symptoms in youth who have received treatment (Chung and Maisto 2006). The reduction in substance use and improvement in related problems are appropriate measures of treatment outcome. Predictors of adolescent SUD treatment outcome have been historically categorized into pretreatment, in-treatment, and posttreatment determinants.

Pretreatment factors, in general, represent background and personal characteristics that, upon entering treatment, may be associated with outcome. Multiple pretreatment characteristics have been identified as potential variables that may have an impact on outcome, but study findings and the manner of reporting factors associated with treatment outcomes are inconsistent. However, a few pretreatment determinants are worth considering, these being severity of substance use, school functioning, and social supports. Demographic characteristics of gender and ethnicity, overall, have not been found to predict outcome.

The in-treatment factors most consistently associated with favorable treatment outcomes are treatment completion, with its correlation to programs that provide comprehensive services, and longer time in treatment. Posttreatment factors include a wide range of psychosocial and environmental variables that occur following treatment that may influence outcomes. Posttreatment factors most consistently related to positive outcome include, but are not limited to, participation in aftercare treatment, peer/parental social support, and prosocial activities. As expected, posttreatment factors have been found to be the most important determinant of clinical outcomes (American Academy of Child and Adolescent Psychiatry 2005; Chung and Maisto 2006; Williams and Chang 2000; Anderson et al. 2007). More recently, the literature on adolescent SUD treatment has emphasized the need for evaluation of both moderators and mediators of specific treatment interventions that may affect outcome. Moderators are pretreatment characteristics that influence the association between treatment intervention or other independent variables and treatment outcome. Mediators are intervening determinants that may account for the association between a treatment intervention and outcome (Waldron and Turner 2008).

A better understanding of the impact of risk and protective factors on substance-related outcomes improves the ability to enhance treatment and relapse prevention programs (Anderson et al. 2007). For example, in an adolescent treatment outcome study, persistent cigarette smokers and smoking initiators during the follow-up period of 1 year were found to be significantly at greater risk for relapse of any substance than those who quit smoking or were non-smokers. The implications of this study would be to incorporate smoking cessation treatment in the context of adolescent SUD treatment and relapse prevention programs (de Dios et al. 2009).

Several adolescent SUD studies have identified the impact of psychiatric comorbidity on treatment outcomes across treatment modalities (residential, short-term

inpatient/residential care, and outpatient programs). In general, those adolescents with mixed comorbidity of both internalizing and externalizing disorders or with a greater number of comorbid mental disorders showed an increased rate/level of substance relapse/use. Findings from certain studies have supported a more rapid time to relapse of substance use than those adolescents without comorbidity at treatment follow-up of 6 or 12 months (Grella et al. 2001; Rowe et al. 2004; Tomlinson et al. 2004; Shane et al. 2003). The majority of adolescents with comorbidity in these treatment studies presented with both comorbid internalizing and externalizing disorders. In an adolescent SUD treatment study that investigated the impact of internalizing and externalizing behaviors on clinical outcomes over both short-term (1 year) and long-term (4 and 5.5 years) follow-up, it was found that adolescents with externalizing behaviors had significantly more rapid and higher rates of substance relapse as well as lower treatment retention than those with internalizing behaviors. The authors concluded that these results suggest poorer prognostic treatment outcomes for youth who show core features of delinquency or deviant behavior (Winters et al. 2008).

Comorbid CD has been implicated in poorer SUD treatment outcomes. Kamon and colleagues (2005), in an open study involving a family-based contingency management model including individual CBT, provided support for the feasibility and potential for improved retention, substance use outcomes, and reduction of conduct problems in adolescents with SUD (all met criteria for cannabis use disorder), who received this intervention.

134.2.5.3 Aftercare Treatment

There is a paucity of studies examining the effectiveness of continuing care (CC) in adolescents who have received SUD treatment. Godley and colleagues (2002) provided preliminary evidence in their randomized study to support the role of assertive continuing care (ACC) involving case management and ACRA over referral to CC as usual for adolescents discharged from residential SUD treatment. Adolescents who received ACC were more likely to show greater initiation and retention in CC and improved short-term substance use outcomes in comparison to those referred for CC as usual. Adolescents who receive residential SUD treatment often have the most serious SUD and are at high risk for relapse.

Kaminer and colleagues (2008) conducted the first and what would appear to be the *only* published prospective randomized controlled trial (RCT) of active aftercare intervention (five in-person or brief telephone sessions) in outpatient adolescents with AUD. The adolescents were identified for the study as having alcohol use disorders (AUD) and completed outpatient group CBT treatment for SUD with aftercare intervention being delivered in the first 3 months posttreatment. Adolescents who received aftercare were significantly less likely to experience relapse to alcohol use versus those who did not receive aftercare, despite the overall significant increase in relapse occurrence at the end of aftercare compared to the end of treatment. The authors concluded that active aftercare posttreatment was relatively efficacious but that the dose of aftercare may not have been sufficient to maintain treatment gains.

134.2.5.4 Pharmacotherapy for SUD

Open-label studies of naltrexone and ondansetron treatment for adolescents/youth with alcohol dependence have shown a reduced frequency of alcohol use (Deas et al. 2005; Dawes et al. 2005). In an open study and a case series of naltrexone and extended release naltrexone, respectively, in youth with opioid dependence both showed a reduction in frequency of opioid use (Fishman et al. 2010).

Youth with opioid dependence participated in a randomized double-blind parallel group clinical trial of buprenorphine ($n = 18$) or clonidine ($n = 18$) for detoxification over 28 days (Marsch et al. 2005). Irrespective of group assignment, all youth received counseling and contingency management. The researchers reported significantly greater treatment retention and greater number of negative opioid urine screens for those youth who received buprenorphine than for those who received clonidine. Following detoxification, youth were offered to continue treatment for opioid dependence with naltrexone. Sixty-one percent of the youth from the buprenorphine group and 5 % of those from the clonidine group opted to initiate treatment with naltrexone. The authors concluded that buprenorphine as an adjunct to behavioral therapies was a more effective intervention than clonidine in combination with behavioral therapy (Marsch et al. 2005).

Treatment-seeking youth with opioid dependence ($N = 152$) participated in a randomized clinical trial (RCT) of 12 weeks of buprenorphine–naloxone treatment ($n = 74$) or short-term (14 days) detoxification ($n = 78$) in addition to weekly group and individual counseling (Woody et al. 2008). Woody and colleagues reported significantly greater numbers of negative opioid urine screens at weeks 4 and 8 for youth who received buprenorphine–naloxone compared to short-term detoxification. Greater treatment retention at week 12 was found for the youth in the buprenorphine–naloxone treatment group in comparison to those youth who received short-term detoxification. Follow-up at months 6, 9, and 12 found that those youth who had received buprenorphine–naloxone treatment had fewer positive opioid urine screens than those adolescents who had received short-term detoxification, although rates were high for both groups (Woody et al. 2008).

A small RCT ($N = 26$) of acamprosate treatment for 90 days in adolescents with alcohol dependence reported the number of youth continuously abstinent, and the number of continuous days abstinent was greater in the acamprosate group than those in the placebo group (Neiderhofer and Staffen 2003).

Gray and colleagues investigated the benefits of n-acetylcysteine (NAC), in an eight-week double-blind RCT ($N = 116$) of cannabis-dependent youth who also were receiving weekly contingency management and brief cessation counseling (Gray et al. 2012). The authors found that youth in the NAC group had a greater than twofold likelihood of a negative cannabis urine screen compared to those youth in the placebo group at treatment end. At 4 weeks posttreatment follow-up, youth who had received NAC did have a greater frequency of negative urine screens than those who had received placebo, but the difference was not statistically significant.

All of these studies reported pharmacotherapy in the context of concurrent psychosocial or behavioral therapies for SUD. The exact role of each therapy cannot

be determined definitively. Furthermore, due to methodologic differences in research studies, results may not be replicable and are not directly comparable, rendering it difficult to assess the preference of one pharmacotherapy over another. Nevertheless, the limited research suggests a certain advantage for those using pharmacotherapy in the treatment of adolescent substance dependence, in conjunction with either psychosocial behavioral therapy, in particular for opioid dependence.

In a case series study by Duffy and Milin (1996) of withdrawal syndrome in adolescents with cannabis dependence, the authors commented on the clinical utility of using trazodone 50–100 mg at bedtime to assist with withdrawal insomnia. Since then, our center has also found quetiapine 50–100 mg at bedtime to be helpful for cannabis withdrawal insomnia in outpatients. Research studies are required to investigate whether selective pharmacotherapy may be beneficial in the management of cannabis withdrawal symptoms and enhance rates of discontinuation of cannabis dependence in adolescents.

134.2.5.5 Pharmacotherapy for Comorbid Disorders

A small randomized, pilot study of sertraline in outpatient adolescents with alcohol dependence and comorbid clinical depression showed that both groups (sertraline and placebo) experienced a reduction in number of drinking days, a reduction in depression scores, and no significance between group differences. These results may have been due, at least in part, to the requirement that all subjects received CBT regardless of group membership, suggesting the potential effectiveness of CBT in treating MDD and alcohol dependence (Deas et al. 2000).

A small open trial of fluoxetine in adolescents with comorbid MDD, SUD, and CD who were in residential treatment for SUD found promising results. Subjects were included in the study if their depression persisted after at least 1 month of residential care and they were abstinent from substance use (Riggs et al. 1997). The findings showed an improvement of depressive symptoms and functioning. Cornelius and colleagues (2005) examined the effectiveness of fluoxetine, in an acute open-label trial and 5-year naturalistic follow-up study of a small group of adolescents with comorbid AUD and MDD who also received treatment as usual, individual psychotherapy, over the acute phase of the study. The acute-phase study results showed a significant reduction (improvement) in depression symptoms and alcohol use. In the 5-year follow-up phase of the study, the subjects (who were now young adults) continued to maintain improvements in depressive symptoms although recurrent episodes were common, and comorbid AUD continued to improve over the course of follow-up.

To date, the largest published RCT of pharmacotherapy in adolescents with comorbidity ($N = 126$) evaluated the efficacy of fluoxetine and individual CBT for SUD in adolescents with MDD, SUD, and CD (Riggs et al. 2007). Riggs and coauthors reported that fluoxetine combined with CBT had demonstrated greater efficacy on one of the two depression response measures with a significantly greater reduction in depressive symptoms than placebo and CBT. Both treatment groups demonstrated a higher-than-expected rate of treatment response, which suggested to the researchers that CBT may have contributed to this occurrence with mixed

efficacy results. There was an overall decrease in substance use and CD symptoms in both conditions but no between-group differences were found. It was also reported that those adolescents or those who experienced remission of MDD had a greater proportion of negative results on weekly urine drug screens and self-reported days of drug use in the past month, compared to those without remission, irrespective of treatment group assignment. In terms of clinical implications, the authors proposed that the study findings showed that in the context of CBT for SUD, comorbid depression may improve or remit without antidepressant pharmacotherapy. However, if depression does not appear to be improving early in the course of SUD treatment with CBT, then fluoxetine treatment should be considered even if the adolescent is not abstinent, with careful follow-up monitoring of adherence and progress in treatment.

A subsequent RCT in adolescents ($N = 50$) with comorbid MDD and AUD also investigated the efficacy of fluoxetine treatment with all subjects receiving individual manualized CBT, for the treatment of MDD and AUD, and manualized MET for SUD. Cornelius and colleagues (2009) found no significant treatment outcome differences between the fluoxetine and placebo treatment groups. Both treatment groups showed significant improvements in alcohol use and depressive symptoms over the duration of the study, with having received a course of CBT/MET therapy. The number of heavy drinking days was significantly associated with the lack of remission of self-reported depressive symptoms. The study results lead the researchers to consider various reasons for their findings including limited medication efficacy, small sample size, the efficacy of CBT/MET psychotherapy, and to some extent depressive symptoms that may have been alcohol/substance induced. They suggested that psychological intervention should be the first line of treatment in this adolescent comorbid MDD/AUD population with pharmacotherapy afforded to those adolescents who do not respond to psychosocial intervention alone (Cornelius et al. 2009). In commentary, the findings of these two RCTs of fluoxetine/placebo and CBT add to the evidence of the effectiveness of individual CBT as a treatment intervention for adolescents with SUD and especially for those adolescents with comorbid MDD.

Only one RCT study of adolescents with BD and comorbid SUD has been conducted. Geller and colleagues (1998) in a small RCT ($N = 25$) examined the efficacy of acute lithium treatment in outpatients presenting with bipolar spectrum disorders and comorbid substance dependence with all subjects receiving interpersonal therapy. The lithium treatment group demonstrated a reduced number of positive drug urine screens and an improvement of general psychopathology on a measure of global assessment in comparison to those receiving placebo. However, no between-group differences were found on measures of mood or substance dependence symptoms. Nevertheless, the authors concluded that lithium was an effective treatment for both disorders. Though often reported in the literature, this study has numerous limitations, and there have been no further published trials to replicate or build on the findings.

In a community study, adolescents with ADHD and comorbid SUD and CD participated in an RCT ($N = 69$) to evaluate the effectiveness of

pemoline treatment (Riggs et al. 2004). The study results demonstrated a significant improvement in the severity of ADHD symptoms for the pemoline group as compared to the placebo group. No significant differences were found between the two groups on measures of substance use or conduct symptoms that did not differ from baseline scores. This study was unique as no concurrent psychosocial SUD treatment was provided. The authors concluded that pemoline was efficacious for ADHD but lacked effect on symptoms of CD and SUD in the absence of specific treatments for SUD, supporting the clinical importance of treating comorbid ADHD in the context of concurrent SUD treatment.

A small 6-week crossover ($N = 16$) in adolescents with ADHD and SUD who received treatment with methylphenidate-SODAS, a long-acting formulation, demonstrated a significant reduction in ADHD symptoms and improvement of clinical global functioning versus placebo. There was no significant treatment effect on substance use including no increase in substance use with this long-acting treatment (Szobot et al. 2008).

In a larger RCT ($N = 70$) of atomoxetine for ADHD in adolescents with SUD where all subjects received MET/CBT for SUD, no between-group differences were found for ADHD or substance use. However, both groups, atomoxetine plus MET/CBT and placebo plus MET/CBT, showed a significant reduction in ADHD symptoms. The authors concluded that MET/CBT and/or a placebo response contributed to a high treatment response in the placebo group for ADHD, although substance use findings were more equivocal (Thurston et al. 2010).

Riggs and colleagues (2011) completed a multisite community-based 16-week RCT of OROS methylphenidate, an extended release formulation, in 303 adolescents with SUD and comorbid ADHD who were also receiving CBT. All youth, regardless of treatment arm (OROS methylphenidate and CBT or placebo and CBT), had significant improvements in ADHD symptoms and a significant reduction in substance use at study end, although no significant differences were found between those youth who received OROS methylphenidate and those who did not. The authors concluded that there was no greater efficacy for OROS methylphenidate over placebo for either symptoms of ADHD or decrease in substance use for youth receiving individual CBT for concurrent SUD and ADHD. Adolescents who received OROS methylphenidate and CBT, however, had significantly fewer positive urine drug screens than those who received placebo and CBT (Riggs et al. 2011). An important clinical consideration in the selection of these medications for the treatment of comorbid ADHD in adolescents with SUD has been the understanding that they carry low abuse liability.

In summary, over the last decade, there have been significant advances in the development of evidence-based psychosocial treatments for adolescent SUD in outpatient settings. These fall within the broad categories of family-based interventions and developmentally appropriate CBT as well as the assimilation of MET as part of these interventions. There is accumulating evidence that supports the benefit of adolescent SUD treatment programs across different settings, including residential, short-term residential/inpatient, partial hospitalization/day treatment, and outpatients, as well as some promising findings with respect to aftercare.

It is well defined that treatment of comorbid mental disorders in adolescent SUD remains a priority and a necessity to enhance treatment effectiveness. Pharmacotherapy for the treatment of adolescent SUD remains a work in progress, especially with respect to the direct treatment of substance dependence. At this point, the effectiveness of pharmacotherapy for such common comorbid disorders as MDD and ADHD has not been established in the context of adolescents with active substance dependence. There are mixed findings whether concurrent pharmacotherapy of these comorbid disorders may be beneficial from the onset of treatment in the framework of evidence-based psychosocial therapy for adolescents presenting with SUD.

The current clinical implication being that concurrent pharmacotherapy for comorbid disorders may be best served for those adolescents engaged in SUD treatment who show persisting symptoms of MDD or ADHD with significant reduction in substance use/abstinence. Apart from the need for larger treatment studies, there is also the need for extended or maintenance pharmacotherapy trials in adolescents with SUD and comorbid disorders.

134.3 Conclusion

In sum, SUD among adolescents has multiple implications on normal development, future SUD, and for society in general. Adolescence is a period of significant vulnerability and risk for the development of SUD; as such, SUD must be viewed from a developmental perspective. Treatment approaches must be tailored to developmental patterns of substance use and include comprehensive assessment and a holistic approach. High rates of comorbid mental disorders among adolescents with SUD further emphasize the need for psychiatric care. Thus, an integrated approach to treatment focusing on SUD and comorbid mental disorders is paramount to intervention.

Acknowledgment We gratefully acknowledge Jennifer Goldberg, BA, for all her hard work and help with the literature review for and editing of the manuscript.

Contents

Abstract

Suicide is the second or third leading cause of death among adolescents in the industrialized world. Adolescent suicidal behaviors pose a major global public-health concern since they are highly prevalent and associated with heavy mortality and morbidity. A plethora of data accumulated substantiates the connection between suicide and substance abuse in adolescents and poses substance use disorders as a major risk factor for emergent suicidal behaviors. This chapter reviews the recent patterns and trends of substance abuse, focusing mainly on alcohol and cannabinoid-based substances which are most prevalent among adolescents, and presents the existing evidence linking adolescent suicidal behavior and substance abuse. We address the role of salient moderating factors such as comorbid psychiatric pathologies, age, and gender differences on

this relationship and highlight vulnerable subpopulations such as sexual minorities that are predisposed to be affected by this connection. Perspectives on recent as well as future basic science research studying the connection between adolescent suicide and substance abuse are discussed. Current treatment strategies for substance use disorders as well as for suicidal behaviors are presented, arguing in favor of an integrated approach.

135.1 Introduction

Suicidality is a broad term encompassing a wide range of self-injurious ideation or self-inflicted harmful behaviors executed with at least a partial intent to die. These behaviors are a major global public-health concern since they are highly prevalent and associated with heavy mortality and morbidity in the immediate as well as in long term. This issue is intensified when child and adolescent suicidality is concerned, and therefore, a pressing demand for efficient prevention plans and novel treatment strategies yet remains.

Suicide is a complex behavior and various pathways lead to suicidality. Numerous risk factors associated with suicidality have been described (Bursztein and Apter 2009; Cash and Bridge 2009) and are frequently divided into several categorical groups. This reductionism in classification of suicidality risk factors can be misleading and in many cases not clinically pragmatic. In real-life situations, these risk factors are much too often interwoven (Wolitzky-Taylor et al. 2010), are mutually effective in a nonadditive and unpredictable manner, and ultimately pose a methodological conundrum in the clinical assessment of adolescent suicidality. Nevertheless, in epidemiological studies concerning suicidality, several risk factors including substance use disorders (SUD) stand out more prominently than others.

Much epidemiological data has been gathered in the past decades elaborating the details and extent of adolescent substance use. The information accumulated has been extensively used recently by various health services as well as clinicians to yield a plethora of studies substantiating the impact of SUD on adolescent suicidality. In recent years, one can witness a gradual transformation of the harnessed data from the descriptive to the operative form; suicide risk assessments and odds ratios are being translated into operational plans and large-scale screening and intervention efforts in schools and health facilities. The applicability and efficacy of these measures are yet to be ascertained and validated by evidence-based studies.

Although the boundaries between substance use, abuse, or dependence are clearly defined by DSM criteria, these terms will be interchangeably used in this text as to keep with the general idea of defining the effect of substance use on suicidality and not to constrict this effect in boundaries of time, quantity, level of impairment, and related pathologies. Since the scope of this chapter cannot encompass the specific effect of all illicit as well as legal substances on suicidality, we will focus mainly on alcohol and cannabinoid-based substances since these are the substances which are most widely used and studied worldwide (NSDUH 2012a; UNODC 2012).

135.2 The Multifaceted Relationship Between Suicide and Substance Use

135.2.1 Adolescent Suicidality

There are multiple levels of severity and injury burden within the construct of "suicidality." The scope of suicidal behavior constrained in this term ranges from *suicidal ideation* with or without a specific plan through *suicide attempt* which is a nonfatal, self-inflicted destructive act with explicit or inferred intent to die to finally the fatal act of a completed suicide (O'Carroll et al. 1996).

Suicide is the second or third leading cause of death among adolescents in the USA and Europe (CDC 2013a; Eurostat 2013), and suicidal behavior represents one of the greatest public-health issues for this population. Lifetime estimates of suicide attempts among adolescents range from 1.3 % to 3.8 % in males and 1.5 to 10.1 % in females (Bridge et al. 2006). These numbers should most probably be considered to underestimate the true extent of this malady; a large portion of suicidal attempts remain unnoticed and unreported since most data rely on self-report or emergency-department (ED) admissions. Indeed ED visits in the USA due to self-inflicted injury are highest among the 15–19-year-old age group, and the visit rate in this group has doubled in the past 16 years (Ting et al. 2012). In the USA, youth risk behavior surveys (YRBS) assessing health-risk behaviors among youth and young adults have been conducted among representative samples of high school students biennially since 1991 by a nationwide Youth Risk Behavior Surveillance System (YRBSS). The latest survey released in 2012 reports disconcerting data describing teenage suicidal behavior. During the 12 months prior to the survey, 15.8 % of students had seriously considered attempting suicide, 12.8 % had formulated a suicide attempt plan, and 7.8 % had reportedly attempted suicide one or more times, an alarming rise from the prior survey reporting 6.3 % (Eaton et al. 2012). Adolescent suicidality has been identified as a nationwide health improvement priority in the USA. The "healthy people 2020 (HP2020)" initiative has proposed the objective of reducing adolescent suicide attempt rate by 10 % (healthypeople.gov) in the next decade. Given a 27 % decrease in adolescent suicide rate in the previous decade, this goal does not seem unattainable. In 2011, 2.4 % of US high school youth made a serious suicide attempt (resulting in an injury, poisoning, or overdose that had to be medically treated), a rise from 1.9 % recorded in the previous report (Eaton et al. 2012); in order to achieve the HP2020 goal, this number has yet to decrease to 1.7 %.

In light of these figures and those of previous years, numerous suicidality detection and prevention strategies have been proposed and implemented to various degrees of success worldwide (Mann et al. 2005). Most adolescents presenting with suicidal behavior do not end up committing suicide; nevertheless, suicidal ideation in adolescence has been shown to be a harbinger of compromised adult functioning and future axis I diagnoses (Reinherz et al. 2006), stressing the need for early suicidality identification regardless to the obvious dire consequences of suicide itself. In their review of the latest suicidality screening tools applied in educational and health-related community facilities, Horowitz et al. (2009) suggest that the

implementation of targeted suicide screening in schools and universal suicide screening in primary care clinics and ED may be the most effective way to recognize and prevent suicidal behavior. The leading screening tool used today in school settings is the Columbia Suicide Screen (CSS) (Shaffer et al. 2004). This short self-report measure embedded in a general health questionnaire addresses known suicide risk factors such as suicidal ideation, prior suicide attempts, depression, anxiety, and substance use. Those who screen positive in the initial stage progress to treatment referral following clinical confirmation of suicidality. It has been recently shown that by selectively setting the threshold of the algorithm that picks out the initial target cases, it is possible to minimize the false-positive cases that burden the screen site with secondary interviews while allowing a minimal loss of true positive cases (Scott et al. 2010). Another screening tool that is not specific to suicide or substance abuse is the Strengths and Difficulties Questionnaire (SDQ) (Goodman 1997), which has the advantage that it can detect adolescent emotional and behavioral difficulties that are not necessarily strictly DSM based and therefore may be more sensitive to detect distress and psychopathology (Shoval et al. 2013).

Recent encouraging data suggest a decrease in global adolescent suicide rate. A significant linear decrease in the prevalence of US adolescents having made a suicide plan has been noted in the past 20 years (18.6 to 12.8 %), although no significant change occurred in the prevalence of actual attempts (Eaton et al. 2012). During the past decade, the crude death rate from suicide and intentional self-harm among adolescents aged 15–19 residing in the 27 countries of the European Union has also dropped from 6/100,000 people to 4.6/100,000 (Eurostat 2013).

135.2.2 Adolescent Substance Use

135.2.2.1 Alcohol Use

Adolescent alcohol use is related to the three leading death causes in the young (Naso et al. 2008), namely, accidents, suicide, and homicide. These three death causes account for approximately 75 % of all mortality cases between ages 15 and 24 (NVSR 2013), and therefore, alcohol is related to most premature death cases in the young. The use of alcohol increases the likelihood of violent deaths including suicide in direct (acute intoxication) as well as indirect (loss of inhibition, increased impulsivity) means. Most of completed suicide cases are indirectly rather than directly linked to alcohol use. In American youth under 21 years old, an annual average of 480 deaths due to suicide are attributable to excessive alcohol use (CDC 2013b), whereas only a small minority of adolescent suicide cases (4 %) are directly induced by ingestion of alcohol or drugs (NVDRS 2013). A high prevalence of up to 45 % of alcohol involvement has been found in adolescent hospital admissions due to physical trauma (Sindelar et al. 2004).

Alcohol use has been shown to be associated with elevated rates, and increased risk for adolescent suicidality (Borowsky et al. 2001; Esposito-Smythers and Spirito 2004; Kokkevi et al. 2012) even after the effects of depression, impulsivity, peer delinquency, and parental monitoring are controlled for (Swahn et al. 2008). But although

alcohol abuse is strongly related to suicidality, the proof of causality between the two in adolescents is not as evident (Pompili et al. 2010). Patterns of alcohol "use" or "abuse" can vary widely in terms of time (e.g., how many days in a month) and volume (e.g., how many drinks each time), and so it may be more appropriate to examine the association with suicidality in instances in which alcohol is consumed in excess. Consuming five standard alcoholic drinks or more in the same drinking session ("binge drinking") would cause most adolescents to reach at least some degree of intoxication. Although no cross-country or cultural consensus exists to define an alcohol volume of a standard drink or how many drinks constitute a "binge," binge drinking can generally be viewed as a rapid consumption of alcoholic beverages with the intention of becoming intoxicated. On average, nearly half of the students in the USA (54 %) as well as in Europe (47 %) reported that they had been intoxicated in this sense at least once during their lifetime (Hibell et al. 2012; Johnston et al. 2013).

Binge drinking, otherwise known as "heavy episodic drinking," represents a pattern of alcohol consumption which is highly associated with health risks (Miller et al. 2007). It is most prevalent among teenage alcohol consumers and is associated with increased risk for suicidal thoughts and attempts, even when compared to current alcohol drinkers who do not binge drink (Miller et al. 2007). This connection is strongly correlated to frequency of binging; those who binge on more than 10 monthly occasions attempt suicide more than those who binge six to nine times (30 % vs. 16 %) and almost three times as much as those who binge once a month (11.9 %) (Miller et al. 2007).

Binge drinkers tend to explore the use of other psychoactive substances, some of which are associated with increased suicidality risk. Current heavy episodic drinking shows a significant correlation to lifetime use of cannabis (Hibell et al. 2012). Also, adolescent alcohol binge drinking carries an odds ratio (OR) of 60 for concurrent marijuana use as compared to nonalcohol drinkers, much more than that of alcohol drinkers who do not binge ($OR = 5$) (Miller et al. 2007). Adolescents reporting concurrent alcohol and marijuana use presenting to the ED following alcohol intoxication display heavier drinking patterns as compared to those who report alcohol use alone, including increased binge drinking instances as well as elevated alcohol consumption on each drinking occasion (Chun et al. 2010).

Recently Archie et al. suggested that binge drinking raises the risk for suicidality in youngsters only when depression is present (Archie et al. 2012). Using a survey delivered to over 17,000 adolescents aged 15–24 years, they show that binge drinkers and non-binge drinkers shared the same risk for suicidality when no depression was present even when using more stringent definitions of binge drinking (at least once weekly). When the effect of depression was tested, they found that depressed binge drinkers had an increased risk for suicidality as compared to non-binge drinkers who were not depressed ($OR = 6.3$) (Archie et al. 2012). Similar results have also been reported recently for adults (Shoval et al. 2014).

It is generally perceived that in countries in which alcohol per capita consumption is high, binge drinking is low ("social drinking" countries). Indeed, some of the developed West European countries display the most substantial adult per capita consumption rates while also displaying the least risky patterns of alcohol

consumption and a relatively decreased net alcohol-attributable mortality rates (WHO 2013). This perception may very well be true for the adult population, but not necessarily so for adolescents. Data analysis from recent large-scale surveys reports that regular alcohol use does not predict low levels of binge drinking. In fact, no correlation was found between the proportion of students in a country who had been drinking during the past 30 days (current users) and the amounts consumed on the latest drinking day (Hibell et al. 2012). It is thus important not to rely on common notions and beliefs regarding adolescent alcohol consumption patterns, which may be quite unpredictable and unsimilar to adult patterns of alcohol use.

The criteria for alcohol abuse and dependence needed to establish the DSM-IV diagnosis of alcohol use disorders should be viewed carefully when addressing adolescents vs. adults since there are important developmental differences in the clinical characteristics of alcohol use disorders in adolescents and adults (Perepletchikova et al. 2008). Of the seven DSM-IV-TR criteria defining alcohol dependence, for example, the emergence of "withdrawal" is more rare among adolescents, and the behavioral correlates of "tolerance" and "drinking more than intended" criteria are frequently endorsed by adolescents with low levels of alcohol consumption and problem severity (Chung et al. 2005). Winters et al. recently suggested several targeted adjustments to the upcoming DSM-5 diagnostic criteria of SUD so as to make them more applicable to the adolescent population and to ensure the validity of the diagnosis across developmental stages (Winters et al. 2011). Specifically they proposed the exclusion of the "hazardous use" criterion from the "alcohol abuse" diagnosis, reasoning it is highly associated with automobile use which is more applicable to adult behavior. They also advocated adolescent-targeted adjustments to be made for the definitions of "tolerance," "withdrawal," and the DSM-5 "craving" criteria, all of which are influenced by developmental changes. Finally, during DSM-5 discussions, it was proposed to raise the diagnostic threshold for SUD in order to avoid unnecessary labeling and stigmatization of mild or intermittent cases.

Treatment options for alcohol disorders are markedly more abundant today than were in the past. In their review of the various assessment instruments and treatment options currently in use for alcohol use disorders in youth, Perepletchikova et al. suggest Multidimensional Family Therapy (MDFT) and group-administered Cognitive Behavioral Therapies (CBT) in combination with brief individual Motivational Enhancement Therapy (MET) as the most evidence-based supported treatment strategies of adolescent alcohol use disorders (Perepletchikova et al. 2008). A recent study suggested that MDFT may be superior to other strategies in youth presenting with more severe drug use and greater psychiatric comorbidity (Henderson et al. 2010). Although this study performed a secondary analysis of two randomized controlled trials whose subjects were primarily diagnosed with cannabis use disorders and were not suicidal, a substantial minority had an alcohol use disorder and so these results may also be highly relevant to adolescents suffering from alcohol use disorders as well.

135.2.2.2 Trends in Alcohol Use

Adolescent alcohol use in the USA is steadily declining. In 2011, 70.8 % of high school students reported they had ever drank alcohol, a decrease from 81.6 % just two decades ago (Eaton et al. 2012). A drop of more than 20 % in the corresponding years has been demonstrated in youth reporting current alcohol use, from 50.8 % to 38.7 % (Eaton et al. 2012). Data from the ongoing Monitoring the Future (MTF) study corroborate these findings. The latest report presenting adolescent alcohol use has reached a historic low, from 93 % lifetime prevalence of use in senior year high school students 30 years ago down to 50 % today (Johnston et al. 2012). The situation in European countries is quite different; adolescent alcohol use has remained relatively unchanged in the past 15 years. The European School Survey Project on Alcohol and Other Drugs (ESPAD) which is based on data from more than 100,000 European students from 36 countries reports that for youth averaging 15.8 years of age, lifetime use of alcoholic beverages has dropped only slightly from 89 % in 1995 to 86 % in 2011 (Hibell et al. 2012). As can be expected, substantial prevalence differences were found between countries in this study. Although these figures probably reflect different social and cultural norms in drinking patterns, the different rates of decline in adolescent alcohol consumption might also reflect the utility of various alcohol-use prevention plans locally employed. Many educational and preventive policies aimed to reduce the harmful use of alcohol have been formulated and utilized worldwide in the past three decades (WHO 2013) and the use of alcohol in adolescents as aforementioned is since on the decline. Furthermore, temporal trend reports of American adolescent binge drinking prevalence present a 30 % decrease from 1991 to 2011 (31.3–21.9 %) including an impressive 50 % decline in male binge drinking since 1981 (Johnston et al. 2013), perhaps reflecting the success of educational preventive strategies focusing on the behavioral aspect of alcohol use (highlighting negative aspects of "drunkenness" instead of "drinking") and not of restrictive strategies (e.g., increased legal drinking age). It is also debatable whether restrictive measures for alcohol use are applicable, alcohol is perceived by youth to be easily available, and four in five students (81 %) find it fairly or very easy to get hold of an alcoholic beverage (Hibell et al. 2012). Strict policies may also lead to rebellious behavior and an increased prevalence of binge drinking. A recent study exploring the drinking pattern and drunkenness among mid-adolescents in 40 European and North American countries found a trend whereby higher prices and stronger alcohol controls were associated with a lower proportion of weekly drinking but a higher proportion of drunkenness (Gilligan et al. 2012).

Nevertheless, in summary, alcohol remains the substance most widely used today by teenagers, and seven out of every ten students have consumed alcohol by the end of high school (Johnston et al. 2012). Given the close association to suicidality, this should warrant continuing efforts to decrease adolescent alcohol use and not to rejoice over the positive statistical data reporting its decrease.

135.2.2.3 Cannabinoids Use

The US nationwide MTF study utilizes national samples of 45,000–50,000 students in three grades (8th, 10th, and 12th) that have been surveyed every year since 1991 (Johnston et al. 2013). In 2012, the percentages of students indicating any use of an illicit drug in the prior 12 months (representing current users) were 13 %, 30 %, and 40 % in grades 8, 10, and 12, respectively. The percentages indicating any use during their lifetime were 19 %, 37 %, and 49 % (Johnston et al. 2013). Data concerning drug use in European countries has also been gathered in the past two decades and summarized in the ESPAD report. Latest prevalence reports of lifetime drug use were on average 21 % for boys and 15 % for girls (Hibell et al. 2012); clearly these numbers stand out as modest compared to those in the USA.

These differences persist when focusing on current cannabis users alone; the annual prevalence rate in the USA in 2012 was 28 % for 10th graders (Johnston et al. 2013), while the ESPAD reported 13 % prevalence for the corresponding age group (Hibell et al. 2012). According to the latest YRBS report, 23.1 % of high school students had used marijuana on one or more occasions during the 30 days prior to the survey (Eaton et al. 2012), much more than the 7 % reported by European students (Hibell et al. 2012). It is of note in this context that the ESPAD also gathered data from US students and presented lower prevalence data than did the YRBS (18 % use in the prior month) (Hibell et al. 2012).

While cannabinoids by far represent the most prevalent illicit substance group for adolescent use today, data regarding the prevalence of other illicit drugs can be found elsewhere (Hibell et al. 2012; Johnston et al. 2013; NSDUH 2012a) but will not be elaborated here in detail. Briefly, about 4 % of adolescents aged 12–17 years in the USA report the current use of illicit drugs excluding marijuana. Of the several illicit substance groups whose prevalence has been annually monitored, the illicit use of psychotherapeutics (including amphetamines, sedatives, tranquilizers, and narcotics) is second to marijuana, while hallucinogens, inhalants, and other drugs are far less prevalent. The National Survey on Drug Use and Health (NSDUH) obtains information from approximately 70,000 US residents aged 12 years and older regarding several categories of illicit drug use. In the latest report relating to 2011, about half (47.7 %) of youths aged 12–17 reported that it would be "fairly easy" or "very easy" for them to obtain marijuana if they wanted (NSDUH 2012a); indeed, the rate of current marijuana use among this age group remained unchanged in the past decade (8.2 and 7.9 % in 2002 and 2011, respectively) (NSDUH 2012a). But although these numbers imply an apparent stagnancy in the effectiveness of drug prevention programs, the comparison of adolescent marijuana use trends with their reported perception of risk from its use reveals that this may not be so. It is interesting that as the rates of adolescents' perception of "great risk of harm" due to regularly smoking marijuana decreased between 2007 and 2011 (from 54.6 % to 44.8 %, respectively), the rate of its current use increased from about 6.7 % in 2007 to 7.9 % in 2011 (NSDUH 2013). The analysis of the temporal trends suggests that the implementation of education programs directed to specifically explicate the dangers associated with substance use may be useful and so should be continuously encouraged since perception of risk of harm

from marijuana reversely correlates to its use. However, since marijuana use has recently been on the rise, further improvement of these educational programs in warranted.

It is worth mentioning that temporal changes in patterns of adolescent substance abuse clearly exist, stressing the importance of ongoing efforts to monitor drug-use trends. For instance, the use of nonmedical analgesic opioids has recently become second in prevalence to marijuana, surpassing the use of inhalants and hallucinogens (Wu et al. 2011). Recently, the rise in adolescents' use of synthetic cannabinoids has also become a source of major concern due to high rates of reported use and its relative ease of availability. Youth aged 12–17 account for the highest rate of ED visits involving synthetic cannabinoids (DAWN 2012), and its annual prevalence among American 12th graders in 2012 was 11.3 % (Johnston et al. 2013). This high prevalence rate is alarming considering the intensive federal and state efforts to reduce its use. A comprehensive national US ban enacted in July 2012 might decrease the prevalence of this drug group among adolescents. There are no studies yet linking suicidality and synthetic cannabinoids use in adolescents. As clinical observations of their rapid growth of use and harm accumulate in our mental health center, our group is currently designing such a study.

135.2.3 Substance-Related Disorders as a Risk Factor for Suicidality

The link between substance use and suicide among adolescents is well established by evidence from clinical and epidemiological studies (Pompili et al. 2012; Swahn et al. 2012; Wilcox 2004; Wolitzky-Taylor et al. 2010). Moreover, drug and alcohol abuse are strong predictors of reattempting suicide within 12 months (Vajda and Steinbeck 2000). Postmortem examination studies lend further proof to this relationship; one of these studies reported that in pediatric (<19 year) decedents tested positive for illicit drugs, 93 % died from violent causes and of these 15 % had committed suicide (Naso et al. 2008).

Importantly, the strength of this connection appears correlated to the severity level of suicidal behavior. For instance, adult suicide completers are significantly more likely to use alcohol or drugs prior to their suicidal attempt than suicide attempters (DeJong et al. 2010). Moreover, suicide attempters are more likely to be substance dependent than suicidal ideators (Gould et al. 1998; King et al. 2001), suggesting that substance use may in fact facilitate the escalation from ideation to behavior. In a large study among 15,885 French adolescents (Huas et al. 2008), 32 % used cannabis at least once during their lifetime. Of these, 16 % were considered "former users" since they had not used cannabis in the prior month and 8 % others had used cannabis less than six times during that time period and were considered "occasional users," while those using cannabis over six times were deemed "heavy users." In this study, the risk for suicide attempt was 30 % higher among "heavy users" than "occasional users," clearly strengthening the notion of a positive correlation between cannabis use patterns and suicide attempts.

Interestingly, the OR for suicide attempt was $OR = 4.2$ for the "occasional users" and $OR = 2.9$ for the "former users" as compared to "nonusers." In light of the general opinion that the adverse psychosocial effects of cannabis stem from frequent use alone, the finding that the risk for suicidality is also related to occasional and even sporadic use is noteworthy. The causative correlation in the opposite direction between suicidality and the degree of substance use is not as clear. A recent study set out to investigate the relationship between suicidal ideation and cannabis use using data gathered from a 30-year longitudinal study of a birth cohort. Using a statistical model, they show that cannabis use may lead to suicidal ideation in susceptible subjects, but more importantly, that suicidal ideation does not lead to cannabis use (van Ours et al. 2013).

Regarding drug use habits associated with "more of others" as contrary to "more of the same" pattern, polydrug consumption is highly correlated to increased suicide risk. In a recent large European sample of over 45,000 adolescents from 16 countries, the percentage of respondents who reported at least one suicide attempt increased sharply with the number of substances used. Logistic regression analysis revealed that the risk for suicide attempt was $OR = 4.47$ for users of two substances and continued to increase thereafter with the use of additional substances as compared to nonusers (Kokkevi et al. 2012). Quite contrarily to popular belief, regular cannabis use does not substitute or protect from the use of other illicit drugs, rather it is strongly associated with their later use ("gateway drug") in an age-dependent manner (Fergusson et al. 2002). Since adolescent polydrug use is a widespread phenomenon and is most severe among drug abusers (EMCDDA 2009), prevention and treatment strategies should pay specific attention to this subpopulation.

Substance abuse in youth suicide attempters does not appear to conform to socioeconomic boundaries. Reported levels of substance abuse among youth patients presenting with suicidality to EDs in either an academic medical center located in west Los Angeles (LA), California, or a county hospital in southern LA were similar, although many disparities were found between the two locations regarding sociodemographic and background statistics (Asarnow et al. 2008). The effect of substance use on suicidal behavior may be so strong to a degree that it even may reverse social-cultural norms. A national American study of Latino adolescents revealed that immigrant generation status (foreign-born immigrants vs. later US-born generations) was a determinant for suicide attempts, problematic alcohol use, and repeated marijuana and other drug use. In this study the authors describe that first-generation youth were less likely to attempt suicide compared with second- and later-generation youth. They also found a marked linear relation between immigrant generation status and both illicit drug use and problematic alcohol use. Using path analysis, they propose that repeated non-marijuana drug use mediates the effect of generation status on the propensity to attempt suicide (Pena et al. 2008).

Despite drug surveillance programs as well as prevention and intervention strategies applied, the risk of suicidality associated with drug abuse in adolescents remains stable in the past two decades and still poses a major public-health concern.

Recently, using nationally representative samples of adolescents aged 12–17 years recruited and interviewed in two waves in 1995 and 2005, Wolitzky-Taylor et al. presented a dramatic decrease in suicidality risk associated with depression or alcohol abuse, whereas the risk attributable to substance abuse remained constant throughout these years (Wolitzky-Taylor et al. 2010).

135.2.4 The Moderating Role of Psychiatric Morbidity

SUD and suicidality are both highly associated with additional psychiatric comorbidity (Armstrong and Costello 2002; Foley et al. 2006). Unfortunately, the moderating effect of psychiatric comorbidity on the relationship between them is highly complex and hard to clarify. For instance, adolescent SUD patients display high psychiatric comorbidity most commonly associated with externalizing disorders (Armstrong and Costello 2002; Couwenbergh et al. 2006), whereas suicidal adolescents also tend to display psychiatric comorbidity though mainly with internalizing disorders (Foley et al. 2006; Kelly et al. 2004). The presence of a psychotic disorder also displays a moderating effect on this relationship; Shoval et al. presented a significant and strong association between suicide attempts and the use of illicit substances among adolescent suicidal inpatients diagnosed with schizophrenia or schizoaffective disorder as compared to non-suicidal patients (Shoval et al. 2006). The presence of personality disorders (PD) or traits may further intricate the assessment of this connection. Most patients diagnosed with a PD that perform completed suicidal acts (Fleischmann et al. 2005) as well as those who are diagnosed with SUD (Pereiro et al. 2013) are reported to fall into the antisocial or borderline PD classification. It is of importance, however, to note that many studies do not assess or report the presence of PD at all but instead focus on axis I diagnoses.

Not only the nature of the psychiatric disorder present but also the number of concurrent psychiatric disorders may increase the risk for suicidality. In a prospective study investigating suicidality among 180 discharged adolescent psychiatric inpatients followed for up to 13 years, most of those who were suicidal during the follow-up period had concurrent depressive disorders, and many had also displayed disruptive behavioral disorders either alone or concurrently (Goldston et al. 2009). In the same line of evidence, Vander et al. have shown that co-occurring depression and conduct disorder symptoms increase the risk for subsequent suicidality as compared to a single diagnosis of either of these (Vander et al. 2011).

Kelly et al. investigated the effects of psychiatric disorders on suicide attempts among 503 adolescents diagnosed with SUD (Kelly et al. 2004). By comparing non-suicidal to suicidal adolescents, they revealed that concurrent diagnosis of major depression or bipolar disorder conveyed the highest risks for attempting suicide. They also showed that attention-deficit hyperactivity disorder (ADHD) was associated with increased risk for male-attempted suicide, while conduct disorder was associated with attempted suicide among females. Regression hazard

analysis revealed that adolescents with SUD were most likely to attempt suicide when they also had a concurrent mood disorder (Kelly et al. 2004).

135.2.4.1 Mood Disorders as a Model

An estimated two million American youths suffer annually from a major depressive episode (8.2 % of the population aged 12–17) (NSDUH 2012b), and depression is the strongest known risk factor for adolescent suicide (Asarnow et al. 2008; Brent et al. 1993; Shaffer et al. 1996; Wolitzky-Taylor et al. 2010). Recent data suggest that even subthreshold depression, which is highly prevalent and can be found in up to 30 % of adolescents, is associated with increased suicidality risk (Balazs et al. 2013). A simplistic view would hold that the identification of adolescents prone to or suffering from depression should decrease suicidality following their adequate treatment; apparently, this is not as simple as one may reason. An ongoing debate exists regarding the effects of antidepressant on suicidality. Some evidence suggest that antidepressant medication by itself may increase the risk for adolescent suicidal behavior (Hetrick et al. 2012; Schneeweiss et al. 2010), while other studies provide evidence for an adolescent suicidality-lowering effect of antidepressants (Kuba et al. 2011; March et al. 2007). Currently most clinicians agree that treatment benefits outweigh the risks (Bridge et al. 2007).

Adolescent depression displays high comorbidity with alcohol and substance abuse (Armstrong and Costello 2002; Sher and Zalsman 2005). Adolescents suffering from major depressive episodes (MDE) were found to be more likely than those without past year MDE to have used illicit drugs in the past year (36 % vs. 17.4 %) or to be heavy alcohol users in the past month (2.5 % vs. 1.4 %); this disparity increases when comparing rates of substance dependence or abuse (NSDUH 2012b).

The combination of adolescent depression and substance abuse has been shown to elevate the risk for suicidality (Kovacs et al. 1993; Levy and Deykin 1989). This may be true even for mild to moderate substance abuse and subthreshold to diagnostic criteria of SUD (Huas et al. 2008).

Some studies reveal a synergistic effect when comorbidity occurs. For instance, the combination of depressive symptoms and problem drinking in adolescents has been shown to convey a stronger risk for suicidal behavior than problem drinking or depressive symptoms alone (Windle and Windle 1997). This effect on the suicidal risk may be mediated by substance-induced increased impulsivity. Interestingly, this synergism may disappear in the transition to adulthood since in adults with MDE, alcohol dependence does not significantly affect the risk for suicidality (Shoval et al. 2014).

The causative relationship between substance abuse, depression, and suicidality remains unknown. Studies that address this relationship face many methodological challenges (Galaif et al. 2007). A fundamental impediment is that both depression and substance abuse are independently highly associated with adolescent suicidality and their co-occurrence is the rule rather than the exception in adolescents. Large-scale prospective studies addressing this causative connection may aid the construction of suicide screening and prevention strategies. For example, Goldstein et al. used post hoc analyses on data from the Treatment of SSRI-

Resistant Depression in Adolescents (TORDIA) study to demonstrate that the level of substance-related impairments is reversely correlated to the response to antidepressive treatment (Goldstein et al. 2009), suggesting that treating substance abuse may by itself decrease depression and suicidality.

Data concerning suicidality in other mood disorders associated with substance use comorbidity are scarce in the adolescent population and usually hampered by a retrospective design. Most clinicians thus rely on adult studies and execute data extrapolation when considering risks and prevention plans. Nevertheless, the connection between bipolar disorder (BD) and suicidality has been demonstrated in many retrospective studies (Brent et al. 1988; Goldstein et al. 2005, 2008). Recently, a study designed to assess predictors of prospectively observed suicide attempts among youth with bipolar disorder revealed a strong association of this disorder with high rates of suicide attempts (Goldstein et al. 2012). This study utilized subjects enrolled in the Course and Outcome of Bipolar Youth (COBY) study and is the first prospective-designed study to date testing the BD-suicidality connection in adolescents. During the 5-year follow-up period of 413 adolescents diagnosed with BD, 76 (18 %) attempted suicide once or more. Of these, 31 attempted suicide more than once for a total of 163 suicide attempts during the follow-up period. Considering the early mean age of the study recruits (12.6 years), these figures may underscore the actual suicide attempt rate since most of these adolescents had yet to pass through the highest risk period for new onset of suicidal behavior (age range, 16–18 years (Kessler et al. 1999)).

The strength of the BD-suicidality connection may be correlated to the severity of suicidal behaviors. Brent et al. described an extremely high prevalence of BD in adolescent suicide completers. The diagnosis of BD (either type I or II) in suicide completers (22 %) was found to be at least four times more prevalent than in suicidal inpatients admitted for attempted suicide or for having a suicidal ideation (Brent et al. 1988). Surprisingly, suicide completers in this study did not display a higher frequency of the co-occurrence of mood disorder and substance abuse than non-completers. Though in a consequent larger sample study (Brent et al. 1993), they show that substance abuse is a more significant risk factor for suicide completion when comorbid with a mood disorder than when alone ($OR = 17.0$ vs. 3.3). Other studies describe the negative effect of substance use on suicidality in BD; Goldstein et al. reveal a double risk for SUD and lifetime excessive drinking in BD-diagnosed adolescents who concomitantly performed a suicidal attempt as compared to those who did not. During the 8 weeks prior to the attempt, the risk for SUD was tripled (Goldstein et al. 2012). The same group reported that in a large sample of bipolar adolescents in which lifetime prevalence of SUD was 16 %, subjects with SUD demonstrated a significantly greater lifetime prevalence of suicide attempts as compared to those without SUD (Goldstein et al. 2008).

Interestingly, the effect of substance abuse and in particularly that of cannabinoids on suicidality in BD patients may be exacerbated by the emergence of increased psychotic features (Henquet et al. 2005; Wolitzky-Taylor et al. 2010), which have been shown to increase suicidality in pediatric BD (Caetano et al. 2006). Most recently, adolescent high-risk offsprings of BD patients were

compared by a lifetime diagnosis of SUD. Those with a lifetime SUD had a significantly higher likelihood of meeting criteria for a lifetime major mood episode and a significantly higher risk of having experienced clinically significant psychotic symptoms. Consequent predictive models displayed a direct connection between SUD and emergent psychotic features (Duffy et al. 2012).

The rate of suicide attempts in youths with BD-I has been shown to be higher than in youths with BDII (Goldstein et al. 2005). In a retrospective study by Sublette et al. SUD was associated with suicide attempt in BD-I but not BD-II adults (Sublette et al. 2009). In this study the presence of both alcohol and drug use disorders increased the odds of a history of suicide attempt in a multiplicative fashion: an overwhelming 97 % of BD-I who had both comorbid drug and alcohol-use disorders had made at least one suicide attempt (Sublette et al. 2009). Contrarily, a recent study using data from the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) failed to demonstrate such an additive effect of drug use disorders on suicidal behavior in BD patients who also have alcohol-use disorders (Oquendo et al. 2010).

Sublette et al. pointed out three variables that were shown to mediate the increased risk for suicide attempt in this population, namely, traits of aggression, impulsivity, and hostility. The authors suggest these traits arise from the interaction of BD and substance abuse. Since the temporal relationships between the affective manifestations of BD, substance abuse, and suicide attempt are not yet clear, further prospective studies are suggested by them to elucidate the exact role of these traits as mediators of suicide attempt (Sublette et al. 2009). The implication of these traits in suicidality is not solely restricted to BP patients; in adult alcohol-dependent patients, a strong association between impulsivity and severity of depressive symptoms has been demonstrated (Jakubczyk et al. 2012). A recent model describing the constructs of behavioral disinhibition, associated with self-injurious behavior in adolescents, ascribed personality traits such as impulsivity and sensation seeking as key structural elements (Bogg and Finn 2010). A recent study using a large sample of adolescent self-reported questionnaires found significant associations between sensation seeking behavior and depressive symptoms or the occurrence of substance use problems. Students with high sensation-seeking behaviors were three times more likely to have symptoms of depression or substance abuse than students with low sensation-seeking behavior (Ortin et al. 2012). They also had a significantly higher risk for endorsing serious suicidal ideation or for having engaged in a suicide attempt, even after controlling for either depression or substance abuse (Ortin et al. 2012).

135.2.5 Gender Differences in Suicidality

The risk for suicidal behavior does not exhibit gender equality. This likely stems from multiple psychological, biological, and social between-gender distinctions that bear a dissimilar effect on mental states and behaviors associated with suicidal behavior. Trying to evaluate the moderating effect of gender on the SUD-suicidality

connection is fraught with methodological challenges since gender is differentially associated with suicidality, depression, and substance use. For instance, female adolescents are more likely to be depressed; among American youth aged 12–17, females were more likely than males to have past year MDE (12.1 % vs. 4.5 %) or MDE with severe impairment (8.3 % vs. 3.2 %) (NSDUH 2012b). Males, on the other hand, are more likely to use drugs and alcohol. On average, boys report cannabis use to a larger extent than girls do (19 % vs. 14 % in Europe and 25.9 % vs. 20.1 % in the USA) (Eaton et al. 2012; Hibell et al. 2012), although Rey et al. reported no such gender difference for Australian youth (Rey et al. 2002). Adolescent males drink more alcohol and report more frequent heavy episodic drinking (Eaton et al. 2012); additionally, females are more sensitive to alcohol-induced effects due to biological factors.

Regarding suicidality, females are more likely to have suicidal ideation, to make suicidal plans, and to attempt suicide (Eaton et al. 2012), whereas males are more likely to complete suicide (Bridge et al. 2006). Interestingly, in a large study tracking completed adolescent suicide rates in Finland over a period of 40 years, a surprising differential gender-specific trend of suicide rates was found. Although male suicide rates displayed a steady decrease since 1989, the female trend displayed a concomitant steady increase (Lahti et al. 2011).

135.2.5.1 Lesbian-Gay-Bisexual Population

The Lesbian-Gay-Bisexual (LGB) adolescent population is gradually and increasingly being exposed to the public eye and to scientific studies. This population suffers from increased rates of environmental stress which may lead to social isolation and interfere with normal adolescent development (Frankowski 2004). In a recent study, one-third of adolescents aged 16–20 years met DSM-IV criteria for mental disorders and 15 % for major depression (Mustanski et al. 2010). Furthermore, LGB youth are more likely than their peers to have been victimized and threatened and to have been engaged in a variety of risk behaviors (Garofalo et al. 1998).

Although this is a "novel" population for health-related epidemiological research, relevant data can be generally drawn from large-scale adult population studies, in which sexual preference is more stable. These studies reveal increased risks for substance and alcohol dependence as well as for suicidality. A large meta-analysis concerning LGB suicidality and encompassing almost 12,000 nonheterosexual adults found the lifetime risk ratio for suicide attempts among LGBs to be 2.5 compared to the heterosexual population. The pooled data also revealed that alcohol and other substance dependence over 12 months was also 1.5 times higher among LGBs (King et al. 2008). Another large study including representative populations of LGB adults from the UK displayed similar results. Specifically, increased risks for drug dependence ($OR = 1.70$), alcohol dependence ($OR = 2.05$), lifetime suicidal thoughts ($OR = 1.85$), and suicide attempts ($OR = 2.21$) were found in LGBs as compared to heterosexuals (Chakraborty et al. 2011).

Assessing data regarding this subpopulation in the adolescent age group is not a simple task. Most LGB youth do not openly present themselves as such, and many

are not without doubt regarding their sexual preferences, a substantial part of them go on to change their sexual orientation throughout this transitional period (Needham 2012). This task is made even harder when trying to retrospectively assess whether same-gender sexual affiliation was present, requiring the differentiation of self-defined sexual orientation from practiced sexual relationships which may or may not be in accordance with the sexual affiliation.

Among high school youth in the USA, 1.3 % of students identify themselves as gay or lesbian and 3.7 % as bisexual (Kann et al. 2011). Another 4.7 % of students present themselves as "unsure of their sexual identity," yet it is unknown whether this large group shares similar behavioral attributes as the LGB group or not.

Sexual minority students are more likely to engage in health-risk behaviors than other students (Garofalo et al. 1998). They display higher prevalence of binge drinking and report a higher rate of current marijuana use (Kann et al. 2011). A meta-analysis exploring the connection between nonheterosexual sex orientation and substance abuse found an increased risk for SUD among LGBs, including lifetime use of alcohol ($OR = 2.23$) and marijuana ($OR = 2.58$) (Marshal et al. 2008). Data from the latest YRBS report the prevalence of students having attempted suicide to be 6.4 %, 25.8 %, and 28 % for heterosexual, gay/lesbian, or bisexual students, respectively (Kann et al. 2011). Gay/lesbian students were almost six times more prone to commit a suicide attempt that resulted in an injury, poisoning, or an overdose that had to be treated by a doctor or nurse (Kann et al. 2011). Data gathered from a national longitudinal study of adolescent health in the USA revealed that LGB adolescents reported higher rates of suicidal ideation and suicide attempts than did non-LGB adolescents, even after controlling for race, gender, and age (Silenzio et al. 2007). Most importantly, risk factor analyses exposed different patterns of suicide related risk factors between LGB and non-LGB adolescents; problematic drug use was more strongly associated with suicidal ideation among non-LGB adolescents, as was the association between depression and suicide attempts (Silenzio et al. 2007). The authors suggest that different treatment targets should be sought for this population following the elucidation of specific suicidal risk factors relevant to LGB adolescents. A recent meta-analytic review comparing suicidality and depressive symptoms in sexual minority and heterosexual youth found increased suicidal behavior ($OR = 2.9$) and depressive symptoms in this sexual minority population (Marshal et al. 2011). Of note in this analysis was the description of an increase in the level of disparity between both populations as the severity of suicidal behavior increased ($OR = 1.96$, 2.2, 3.18, 4.17 for suicidal ideation, intent, attempt, serious attempt requiring medical attention accordingly) (Marshal et al. 2011), stressing the need for health-care personnel to pay heightened attention to suicidal behavior when encountered in LGB youth and when performing a suicide risk assessment.

Prospective studies are in demand to promote the identification of distinct attributes concerned with suicidality in this population through their transition into adulthood and maturation of sexual preference. In a large longitudinal study following a cohort of over 1,000 children from birth to age 21, the sexual orientation was studied at age 21 retrospectively from age 16 to 21. The correlation

analyses between sexual orientation and suicidality revealed a fivefold risk for such behavior in LGBs through the cohort period. The risk for LGB substance dependence was almost double, although not statistically significant ($p = 0.086$) (Fergusson et al. 1999). The prospective nature of this study allowed for the evaluation of social and familial backgrounds of the subjects, and indeed some differences were found between LGBs and other cohort members in their familial background suggesting a more troubled childhood for LGBs. Interestingly, controlling for these differences in the statistical analyses had a negligible effect on the unadjusted results and thus might reflect a need to focus on developmental and behavioral factors instead.

135.2.6 Age Differences in Suicidality

Zalsman has speculated that the timing of onset of gene-environment interactions leading to adolescent suicidality is crucial. He postulates that specific brain-development time windows may be critical for this interplay to emerge as behavioral phenotypes (Zalsman 2010, 2012). Clinical observations of age influences on suicidal behavior are evident and the risk for suicidal behavior has been shown to increase through the transition from childhood to adolescence in such a way that late adolescents (generally defined as over 15 year old) exhibit increased risks for suicidal attempts and completion as compared to early adolescents (Dervic et al. 2008; Waldrop et al. 2007; Windfuhr et al. 2008). Indeed, in early adolescence suicide is the tenth cause of mortality worldwide and at age 15–19 years there is a dramatic leap to second place (Patton et al. 2009). In older adolescents the perception of risk from using alcohol and marijuana is lower (NSDUH 2013) and the use of drugs and alcohol as well as practicing binge drinking is increased (NSDUH 2012a). For instance, in a study by Rey et al., the lifetime use of cannabis tripled between ages 13 and 15 years and a further increase of about 60 % occurred between 15 and 17 years (Rey et al. 2002). Furthermore, late adolescents' suicidal behavior is more associated with increased alcohol and drug use (Brent et al. 1999; Hysinger et al. 2011; Singh and Lathrop 2008) even though cannabis use (Fergusson et al. 2002) or heavy episodic drinking (Aseltine et al. 2009) may have a more prominent effect on suicidal behavior in school-aged children as compared to older adolescent users. These data clearly strengthen the notion that public-health leaders should prioritize their efforts toward younger school-aged adolescents.

135.2.7 Future Studies

Whereas the epidemiological and clinical data linking substance abuse to suicidality are compelling, basic science research encounters many difficulties in establishing this connection. Several problems arise to hamper the fundamental demand to minimize heterogeneity in the studied variables. First, there is no consensus as to the exact age span of adolescence although it is traditionally

regarded as the time period between ages 10 and 25 years. Furthermore, this time length encompasses developmental stages such as puberty and postpuberty, associated with dramatic hormonal and physiological changes (e.g., the menarch) which cannot be constrained by strict temporal limits. Second, adolescence is a period of a dramatic psychosocial transition from childhood to adulthood, and this change is anatomically supported by a profound increase in brain plasticity (Casey et al. 2008) including rostrocaudal white matter increase (myelinization) and accelerated dendritic pruning (Giedd et al. 1999) leaving few brain regions and neurochemical pathways unchanged. Suicidal behavior or even thoughts might turn out to variably modify brain activity and plasticity in a similar way as does substance abuse (Churchwell et al. 2010) or depression (Tao et al. 2012). Trying to account for this variability in brain connectivity in time and space over at least a 10-year period seems presently impractical. Third, for obvious reasons, studying human brain morphology and activity, particularly those of children and adolescents, should be undertaken by employing noninvasive means. These means are presently scarce and thus most studies rely on comparative neuroimaging techniques alone.

These methodological challenges are demonstrated in a comprehensive overview of the relationship between alcohol and suicide by Pompili et al. (2010). They describe this causal relationship as being inconclusive and highly suggestible at best in light of the many neurotransmitter systems which are affected by ethanol, with varying spatial and temporal modifications regarding target brain regions.

Nevertheless, in the molecular level, a substantial volume of research has been accumulated relating to neurobiological changes associated with suicidality in adolescents. While these studies present convincing data regarding a genetic predisposition to suicidality (Zalsman 2012) as well as altered receptor and signal transduction pathways associated with suicidality (Pandey and Dwivedi 2012), they seldom address the role of substance abuse as a modifier to these neurobiological changes.

Suicidality is undoubtedly a complex behavioral phenotype. Currently, researchers studying the heritability of suicidal behavior are increasingly concerned with endophenotypes of suicidal behavior (Mann et al. 2009) and less so with single genes, although in distinct cases a direct connection can be drawn between single genes and suicide-related features such as impulsivity (Bevilacqua et al. 2010). An important workshop convened for the purpose of the identification of candidate biological and clinical endophenotypes associated with suicidality found the most promising endophenotypes to be aggression/impulsivity trait, early onset major depression, neurocognitive function, and cortisol social stress response (Mann et al. 2009). Most recently specific endophenotypes for drug dependence have also been described (Ersche et al. 2012b) which may be associated with a heritable familial vulnerability to drug dependence (Ersche et al. 2012a). Other studies highlight the role of inherited alterations in regulatory mechanisms of the hypothalamic-pituitary-adrenal (HPA) axis in the development of alcoholism (Sher 2006). It is also suggested that aberrant glucocorticoid modulation of

raphe-hippocampal connections in alcohol consuming adolescents may contribute to the emergence of suicidal behavior (Sher 2007).

It will be interesting to explore how relevant are these newly defined endophenotypes to the adolescent age group and to what extent do they overlap in specific individuals. This might pave the path for early targeted detection of high-risk suicidal patients and enable the utilization of individualized biological-based suicide prevention schemes.

135.2.8 Treatment and Prevention

How effective are drug prevention programs? An optimistic report comes from the Office of Applied Studies, a branch of the Substance Abuse and Mental Health Services Administration (SAMHSA). This report examined age-related developmental increases in rates of substance use among different cohorts of American youths aged 12–17 from year 2002 to 2008. It also compared overall levels of use across different cohorts. As expected, the lifetime prevalence of use of alcohol and marijuana within a cohort increased with rising age. But although in all of the cohorts the prevalence rate by the age of 17 year was more than 60 % for alcohol and over 30 % for marijuana, logistic regression model results showed that adolescents in later cohorts (e.g., those aged 17 in 2008) were significantly less likely to use these substances compared with youths in earlier cohorts (e.g., those aged 17 in 2002 (SAMHSA 2013)). The lower rates of lifetime use of alcohol and marijuana in later cohorts of youths compared with earlier cohorts provide encouraging news for professionals working in substance abuse prevention. This is relevant to global initiatives as well since the decrease in substance use prevalence may be a global- rather than local-scale trend. Data from a recent Australian study encompassing approximately 20,000 school-aged adolescents has shown that the proportion of students reporting past-year cannabis use has halved from 32 % in 1996 to 14 % in 2005 (Roxburgh et al. 2010). Other reports from several European countries display a similar trend although with a less dramatic decrease in cannabis use prevalence (−10 % between 1999 and 2009) (Molinaro et al. 2011).

Despite this reassuring trend in substance use prevalence in the last decade, youth perception of drug prevention efforts is not encouraging. Between the early 2000s and 2011, the percentages of adolescents reporting recent exposure to drug or alcohol-use prevention messages through media and school sources remained relatively stable or displayed a modest decline (NSDUH 2013). Also, in 2011, 40 % of adolescents reported that they did not talk with their parents about the dangers of substance use, and 25 % did not receive prevention messages through media or school sources (NSDUH 2013). In a study spanning several sociodemographic groups in the USA of the attitudes and beliefs about adolescent suicide held by adolescents and their parents, both identified adolescent suicide as a major problem but did not recognize it as a problem in their own community (Schwartz et al. 2010).

Efforts should also be directed to improve available treatment options since data from recent US surveys display dismal reports of severe undertreatment of adolescent illicit drug and alcohol-use problems particularly in specialized centers. A national survey of American adolescents aged 12–17 conducted in 2011 reported that 1.2 million adolescent were in need for treatment for an illicit drug use problem and 978,000 youths needed treatment for an alcohol-use problem. Of these, only 125,000 (10.5 %) received treatment for drug abuse and only 63,000 (6.4 %) for alcohol abuse at a specialty facility (NSDUH 2012a). These statistics are presumed to be even worse in many other countries due to stigma, underdiagnosis, and shortage of relevant clinical facilities.

The Cannabis Youth Treatment (CYT) study, which is the largest psychosocial outpatient treatment trial to date completed in adolescents with SUD (Dennis et al. 2002), compared five promising treatment strategies. The study found that in terms of efficacy and cost-effectiveness, the use of five sessions of Motivational Enhancement Therapy plus Cognitive Behavioral Therapy (MET/CBT5) is the most promising regimen under randomized field trial conditions in treating SUD, at least as an initial treatment effort (Dennis et al. 2004). Translating this evidence-based therapy into community-based settings is not a simple task (Riley et al. 2008), but may very well prove to be effective (Ramchand et al. 2011). For a comprehensive review of further substance abuse-related treatment and prevention strategies, see Toumbourou et al. (2007). However, the CYT as well as other SUD-treatment studies do not provide an answer to the question whether SUD-targeted treatments have a suicide-lowering effect at all. Although some reports imply that this may be true for youth with comorbid depression (Emslie et al. 2010; Goldstein et al. 2009), addressing this question demands a prospective study sufficiently powered to capture these relatively infrequent events.

Suicide prevention programs and treatment strategies are also abundant, and a multidimensional approach is generally encouraged although hard to be implemented using evidence-based approaches (Mann et al. 2005). A major challenge to be overcome for the successful implementation of prevention and treatment strategies stems from the fact that most suicidal adolescents do not reach for help prior to their suicidal acts. Only 14 % of young people in the UK who completed suicide were in contact with mental health services in the year prior to their death, incidentally, 71 % of these reported concomitant substance abuse (Windfuhr et al. 2008). Also, in a case-control study on the utilization of health-care services among Canadian adolescents aged 11–18 years prior to completed suicide, Renaud et al. described that although 95 % of suicide completers suffered from mental disorders, over two-thirds of them had no treatment contact within the month prior to the act, while only 12.7 % were in contact with psychiatric services during that same period (Renaud et al. 2009). Psychoeducational suicide prevention programs have generally shown to positively affect knowledge and certain attitudes concerning suicide (Kalafat and Elias 1994; Portzky and van 2006) although a paucity of large-scale controlled trials limits a clear-cut conclusion regarding their efficacy. Other prevention strategies such as

screening efforts, gatekeepers training, means restriction, and others have also been described (Bursztein and Apter 2009), and their usefulness reviewed elsewhere (Hawton et al. 2012).

The exposure of youth to various suicidal behaviors through the media (newspapers, television, and Internet) may carry a substantial impact on suicidality prevalence which should not be underestimated (Dunlop et al. 2011; Gould and Shaffer 1986; Niederkrotenthaler et al. 2010; Shoval et al. 2005). Despite that, media sources and particularly Internet sites may also lend real-time, confidential, and easy-to-access sources for suicidality counseling and support and provide an accessible route for treatment referral.

135.3 Conclusion

Although the act of completed suicide is extremely hard to predict, many risk factors have been well established and studied. Efforts to further maximize the accurate assessment of high-risk individuals based on these should be encouraged. Reducing suicide attempts in these individuals remains a challenge since it is not yet clear to what extent eliminating the associated risk factors will in effect result in the reduction of the risk for suicidal behaviors. In this context, efforts to strengthen anti-suicidal resiliency (Borowsky et al. 2001; Forman and Kalafat 1998) through local or national initiatives (McNamara 2013) have gathered interest, although their effectiveness remains to be proven.

It is apparent that both suicidality and SUD are highly prevalent in the young population and that both carry an increased risk for morbidity and mortality, increasing with older age. The counter-effect of these two complex behavioral states on each other increases the risk for suicidal behavior in adolescents with SUD as opposed to those without. This may largely be due to the fact that both are associated with decreased inhibition and increased impulsivity that lead to impaired decision making manifested in risk-taking and reckless behaviors. In the proximal time scale, co-occurring SUD may facilitate the transition of ideation to action, whereas in the distal time scale, it may contribute to increased stress by adversely affecting the adolescent's environment and circumstances (Esposito-Smythers and Spirito 2004).

The ongoing efforts of large-scale initiatives that monitor teenage substance use trends and suicidality should also be supported. Relevant data gathered from these facilitate the analysis of global as well as local trends in substance use and their correlation with suicidality. Future clinical studies should follow these changes in temporal trends to provide rapid and relevant reports of the usefulness of prevention efforts utilized. To date, available treatment options only partially rely on evidenced-based knowledge due to a lack of studies on the one hand and methodological difficulties on the other. Carefully planned large-scale prospective studies are in need to provide a stronger evidence base for assessing clinical benefits of prevention and treatment plans. A major goal for basic science research remains to locate a low-cost, minimally invasive, and highly specific endophenotype marker

for suicide. Such a marker may be more pronounced or relevant in adolescents with SUD due to the strong association between the two phenomena.

The prevention of suicide in youth and children has become one of the most challenging goals of health systems worldwide. In defined high-risk populations such as the LGBs, efforts for early detection must be increased by the health system, and careful evaluation of suicidality should be made based on validated assessment scales and established risk factors while avoiding stigmatization. Wide gaps appear between therapeutic strategies in different countries and even within countries. This may reflect the paucity of evidence-based proven efficacy of current therapies targeted either for SUD or suicidality. The association between SUD and adolescent suicidality is highly influenced by other psychiatric comorbidities, primarily but not exclusively mood disorders, which are most prevalent among these patients and confer an increased risk for additional psychopathology and completed suicide. SUD patients with suicidal behaviors are increasingly diagnosed as suffering from "dual diagnosis" without a concomitant referral to specialized treatment facilities. Regretfully, in most countries, the therapy for SUD is not part of the "mainstream" psychiatric health system, and this artificial dichotomy most probably hampers the integrative treatment effort which suicidal adolescents and their families require. We propose that for these patients, a holistic treatment approach is needed to be implemented in specialty facilities. SUD as well as other psychiatric comorbidities and emergent suicidal behaviors should be addressed concurrently because a mutual effective connection between these conditions, although not yet well understood, is most evident.

Acknowledgment We would like to thank Prof. Abraham Weizman for reading the manuscript and for his wise and enlightening comments and suggestions.

Contents

Abstract

This chapter presents an overview of international research into the risk and protective factors, developmental course, and long-term consequences of adolescent substance use within a contextual developmental framework informed by Family Interactional Theory (FIT). According to this theory, adolescent substance use is best understood as determined by a multitude of risk factors in different developmental contexts (i.e., individual, micro- and macro-contextual).

The chapter also describes how the developmental pathways to adolescent substance use can be modified by protective factors, which have the ability to mitigate the impact of risk factors on adolescent substance use and abuse. FIT focuses on the role the parent-adolescent relationship, especially a non-conflictual mutual attachment relationship, plays in insulating children and adolescents against risk factors for substance use and abuse. The chapter also presents approaches to the prevention of adolescent substance use. In addition, the chapter emphasizes the importance of relevant and appropriate cultural and developmental factors in prevention. Directions for future research are presented.

136.1 Introduction

In the following, we present an overview of the etiology, developmental course, and long-term consequences of adolescent substance use within a contextual developmental framework (Brook et al. 1990). Our research and that of others indicate that adolescent substance use is a complex phenomenon that is best understood as determined by a multitude of factors at different levels of development (i.e., individual, micro- and macro-contextual; e.g., Bronfenbrenner 1979). In addition, some of the precursors of adolescent drug use may be mitigated by later events and circumstances. These developmental pathways and mechanisms are reflected in Family Interactional Theory (see below), a developmental framework for understanding some of the determinants of substance use and abuse.

136.1.1 Theoretical Orientation

Several theories (e.g., FIT, Brook et al. 1990; Fagan and Hawkins 2013; Farrington and Loeber 2013) emphasize the importance of examining multiple predictors of deviance and highlight the significance of viewing substance use from a developmental perspective. For instance, individual risk factors and risk factors in the family setting such as a distant parent-child attachment relation and low monitoring are especially significant in the early years (Moffit 1993). At a later stage of development, in late childhood and adolescence, the peer group and school take on added significance. During middle and late adolescence, community factors play a greater role (Farrington 2003). Consequently, as noted by Brook and colleagues (2006d) and Fagan et al. (2011), the factors that lead to drug use may differ depending on the individual's stage of development. Finally, some risk factors such as the family bond and ego integration are of significance at each of the stages of development.

As noted by Fagan and Hawkins (2013), the most significant targets for intervention include risk factors and protective factors noted in theories of criminology and substance use (Fagan and Hawkins 2013) and found in longitudinal studies of substance use (Farrington and Loeber 2013).

Family Interactional Theory (Brook et al. 1990) is a multidimensional conceptual model, which postulates that the development of substance use over time is best explained by a sequence of influences from multiple individual-level and contextual domains. The primary developmental context is the family of origin, including parental personal attributes and attitudes (e.g., psychopathology), parental behaviors (e.g., substance use), parental child-rearing behaviors, and the quality of the parent-child relationship as well as the quality of the marital relationship. The familial context helps shape the most proximal influence on adolescent substance use, namely, the adolescent's personal attributes, including personality, attitudes, and behaviors. Personal attributes, in turn, influence the adolescent's choice of peer affiliations. Both personal attributes and peer affiliations are directly related to substance use. Adolescents who have personalities characterized by emotional under-control, who endorse more unconventional attitudes, and who experience high levels of affective distress are more likely to use drugs, as are adolescents who affiliate with deviant peers.

The cornerstone of FIT, which incorporates elements of attachment theory and social learning theory, is the parent-child mutual attachment relationship, as it operates at the center of other psychosocial domains which are related to adolescents' substance use. Attachment mediates other familial and contextual dimensions and serves as a major buffer for risk conditions. FIT also describes intervening mechanisms, which can modify the relationships between risk and protective factors and substance use. Thus, FIT describes the major pathways to substance use from childhood to adulthood and explains variations in these pathways. Finally, FIT focuses on the interaction of risk and protective factors as noted below.

136.1.2 Interaction of Risk and Protective Factors

Risk factors include factors that are antecedent or concomitant to substance use and increase the probability of adolescent substance use. Such risk factors include attributes of the individual, family, peer group, school, and community. Protective factors, on the other hand, reduce the risk of adolescent substance use and abuse. Protective factors exist at the community level (e.g., community rewards for prosocial involvement), family level (e.g., family attachments), school level (e.g., school rewards for prosocial involvement) (Briney et al. 2012; Brook et al. 2008), and personality level (e.g., ego integration). Besides having a linear negative relationship with substance use, protective factors can also offset risk factors or enhance other protective factors. In the first type of interaction (risk/protective), risks are attenuated by protective factors by buffering individuals against the pathogenic influences of risk factors. For example, among ethnic and racial minority youth, having a strong ethnic identity may mitigate the influence of risk factors for substance use (e.g., from substance-using peers) (Pahl and Brook 2004). The second type of interaction (protective/protective) is a synergistic process, in which one protective factor strengthens another, so that the combined effect of both protective factors is greater than their sum.

136.1.3 Developmental Course of Substance Use

Research conducted in the past decade has identified developmental patterns of substance use in the form of differential longitudinal trajectories from adolescence into adulthood using such methods as growth mixture modeling and cluster analysis (e.g., Brook et al. 2006a; Chassin et al. 2008; Costello et al. 2008; Flory et al. 2004; King and Chassin 2007; Orlando et al. 2004; Schulenberg et al. 2005; Windle and Wiesner 2004). These studies have found different classes of substance users characterized by different rates and levels of substance use over time. Varying by substance (i.e., tobacco, alcohol, marijuana), research has identified between three and six different trajectories of substance use. For example, studies of tobacco use typically find a group of low or nonusers, an early-starting group of continuous heavy smokers, and a group of quitters (e.g., Chassin et al. 2008; Orlando et al. 2004). Some also find late starters (e.g., Brook et al. 2006b) and/or increasers (e.g., Pahl et al. 2011). Trajectories of substance use can be used to predict long-term outcomes and thus provide information about the consequences of specific developmental patterns of use over time (e.g., of early-onset heavy use versus moderate use).

Recent work has also identified trajectories of the co-occurrence of tobacco and marijuana use and psychological outcomes (e.g., Brook et al. 2012a). Other papers have looked at the co-occurrence of substance use with psychological symptoms (e.g., Otten et al. 2010; Pahl et al. 2013) and other adverse outcomes (e.g., victimization; Pahl et al. 2013). These studies have the advantage of mapping the occurrence of use of two or more substances and/or other outcomes over time, thus highlighting patterns of dual and polysubstance use and the joint developmental patterns of substance use with other risk outcomes. These studies can identify groups of high-risk individuals and help predict membership in such a group from earlier risk factors, which provides important information for both prevention and treatment.

Research supports the stability of substance use from adolescence to young adulthood. Stability in substance use has been documented for alcohol use (Flory et al. 2004), tobacco use (Palmer et al. 2009), and the use of illegal drugs (Bachman et al. 1984). Several researchers (Brook et al. 2007; Flory et al. 2004; Roche et al. 2008) have found that early-onset substance use is highly related to later substance abuse (Brook et al. 2007; Flory et al. 2004). Jenkins and colleagues (2011) reported that early-onset alcohol use is correlated with vulnerability to later alcohol abuse as well as dependence. Nevertheless, it is important to note that adolescents who use drugs do not necessarily become addicted to drugs (Frisher et al. 2007). There is also evidence that adolescents who use legal drugs are more likely to use marijuana at a later point in time, as well as become dependent on illegal drugs (Brook et al. 1999, 2007). For example, Lessem et al. (2006) reported that adolescent marijuana use is associated with the use of other illegal drugs at a later point in time. Studies conducted internationally have also found that adolescents' use of legal drugs generally precedes the use of illegal drugs (e.g., Patrick et al. 2009). Agrawal et al. (2013) also report that tobacco use often precedes the use of other substances.

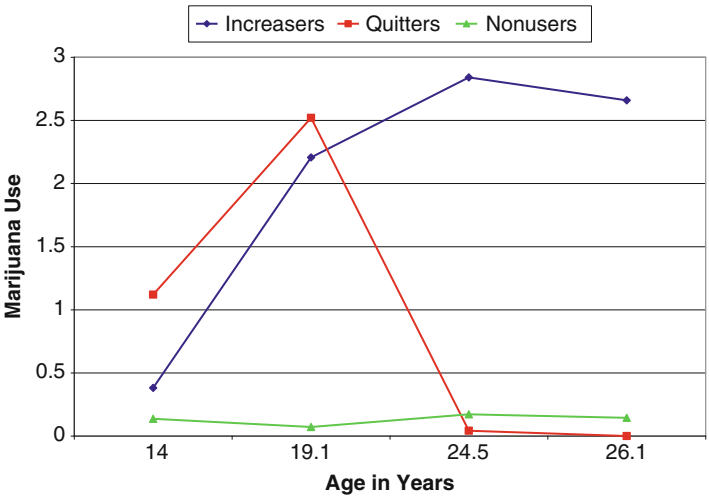

Fig. 136.1 Trajectories of Marijuana Use for African American and Puerto Rican Women (N=474)

136.1.4 Consequences of Substance Use and Abuse

Substance abuse in adolescence is a serious health concern as it is related to underachievement at school, delinquency, adolescent pregnancy, sexually transmitted diseases, psychiatric morbidity, physical health conditions, and dysfunction in the family (Greenblatt and Gfroerer 1994). The harm to society as a consequence of adolescent substance abuse includes costs related to the criminal justice system and increased costs of health care. There is also ample evidence from international studies that the use of substances is related to these adverse outcomes (e.g., Pluddemann et al. 2008) and to violence and unintentional and intentional injuries (e.g., Peltzer and Pengpid 2012; Rudatsikira et al. 2007). The use of substances during adolescence is also associated with poorer educational attainment, in terms of the completion of a degree or college attendance in young adulthood (King et al. 2006).

In a recent longitudinal study, Pahl et al. (2011) examined the developmental patterns of marijuana use and their relationship with subsequent psychological adjustment in a community-based sample of urban African-American and Puerto Rican women. They identified three trajectories of marijuana use among these females (see Fig. 136.1).

The findings the indicated that high-frequency marijuana use over time among females was related to greater psychopathology as reflected in higher scores on indicators of psychological maladjustment (e.g., anxiety, depression). Marijuana use should thus be considered a risk factor for the development of psychological distress. In treating marijuana users with such a pattern of long-term, high-frequency use, practitioners should be aware of the adverse effects on

psychological adjustment. Similarly, prevention programs should focus on the long-term psychological cost associated with marijuana use, noting that the best psychological health is reported by those who abstain from the drug.

136.2 Summary of Risk Factors for Substance Use

136.2.1 Demographic Risk Factors for Adolescent Substance Use

136.2.1.1 Male Gender

Gender differences in substances use are evident in legal and illegal drug use (Johnston et al. 2012a). In the United States, adolescent males tend to report greater use of alcohol and illicit drugs, particularly frequent use (Johnston et al. 2012a). For example, males report higher rates of heavy drinking. Among US teens, tobacco use is approximately equal between boys and girls though boys tend to smoke more than girls as they get older. For example, in 2012, among 12th-graders, the 30-day prevalence of tobacco use was 19 % for males and 14.5 % for females (Johnston et al. 2012b).

Gender differences in substance use vary by country and cultural subgroups, depending on the prevalent cultural and gender norms. For example, in South Africa, males smoke more than females. This gender difference is particularly strong among Black adolescents. There are strong cultural taboos against smoking for South African women (Steyn et al. 2002), which seem to result in lower levels of cigarette use (Marks et al. 2001; Steyn et al. 2002).

136.2.1.2 Low Parental Income/Socioeconomic Status (SES) and Education

Some recent research has found that adolescents from higher socioeconomic groups may be more likely to engage in drug use during early adulthood, although these results were not true for all ethnic groups or for the use of all drugs (e.g., Humensky 2010; Ritterman et al. 2009). In a longitudinal study conducted among adolescents in Mexico, Bojorquez et al. (2010) found that the father's lower level of education was associated with more drug use initiation. In another study conducted in Mexico, Ritterman et al. (2009) found that higher SES adolescents were more likely to report tobacco and alcohol use, but no more likely to report illicit drug use. The increased disposable income that permits easier access to drugs is often cited as a reason for these findings. Indeed, Hanson and Chen (2007) found that higher financial resources were more strongly associated with substance use than social status.

136.2.1.3 Parental Divorce and Single Parenthood

The literature regarding parental marital status and substance use is somewhat inconsistent. Hope et al. (1998) reported that there was a weak relationship between parental divorce and substance use. In a prospective study of a birth cohort followed up until the age of 21, Hayatbakhsh et al. (2006) reported that children whose mothers changed their marital status were more likely to have used marijuana (or have a cannabis use disorder) than those whose mothers' marital status was

stable. When examining the effect of marital status on children, it is important to take into account a number of factors such as the mothers' and fathers' relationships with their offspring, the age when the separation occurred, relations with other family members, and so on. Clearly, further research is needed to gain an understanding of the effect of marital status on the offspring's substance use.

Single parenthood has also been examined as a predictor of adolescent substance use, with the results varying by parental gender (Eitle 2006). Some studies suggest that adolescents who are raised only by a mother may be more likely to engage in drug use due to reduced socioeconomic resources and less monitoring (Amato 2000; McLanahan and Sandefur 1994). However, one study found that the risks for alcohol use are higher for children living only with a father (Eitle 2006). The results for the use of other drugs and those pertaining to different ethnic groups were inconsistent (Eitle 2006).

Another family structure that is more common in low- and middle-income countries is the child-headed household, or situations where children live as orphans. Evidence is emerging to show that children who are orphaned, homeless or live on the streets without parental or adult supervision are at greater risk of using substances (Meghdadpour et al. 2012).

136.2.1.4 Adolescent Employment

During adolescence, the number of hours worked per week is related to substance use (McMorris and Uggen 2000). Schulenberg et al. (2005) reported that adolescents who worked l6 h or more per week were more likely to become chronic marijuana users. It has been argued that increased work is associated with increased stress and peer associations that may increase adolescents' risk of drug involvement (Kaestner et al. 2013).

136.2.2 Personality and Psychopathology as Risk Factors for Adolescent Substance Use

136.2.2.1 Internalizing and Externalizing Behavior and Comorbidity with Substance Use Disorders

Investigators have identified two major pathways among individual predictors of addiction. The first pathway is through negative emotionality, sometimes referred to as internalizing psychopathology. The second pathway is through deviant or externalizing behavior (Krueger et al. 1998). According to Krueger et al. (1998), internalizing disorders include several disorders such as depression and anxiety. Externalizing disorders refer to antisocial behavior disorders [e.g., conduct disorder (CD), oppositional defiant disorder (ODD)]. There is also evidence of comorbidity or the co-occurrence of internalizing and externalizing disorders with SUDs. Results from the Dunedin Birth Cohort Study (Anderson et al. 1987) showed that over one quarter of the adolescents with SUDs also experienced depression. Research has also suggested that there is comorbidity between SUDs and anxiety among adolescents, with prevalence rates of about 7 % in the Children in the

Community Study (Brook et al. 1998; Cohen and Cohen 1996). Similar results emanate from research in various parts of the globe, including South Africa (Saban et al. 2010). In China, smoking was associated with depression and anxiety as well as with hostility among adolescents in a study involving 7th and 11th graders (Weiss et al. 2008).

Brook et al. (2006c) noted that individuals following a trajectory of early-starting continuous cigarette smoking were more likely than other individuals to be classified as having experienced internalizing problems during childhood. Several investigators have found that measures assessing aspects of externalizing behaviors are related to substance use, including tobacco use, marijuana use, and cocaine use. Such dimensions of externalizing behaviors related to substance use include unconventionality (Brook et al. 1999), delinquency (Morojele and Brook 2001), and antisocial or conduct problems (Bor et al. 2010).

Several types of drug use disorders are frequently comorbid with externalizing disorders. Chan et al. (2008) reported that over three-quarters of adolescents with a substance use disorder had at least one externalizing problem. Conduct disorder has been found to both co-occur with and predict SUDs (Brook et al. 2010; Elkins et al. 2007).

136.2.2.2 Comorbidity of Substance Use Disorders with Other Psychiatric Disorders

In a longitudinal study of co-occurring psychiatric disorders and substance use, Brook et al. (1998) reported that tobacco, alcohol, and marijuana use disorders predicted high rates of antisocial personality disorder in adulthood. ADHD has also been found to be comorbid with SUDs (Brook et al. 2010). In addition, research has found comorbidity of substance use disorders with post-traumatic stress disorder and major depressive disorder in adolescent populations (Kilpatrick et al. 2003).

There are several hypotheses regarding the comorbidity of disorders. First, comorbid disorders may share causal factors. It may be that common genetic influences account for the comorbidity between disorders of addiction and externalizing behaviors. Shared underlying psychosocial factors may also play a role in explaining the comorbidity of substance use and internalizing disorders. For example, comorbidity between substance use and depression may be due in part to impulsivity (Zilberman et al. 2007), low self-control (Otten et al. 2010; Pahl et al. 2013), or lack of social support (de Graaf et al. 2004).

Second, there may be a reciprocal relationship between substance use and other psychiatric disorders. For example, alcohol use may increase the likelihood of depression and depression may lead to greater alcohol use. Finally, according to the self-medication theory (Khantzian 2012), substance use is preceded by other psychiatric disorders.

It is most likely that the complex interplay of genetic predispositions and environmental influences ultimately leads to both substance use disorders and internalizing disorders. According to Tsuang and colleagues (2012), "[. . .] psychosocial and environmental factors interact with genetic predispositions toward internalizing and addictive pathology, influencing the neurobiology and neurochemistry

of affected individuals" (p. 152). Future longitudinal research should attempt to disentangle the mechanisms that operate between the addictive diseases and other forms of psychopathology.

136.2.2.3 Other Personal Risk Factors

Additional personal characteristics that are often associated with substance use among adolescents include various personality attributes such as low self-esteem and low religiosity. Although much research suggests that adolescents with lower self-esteem are more inclined to use substances, the association between self-esteem and substance use is complex and dependent on the substance of interest (e.g., Wild et al. 2004). Wild et al. (2004) found among Grade 8 and 11 students in a study in Cape Town, South Africa, that self-esteem within the family and school domains were particularly important. A study with adolescents in six countries across Europe found no significant association between self-esteem and substance use (Kokkevi et al. 2007).

The more involved in religious activities, the less likely adolescents are to use substances (e.g., Miller et al. 2000). Religiosity has also been found to be negatively associated with drunkenness among adolescents in a study conducted in Cape Town, South Africa (Parry et al. 2004). However, these effects are not consistently found and may be a function of factors such as ethnicity, as found in a study among adolescents in Russia (Pokhrel et al. 2011), or gender, as found in a study in Hungary (Piko and Fitzpatrick 2004). Other personality traits related to substance abuse include sensation seeking (Cloninger et al. 1988) and poor planning (Clark et al. 2005). Behavioral problems that predict drug use include physical aggression (Unger et al. 2003), bullying (Farrington et al. 2011), and early sexual involvement (Hallfors et al. 2002).

136.2.3 Familial and Peer Risk Factors for Adolescent Substance Use

136.2.3.1 Familial Substance Use

Familial substance use is another risk factor for adolescent substance use and abuse. In a longitudinal study about the effects of parental smoking, occupation, and education on offspring tobacco use in adulthood, Fagan et al. (2005) found that parental smoking, blue-collar occupational status, and low parental educational achievement were related to smoking among adult offspring. Findings imply that parental smoking is important to consider in the establishment of prevention and intervention programs. Results suggest that the parent-child bond serves to intervene between parental smoking, educational and occupational status, and offspring smoking (see Fig. 136.2).

In a series of papers, Chassin and colleagues (2002; King and Chassin 2007) reported that the offspring of alcoholics studied from childhood to young adulthood were far more likely to be binge drinkers or have an alcohol use disorder than those of nonalcoholics. Maternal substance use has also been found to be related to adolescent

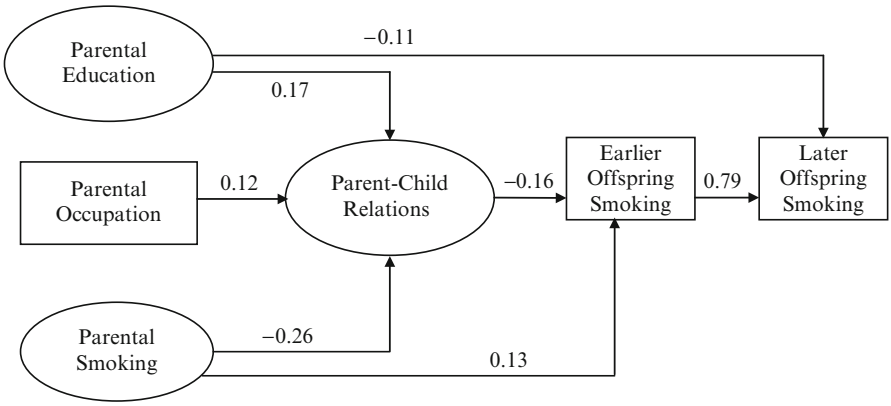

Fig. 136.2 Structural equation model predicting offspring smoking in late twenties (T5) from parental education, occupation, smoking, and child-rearing variables. All coefficients are statistically significant $p < .01$

substance use (Buu et al. 2009). A family history of substance misuse is also associated with increased adolescent alcohol consumption (Moore et al. 2010). When both parents use substances, there is an increased likelihood that the offspring will also use substances. Brook and colleagues (2006a) have emphasized the need to examine the mediators and moderators of the association between parental and adolescent substance use. For instance, Maalouf (2010) reported that parental substance use was associated with the parent-offspring relationship, which, in turn, was related to the offspring's substance use. There is also evidence that siblings play an important role in the adolescents' drug use (Boyle et al. 2001; Brook 1991).

136.2.3.2 Family Relations

Family conflict, whether between the parent and partner or parent and offspring, is related to adolescent substance use (Madu and Matla 2003; Caballero et al. 2010; Madruga et al. 2012) and dependence on alcohol and drugs (Chen et al. 2005; Morojele and Brook 2001; Zhou et al. 2006). In terms of protective factors, four dimensions of parenting practices have been identified as important in lessening the risk of adolescent substance use: (1) a close mutual attachment relationship between parent and child, (2) parent-child communication, (3) parental monitoring, and (4) effective role modeling. A warm, close mutual parent-child attachment relationship insulates the child and adolescent from drug use (Brook et al. 1990). It is important to establish a close parent-child mutual attachment relationship early on in order to reduce the risk of substance use in the offspring (Brook et al. 2009). Lack of family support or bonding has been found to predict legal and illegal drug use (Brook et al. 1990; King and Chassin 2004). Family support also moderates the relationship between adolescents' personality attributes and their substance use (Engels and Willemsen 2004).

Parental monitoring is also important, as it enables the parent to supervise the child's behavior more generally and his/her drug use more specifically.

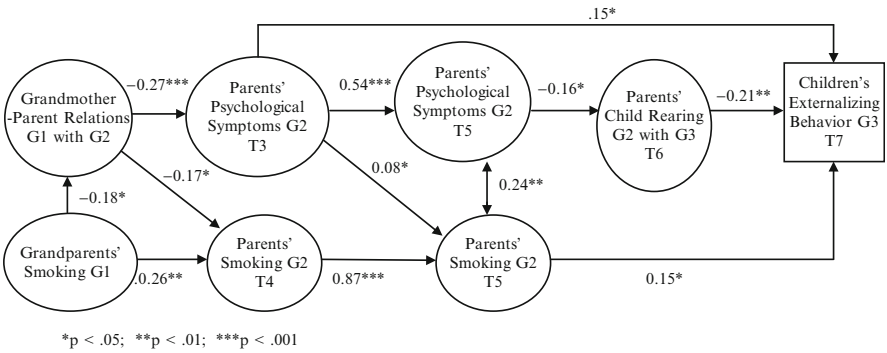

Fig. 136.3 Transgenerational transmission of risk factors for externalizing behavior. Structural equation model: standardized pathways (z statistic) to children's externalizing behaviors ($N = 230$). *$p < 0.05$; **$p < 0.01$; ***$p < 0.001$. T = Time

For instance, parental monitoring was related to a decreased risk of alcohol dependence (Guo et al. 2001) and of tobacco and alcohol use (Amoateng et al. 2006). Parental role modeling in the context of a close parent-child attachment is also critical for children's health behaviors. If the parent abstains from drug use and the adolescent identifies with the parent, the adolescent is less likely to use drugs.

The risks associated with parental substance use can also be transmitted across generations (Brook et al. 2012c). Based on Family Interactional Theory (FIT), Brook and colleagues (2012b) conducted a longitudinal study and examined the grandmother's (G1) relationship with her child (G2) and the association between the grandparents' smoking and the grandchild's (G3; mean age 11 years) externalizing behavior (see Fig. 136.3). The findings showed that a weaker G1-G2 attachment relationship and the grandparents' smoking were linked with externalizing behavior in the G3 child via G2 psychological symptoms (e.g., depression and anxiety), G2 smoking, and G2-G3 child-rearing practices.

136.2.3.3 Peer Risks

Peer substance use and peer encouragement of substance use are consistently the strongest predictors of adolescent substance use in all ethnic groups (Brook et al. 1990; Hussong 2002; Kandel 1996). Some research has found that the degree to which peers' substance use influences adolescents' own substance use varies by ethnicity. Unger and colleagues (2001), for example, found that the influence of friends' smoking on adolescents' smoking was stronger among White adolescents than among Pacific Islanders, African Americans, and Latinos.

The relationship between peers' substance use and that of adolescents themselves is reciprocal. On the one hand, adolescents' substance use may be influenced by that of their friends. On the other, adolescent drug users are more likely to choose friends who use drugs as well (assortative peer selection; Kandel 1996). Peer norms favoring drug use are also of importance. If adolescents think that the majority of adolescents their age use drugs, they are more likely to use

drugs. Consequently, drug prevention efforts can use this "perception bias" by providing adolescents with valid information about the number of adolescents who use drugs. More generally, associating with deviant and delinquent peers is a risk factor for adolescent substance use (Fergusson et al. 2002).

136.2.4 Environmental Risk Factors for Adolescent Substance Use

136.2.4.1 Exposure to Violence and Trauma

Another important risk factor for adolescent substance use is exposure to violence and trauma, including contextual violence (e.g., Brook et al. 2003a), violent victimization (e.g., Boynton-Jarrett et al. 2008), and childhood maltreatment and/or sexual abuse (e.g., Anda et al. 2006; Fergusson et al. 2013). Violent victimization is frequently associated with substance use and abuse (Boynton-Jarrett et al. 2008; Kilpatrick et al. 2000; Schneider et al. 2011). Fergusson et al. (2002) found that sexual abuse during childhood was associated with dependence on alcohol and illicit drugs. People who have been victimized may use drugs to ameliorate the painful psychological consequences of victimization, and in part, to self-medicate symptoms of post-traumatic stress disorder (Anda et al. 2006; Boynton-Jarrett et al. 2008).

136.2.4.2 Neighborhood Risks

Neighborhood factors influence adolescent substance use both directly and indirectly (Chuang et al. 2005). Neighborhood characteristics which have a direct effect include the availability and offering of substances to adolescents (Crum et al. 1996) and the lack of informal social controls (Sampson 1992). In addition, living in a neighborhood characterized by drug abuse, unemployment, crime, and unresponsive police is psychologically distressing, and adolescents may drink and use drugs to regulate their anxiety and depression (Hill and Angel 2005). Buu (2009) reported that neighborhood instability was linked with the development of substance use and child psychopathology. Brook et al. (2011) found that environmental stressors were associated indirectly (by being mediated by individual stressors) and directly with tobacco and alcohol use among adolescents in South Africa. Living in disadvantaged neighborhoods also affects adolescent substance use via the family and peer contexts. However, Chuang and colleagues (2005) found that residing in a low-SES neighborhood was associated with increased parental monitoring and less tobacco use. It was also associated with increased peer drinking and increased adolescent alcohol use (Chuang et al. 2005).

136.2.4.3 School Risk Factors

Like neighborhood effects, the influence of school contexts on adolescents' substance use problems is both direct and indirect. For example, lack of enforcement of rules and low levels of school safety are directly related to students' substance use

(e.g., Reid et al. 2006). Mediating variables include the quality of the social networks (Mason 2010) and violent victimization (Reid et al. 2006). One school-related risk factor that is directly associated with substance use is academic adjustment (Ljubotina et al. 2004). In a cross-sectional study conducted among adolescents in Hungary, Piko and Kovacs et al. (2010) found that lower academic performance was associated with the use of legal drugs (tobacco use and binge drinking) and low school satisfaction and less communication with teachers about the use of illegal drugs. In another cross-sectional study conducted in Switzerland, Stronski et al. (2000) also found that better academic performance was associated with nonprogression to illicit drug use among adolescents.

In addition, a sense of belonging to one's school seems to act as a protective factor against substance use and abuse (Bond et al. 2007; Napoli et al. 2003; Rostosky et al. 2003). For example, Napoli and colleagues (2003) found that among Native American youth, a sense of belonging to their school was associated with lower levels of substance use.

136.2.4.4 Cultural Risk Factors

Numerous cultural factors can have an impact on adolescents' use of drugs, including levels of acculturation (Luengo et al. 2008), acculturative stress (Buchanan and Smokowski 2009), and cultural values (Soto et al. 2011). In the United States, it is generally found that among youth from immigrant families, those who are US-born and those who have lived in the United States longer use more substances than foreign-born adolescents and those who have lived in the United States for a shorter period of time (Epstein et al. 2001; Gfroerer and Tan 2003). However, this does not necessarily seem to be the case in other countries. An Israeli study compared adolescents who were born in the former Soviet Union to those born in Israel in terms of substance use (Isralowitz and Reznik 2007). The study found higher rates of binge drinking, current drinking, and ecstasy use among adolescents who were foreign-born.

Brook et al. (2003b) studied marijuana use in a cohort of Colombian youths and found that there was a relationship between earlier adolescent marijuana use and later adolescent problem behavior in a society in which drug use, crime, and violence were pervasive.

The direction and strength of the associations between acculturation and substance use thus vary depending on the context, as well as on the type of acculturation strategy adopted by the adolescent. Chédebois et al. (2009) found that three acculturation orientations (i.e., individualism, integration, and assimilation) were negatively associated with cannabis use among adolescents in France who had one (or more) parents who were foreign. The association between acculturative stress and substance use has been found to be mediated longitudinally by family relationships, internalizing and externalizing problems, and associations with deviant peers (e.g., Buchanan and Smokowski 2009) among Latino adolescents.

136.2.5 Gaps in the Literature: Future Directions for Research

136.2.5.1 Life-Course Perspective

In the past, research has focused on the period of adolescence in order to prevent substance use initiation or thwart its escalation, once begun. Despite the value of this approach, it does not take into account the long-term vicissitudes of substance use, i.e., the changing patterns of substance use over time, such as distinct trajectories of late starters, escalators, those who quit, or those who move into and out of substance use throughout the life course. Therefore, it would be important to study *within*-individual changes in risk and protective factors as related to *within*-individual changes in substance use and psychopathology at various developmental stages. A greater understanding of the longitudinal and concurrent risk and protective factors for substance use from several domains (the individual's personality, neurobiological factors, the family, the peer group, and contextual influences), and their interrelationships, should prove invaluable to informing both the content and the timing of prevention and intervention programs.

136.2.5.2 Multigenerational Studies

Multigenerational studies can also shed light on the etiology of substance use, psychopathology, and problem behaviors. A vulnerability to substance use may be transmitted via the adverse effects of parental substance use on parenting abilities, which, in turn, are linked with personality attributes in the child that are conducive to substance use (e.g., externalizing behaviors, low self-esteem). Further investigation of the specific mechanisms involved in the intergenerational transmission of substance use could help inform prevention programs.

136.2.5.3 Consequences of Adolescent and Young Adult Substance Use

Future research should continue to examine developmental trajectories (including comorbid trajectories) of adolescent substance use in relationship to key predictors and outcomes. Of particular interest are the following areas of functioning, which should be studied in conjunction with substance use histories: future research should examine a broad range of psychiatric diagnoses, including personality, mood and anxiety disorders, and impulse control disorders (e.g., pathological gambling), as outcomes of substance use trajectories in emerging adults and adults.

In sum, the identification of the consequences of persistence and cessation of substance use over this span of the life course will provide information crucial to the development and timing of intervention programs for substance-using adolescents and young adults. Understanding these relationships can help to clarify and validate theoretical models and may enhance efforts at prevention and treatment intervention.

136.2.5.4 Electronic Media

Technology has been advancing rapidly, and adolescents are becoming increasingly dependent on a multitude of media applications (especially social media sites such

as Facebook and Twitter) and devices (i.e., computers, tablets, and cell phones), as well as gaming systems (e.g., Xbox). A recent study in the United States found that on average, youth aged 8–18 years spend over 7 1/2 hours using entertainment media per day (Lamontagne 2010). Much of this time is spent using more than one electronic medium at a time, thus resulting in adolescents consuming an actual 10 hours and 45 minutes worth of media content each day. In addition, social media sites have become a means by which bullying behavior occurs among youth. Future research should examine the relationship between compulsive electronic media use and emotional and behavioral problems as well as a variety of addictive disorders.

136.2.5.5 Neurobiological and Genetic Effects

In recent years, technological advances (e.g., PET scans, *f*MRI) have contributed to a greater understanding of basic neurobiology, in general, and the effects of various substances on the brain, in particular. The findings of most gene-environment studies suggest that both genes and the environment, in combination or in interaction, play a role in addiction (Gelernter and Kranzler 2008). The study of gene x environment interactions has the potential to provide important implications for research and clinical practice. Increased knowledge resulting from such work may help geneticists better understand endophenotypes related to specific behavioral disorders, such as substance use. Genetic effects may be found to express themselves only under specific environmental risk conditions. Therefore, it is important to study epigenetic and genetic effects in adolescents exposed to certain psychosocial risk factors. Such work may yield information on the interrelation of genetic and environmental factors and substance use and dependence. Such research may also identify specific genetic factors which protect against psychosocial risk factors or which increase susceptibility to substance use. Studies of behavioral risk factors in connection with genetic studies may enhance understanding of the conditions under which psychosocial risk factors may result in the development of substance use and dependence in some, but not all, adolescents during the course of development.

Future studies should contribute to greater knowledge of the role of genetic factors in individual differences in sensitivity and exposure to environmental influences (e.g., Lynskey et al. 2002). Such knowledge is of great importance to help us understand vulnerabilities to addiction and the crucial role of gene/environment interactions in risk and protective processes (e.g., whether certain psychosocial factors may offset specific genetic predispositions to tobacco and drug abuse/dependence). Such work will contribute to the design and implementation of both prevention and treatment programs.

136.2.6 Implications for Prevention

136.2.6.1 Universal Prevention

Because of its biopsychosocial nature, the prevention of substance abuse must take place on several levels. Substance abuse is the phenotypic expression of the

interactions of a genetic predisposition(s) (genotype), psychosocial risk factors, and the psychopharmacological effects of the drugs used or abused. Also, other as yet poorly known factors, such as receptor activity, may play a role in the expression of substance abuse. As discussed above, the psychosocial aspects of substance abuse are rooted in the family, but also are located in the interactions and groups which individuals encounter, and the environments in which they spend their time during the course of growth and development.

Prevention must therefore begin in the family, preferably as early as possible. Families at risk may be identified by examination of several factors. These include (1) a family history of substance abuse, (2) the nature of the mutual parent-child interaction, (3) aspects of the marital or partner interactions, (4) the presence of comorbid psychiatric disorders or medical illnesses, (5) the presence of parental or familial psychopathology, (6) socioeconomic and cultural factors, and (7) aspects of the peer and sibling attributes and interactions.

Within the family, prevention may include (1) the provision of appropriate prenatal care; (2) parenting classes, especially for those families at risk; (3) marital counseling; (4) the treatment of psychiatric disorders or medical illnesses; (5) attempts to enhance the quality of the mutual parent-child relationship; and (6) efforts aimed at helping to improve the family's socioeconomic status.

Research has shown that some universal family-based interventions can be effective for preventing alcohol use (Foxcroft and Tsertsvadze 2011b) and the initiation of tobacco use (Thomas et al. 2008) among young people. Foxcroft and Tsertsvadze's systematic review (2011b) revealed that nine of 12 studies (with one being from the Netherlands and the remainder from the United States) showed significant positive intervention effects on various alcohol use measures among children and adolescents up to age 18 years. These interventions comprised psychosocial and educational programs that were delivered to parents and other caregivers with a view to having an effect on their children's alcohol consumption. Thomas et al.'s (2008) systematic review examined the effectiveness of interventions to prevent smoking initiation. Thomas and colleagues (2008) showed the greatest promise for family programs compared with controls but less promise when family programs were compared with school only interventions. In general, research reveals that early interventions are most effective (e.g., Carney and Myers 2012). Indeed, the 2001 United Kingdom (UK) report to the European Monitoring Centre for Drugs and Drug Addiction (EMCDDA) emphasizes the significance of drug education beginning prior to the "age of onset" (Jeffrey et al. 2002).

Preventive interventions for tobacco use among young people can also be effective when delivered at the level of the community (Carson et al. 2011). In a systematic review which included 25 studies, ten were found to demonstrate positive intervention effects for community programs, with the most successful programs involving multiple components (e.g., with school and parental involvement), being of longer duration, having flexibility to enable adaptability to different contexts, having community involvement in elements of program development and implementation, and being theory-based (Carson et al. 2011). In the neighborhood, enhancing the work of prosocial community organizations,

support of neighborhood schools, efforts to diminish neighborhood crime and violence, and support for the provision of neighborhood amenities (such as stores, sanitation services, and other community resources) are most promising. In addition, mass media interventions may be effective for tobacco prevention (Brinn et al. 2010).

At a later point in the child's development, preventive interventions should embrace treatment interventions when appropriate and acceptable to family members. Such interventions could include family counseling, group and individual psychotherapy, and family-focused meetings.

There is also some evidence that multicomponent programs can be effective (Carson et al. 2011; Foxcroft and Tsertsvadze 2011a). In their comprehensive report, Frisher et al. (2007) concluded that improving the social environment of children as well as providing support for parents will "be the most effective strategies for primary prevention of drug use" (page iv). Interventions can have preventive effects when they focus on enhancing protective factors and diminishing risk factors. The treatment of comorbid psychiatric disorders in family members is especially important. Prevention programs for children and adolescents should be developmentally, culturally, and linguistically appropriate. As ethnic identification has been found to have strong protective effects (Burrow-Sanchez and Wrona 2012), attempts at strengthening ethnic identification can play an important role in preventive efforts and in helping treatment interventions to have further preventive and protective effects.

Adolescence is a crucial time for efforts to prevent or diminish substance abuse, as the precursors of most substance abuse begin by early or mid-adolescence (Dennis and Scott 2007; Tarter 2002). Adolescence involves a number of significant biopsychosocial and maturational changes, including separation from parents, closer attachment to peers, the psychosexual changes of puberty, the development of sexuality, the development of autonomy, and the growth of interest in the choice of a vocation. Because adolescence is the most common period of onset for the use of illicit drugs (Swendsen et al. 2012), it is therefore the most opportune time to use preventive interventions to help adolescents go through this period, marked by many stressful changes, without turning to the use of illicit drugs. Such preventive programs should focus on the enhancement of protective factors as noted above, such as a strong mutual parent-child relationship, ethnic identification, the treatment of comorbid psychiatric disorders, and the encouragement of involvement with prosocial peers.

Universal prevention programs are often delivered in school settings, although evidence of the effectiveness of school-based programs is less compelling than that of interventions delivered in family and community settings. Reviews of school-based universal programs indicate that some programs can lead to reductions in the use of alcohol (Foxcroft and Tsertsvadze 2011c), tobacco (Thomas and Perera 2013), and illicit drugs (Faggiano et al. 2005) among adolescents, although certain approaches are more effective than others. For example, the life skills training approach in the United States, the social influence approach (the Unplugged program) in Europe, and a program focusing on classroom management

(known as the Good Behavior Game) in both Europe and the United States had the best evidence for reducing alcohol use (Foxcroft and Tsertsvadze 2011c). For tobacco use, certain intervention elements and approaches, namely, delivery by adults rather than by peers, and social competence and social influence-type approaches were most important. Finally, for illicit drug use, skills-based interventions have been found to be the most effective in preventing various types of drug use behaviors (Faggiano et al. 2005).

136.2.6.2 Selective Programs

Selective programs should focus on prevention among adolescents who are at high risk of developing substance use-related problems. Many of the psychosocial origins of substance abuse in adolescence often are found in family interactions, as well as in many of the groups which form during growth and development (Vakalahi 2001). Therefore, prevention of adolescent substance abuse can include a number of different prevention approaches. For example, mentoring programs among high-risk groups can be effective (Thomas et al. 2011). Thomas et al.'s (2011) review showed that mentoring programs can be particularly effective among minority and "deprived" adolescents for preventing the initiation of alcohol and other drug use.

Medications may be used to treat any underlying pathophysiological predispositions, as well as any comorbid psychiatric disorders, which are found in a large percentage of substance abusers (Compton et al. 2007; Pettinati et al. 2013). Adverse environmental and familial factors may be prevented by interventions focused on changing the risk and protective factors for substance abuse which have been discussed previously in this chapter. Group and family interventions target adverse interpersonal interactions and also seek to prevent the adverse behavioral effects of the drugs themselves with emphases on diminishing craving and fostering relapse prevention and rehabilitation. Prevention programs that combine several types of psychosocial interventions often prove to be most effective.

Adolescent substance abuse prevention can occur in a variety of settings, including outpatient programs, schools, and churches, among others. The level of care should reflect the needs of the particular adolescent and her/his specific context (e.g., peer group, family, and neighborhood). Adolescent prevention may call for repeated efforts over a long period, and the prevention approach may vary depending on the needs of the adolescent at a particular time. A general rule is the longer the adolescent remains in prevention programs, the more effective the prevention and treatment (e.g., Latimer et al. 2000). Positive prevention effects may, and hopefully will, take place, even after the termination of the specific program (Hubbard et al. 2003).

It is important in the prevention of adolescent substance abuse that prevention interventions are developmentally and culturally appropriate (Whitbeck et al. 2012). The timing of each particular intervention should be synchronized with each adolescent's particular psychosocial context, as well as with her/his stage of development. As an example, in early adolescence, it is important to intervene with the parents and the child to focus on their relationship, but in later adolescence,

interventions might focus more on peer issues or on specific adolescent issues in adolescent groups.

The importance of cultural issues in prevention cannot be overstated. Cultural variations in each psychosocial domain must be factored into prevention. Cultural differences in important domains, and in their meanings, can be found across different ethnic and racial groups. The individual conducting the prevention program must understand and respect such differences and must include them in a sensitive way in any prevention program. Different cultures may view psychosocial interventions and therapy in different ways, and awareness of such cultural issues, combined with interventions that are culturally and linguistically competent and appropriate, is important for intervention effectiveness (e.g., Whitbeck et al. 2012).

136.2.6.3 Indicated Programs

For adolescents who have already started using substances, but who do not yet meet abuse or dependence criteria, indicated programs can be implemented to halt such progression. At the individual level, individuals who are already experiencing problems can be assisted via various programs. For example, interventions with elements of motivational enhancement approaches or transtheoretical model interventions where individuals' degree of readiness to change is taken into account can be effective for smoking cessation among adolescents (Grimshaw and Stanton 2010). Community-based interventions (harm reduction, syringe exchange for injection drug use and various outreach activities) can serve to minimize the chances of the behaviors becoming entrenched.

136.3 Conclusion

This chapter summarizes findings from several recent studies which have examined the psychosocial risk and protective factors for drug use and drug abuse using a developmental approach. This approach, based on Family Interactional Theory (FIT), focuses on the role played by the parent-child relationship and, particularly, aspects of the non-conflictual mutual attachment relationship between parents and child. According to FIT, the parent-child mutual attachment relationship is of special significance in preventing the development and maintenance of risk factors for drug use. The chapter examines risk and protective factors in several psychosocial domains, with special emphasis on the developmental pathways leading to the presence of both risk and protective factors for drug use, starting in childhood and continuing in adolescence. The chapter has also focused on research which has examined the risk/protective and protective/protective interactions among psychosocial factors related to drug use/abuse. In the design of preventive or treatment interventions, it is especially important to consider the total psychosocial environment of the adolescent. The various psychosocial domains have complex interactions with one another, and so it is of great importance to strengthen protective factors (e.g., enhanced family functioning) in those domains and interactions that

will be the most effective in mitigating risk factors, as well as in those which have been shown to directly affect the adolescent's substance use. In addition, effective interventions must be developmentally, as well as culturally, appropriate. These fundamental findings, taken together, indicate that preventive and treatment interventions for adolescent substance abuse should be designed for different adolescents, considering their psychosocial and cultural environments, as well as their developmental level. Treatment itself can be preventive.

Although research efforts have clearly specified particular psychosocial risk and protective factors involved in adolescent substance use and abuse, there are a number of questions which remain to be answered by future research efforts. To begin with, current knowledge of the genetic bases for substance abuse is quite limited, and more needs to be done to expand knowledge in this area. Variations in specific genes that affect risk or protective factors for substance use/abuse must be identified in order to enhance clinical applications of knowledge. In addition, interactions between genetic vulnerabilities and environmental factors must be explored further, with assessments of both gene-environment and gene-gene interactions needed. In order to carry out these assessments, improvements are needed in identifying and accurately measuring varying aspects of the individual's environment through the use of innovative and creative research efforts. By focusing on these challenges, we can bring about the development of a more accurate biopsychosocial perspective of the development of adolescent substance abuse.

ADHD and Substance Abuse

137

Sam Chang

Contents

Abstract

The interaction and relationship between attention deficit hyperactivity disorder (ADHD) and substance use disorders (SUD) have long been recognized. Many hypotheses for this relationship have been advanced. However, it took contributions from many fields to shed light on this very prevalent problem, often starting in late childhood or early adolescence but continuing well into adulthood. These included contributions from epidemiology, genetics, neuroimaging, psychopharmacology, and of course long-term clinical follow-up to understand that SUD and substance abuse are significant complications of the lack of adequate treatment of ADHD, often dating from early childhood. There is also a bidirectional influence, esp. with the use of tobacco and alcohol during pregnancy increasing the risk for the development of ADHD in the fetus. That ADHD and SUD are public health issues is now well recognized and has resulted in formal clinical trials to elucidate the best treatment when both disorders co-occur or are concurrent/comorbid. This is particularly relevant as treatment of ADHD is often with medications with a risk of diversion and hence abuse. As such, clinical trials to understand the relative benefits versus risks are very

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment: International Perspectives*, DOI 10.1007/978-88-470-5322-9_125,

important clinically. A review of the literature in these areas leads then to an attempt to translate research findings into evidence-based practice that maximizes benefits but minimizes risks. Practice guidelines in this respect are reviewed.

137.1 Introduction

In North America, the presence of SUD earlier into adolescence and even childhood is increasingly being recognized and responded to by various prevention, early identification, and treatment programs. These programs were plagued by lots of initial uncertainty and skepticism as to even the validity of the diagnosis of SUDs in the adolescent population. This was also the case for the efficacy of various programs of prevention and treatment (Substance Abuse and Mental Health Services Administration 2010). These are now far better understood including the confounding presence of developmental comorbidities, especially increasingly by the presence of another major childhood psychiatric disorder, that of ADHD (Biederman et al. 1993). It has been known for some time that ADHD is a very significant pediatric disorder from a prevalence standpoint (Offord et al. 1989) but also of its negative influence on functioning needed for successful child and adolescent development (Barkley et al. 1991; Klassen et al. 2004). We are finally now more aware as to its *influence* in terms of etiological and possibly pathophysiological factors esp. in the development of SUD. In fact, we are more and more aware of the influence of ADHD in the development of the *disruptive behavioral disorders* (Jensen et al. 1997) and of its profound role and cost not only to the individual but also to the family and in particular to society as a whole (Pelham 2007). This knowledge has lead to ADHD being labeled as a *public health issue* in some countries, due to its high prevalence, high cost and sequelae if untreated, and the efficacy of available treatments (Rowland et al. 2002; Centers for Disease Control and Prevention). This suggests the issue is not one just to be dealt with by physicians and their patients but also by larger government policy and societal attitudinal shift. ADHD is also a worldwide phenomena, present in all areas of the world where it has been studied (Farone et al. 2003; Polanczyk et al. 2007). It also has one of the highest interrater reliability of diagnoses in the DSM (Freedman et al. 2013). Its presence in adults has now been well established in well-conducted epidemiological studies (Kessler et al. 2006) and has been estimated to have a prevalence of 4.4 %. Finally, it is now generally accepted that medication treatment results in protection for the development of SUD in meta-analysis (Wilens et al. 2003). At worse, some longitudinal studies have demonstrated that medications for ADHD have a neutral effect for the protection and for the causation of SUD.

In this chapter, we will try to review some of the more significant developments from ADHD research and of its connection to SUDs, not only in adolescence but down into childhood and forward into adulthood. This will illustrate the costs and the benefits of treatment of this very prevalent and costly psychiatric disorder first developing generally in childhood.

137.2 Clinical Correlates

137.2.1 Diagnosis

Even in countries officially using the ICD system of diagnosis, the Diagnostic and Statistics Manual of the American Psychiatric Association, now in its fifth edition, is used and widely accepted as the most useful criteria clinically. DSM 5 has made improvements for the diagnosis of ADHD in adults (DSM 5 2013). These include symptoms fitting better with the adult experience versus the previous child-based ones. There is also a recognition of symptomatic evolution into adulthood by a slight relaxation of symptomatic recall by a change to an onset by age 12 from age 7 and the number of symptoms required as an adult.

There are also free rating scales available. These include the ASRS (Adult Symptom Rating Scale) of the WHO. This scale is composed of two parts. Part 1 has the best predictive value for the diagnosis of ADHD. Part 2 is also helpful to elucidate the additional symptoms needed for the diagnosis. Although it is a self-report rating scale, it is best used in conjunction with the clinician to build rapport and to fine-tune for more specific symptoms and especially for functional impairment. This not only is important for the diagnosis but then becomes the focus and target of treatment. As in all rating versus diagnostic scales, its real strength is in follow-up where symptomatic and functional improvements can be followed and quantified to optimize and fine-tune the treatment process. Our ultimate goal of course is not to just improve symptoms and functioning but to normalize it, i.e., to treat to *remission* as in other psychiatric disorders such as major depression. There is also the availability of free child and adolescent rating scales, again for the key purpose of following and quantifying the course of treatment. The scale often used for this purpose includes especially the SNAP IV parent and teacher scale. There is a full SNAP scale useful for the screening of the most common major comorbidities of ADHD. There is also a short SNAP IV 26 and a very similar Vanderbilt University Scale, both of which encompass only the 18 DSM symptoms (nine for inattention and nine for hyperactivity/impulsivity) as well as the eight symptoms for oppositional defiant disorder (ODD). This is due to the very frequent clinical and research finding of the presence of ODD as the most common comorbidity of ADHD (The MTA Co operative Group 1999). Also very frequently noted is that successful treatment of ADHD medically also greatly improves and often drives the ODD also into remission (The MTA Co operative Group 1999; Elia et al. 2008). This is especially important in the case of concurrent SUD since the disruptive behavior disorders are so commonly also comorbid with SUD. While the SNAP 26 and the Vanderbilt Rating Scale also come with a scoring guide, a very commonly used method clinically to score this is to aim for symptoms to be in the *not at all* or *sometimes* columns but not in the *often* or *very often* columns. As the *not at all* or *sometimes* columns denote normal functioning, we are in fact advocating for *normalization* or *remission* of symptoms as the treatment goal. To further aid the computerized office or computer-literate patient and physician is the availability of a website "adhd*ratingscales.com*" which aids the physician and the family to be

able to log in and do the rating scales online. This way, teachers and parents can do the rating scales wherever they are and have web access. The physician once he or she has registered gets an e-mail of the scale which is prescored thereby saving this often tedious and time-consuming task. The website is secured and only for the use of registered physicians and their patients.

137.2.1.1 Associated Symptoms

Other than the three core areas of symptoms, i.e., inattention, impulsivity, and hyperactivity, there are also frequent areas of associated symptoms that are important to recognize as these can become very critical clinical areas for treatment if optimal functioning is to be gained. One of the most key areas especially for those whom are also suffering from SUDs is the area of sleep or, more specifically, the relative lack of sleep or of poor sleep.

Sleep

Patients with ADHD often complain of poor sleep (Owens 2005). The usual complaint is of phase-shifted sleep where, at the usual bedtime, the patient is *not tired* or *too revved up* or *thinking too much* to be able to wind down and get to sleep. As a result, the patient often uses electronic audiovisual equipment, e.g., TV, computers, and, worse of all, video gaming. This then results in very late nights and hence the inability to get up in the mornings. Very often the patient blames the medication (usually a stimulant) for *keeping me up at nights*, yet, upon closer history taking, we then hear the patient has never been a good sleeper and has always had problems falling asleep. This is a major problematic area for several reasons. First is the expected problems focusing when tired thus compounding the deficits from the underlying ADHD. Secondly, as ADHD patients are far more prone to addictions of all kinds including behavioral addictions, the risk of video gaming addiction becomes much higher, again compounding the patient's already compromised level of functioning (Weiss et al. 2011). In fact, it is not uncommon for the *video gaming addict* to spend every waking moment playing videogames so that even self-care and activities of daily living are compromised, not to mention work, school, or relationships.

Thirdly, the poor sleep often results in the use of substances, typically cannabis, at night time in order to facilitate sleep (Conroy et al. 2010). This self-medication strategy is especially concerning, as we have become more aware that if we are unable to help our SUD patients with sleep, then sobriety is likely to be compromised and short lived. Thus, this associated ADHD

symptom is especially critical for patients with ADHD and SUD to get under control and, quickly, if they hope to be successful in both sobriety and also functioning.

Short Tempered, Easily Frustrated, and Stressed

This is the common complaint of the family of the patient with ADHD (Wehmeier et al. 2010). The patient may or may not be aware of this, but, nevertheless, it is a major reason for dysfunction especially in areas where there is social interactions like school and work and of course within the family system. This associated symptom is in fact a big part of the reason why adults with ADHD are often misdiagnosed to have bipolar disorder. Of course, bipolar disorder is a relatively common comorbidity of ADHD and "co-segregate" in other family members (Faroane et al. 1997; Klassen et al. 2010) and increases greatly the relative risk for SUD over and beyond that of ADHD alone. This group of patients is among the highest risk group to develop a SUD. However, ADHD individuals do not present with the usual endogenous cycling of bipolar disorder but with chronic developmental easy irritability and frustration due to environmental stressors. There are also no episodic euphoric, manic, and psychotic symptoms. The differential diagnosis here includes ADHD with concurrent substance abuse resulting in cycling moods and psychotic symptoms. It is now quite obvious why those with ADHD whom are in the early stage of substance abuse treatment and likely to be withdrawing, or the video gaming addict with ADHD and trying to cut back, can be so oppositional and difficult to deal with. In fact, in our Adolescent Concurrent Disorders Program in Calgary, this is the group of patients most likely to require the highest level of parental support for behavioral containment and pharmacological intervention for their often out-of-control behaviors.

Risk-Taking/Thrill-Seeking Behaviors

This is an associated symptom which is the costliest to society and is one of the major causes of crisis and containment of the adolescent. It is also often inextricably tied into substance abuse. In its extreme form it can lead to the development of a conduct disorder and can predict ongoing criminal behaviors. Conduct disorder in fact is the risk factor that confers the highest risk for a SUD in adolescents (Molina et al. 1999). The actual behavioral manifestations of this associated symptoms has a lot to do with the psychosocial milieu of the child and adolescent. In particular, if appropriately channeled, this can become a very prosocial strength of the ADHD individual and can be the source of much self-confidence and self-esteem. The individual will then be conferred status and respect. On the other hand if inappropriately channeled, there is a very high risk of the development of antisocial behaviors which can lead to permanent underclass status.

As an example, there are lots of ADHD children and adolescents whom have gained lots of skills and status and confidence and esteem from involvement in athletic activities (Halperin and Healey 2011; Verret et al. 2012).

ADHD individuals often do better in individual or parallel pursuits versus in a team setting. They enjoy and often excel in thrilling sports, e.g., ski racing and ski jumping, mountain and BMX *trick* biking, mixed martial arts, boxing, etc. The key to good outcomes is involvement in a structured program rather than ad hoc on one's own. The alternative if these more prosocial activities are not available, such as due to poverty or systemic family instability, may be the enveloping of the ADHD individual into the antisocial world of substance abuse and criminality and a gradual isolation of oneself into the criminal world. Due to the immersion of the adolescent or young adult in these alternative values, there is great risk of their leaving to join the *street life* or being kicked out of the parental home due to the intractable nature of their negative behaviors and associates. Worse would be arrest and incarceration to fully ostracize them and to solidify their identity as part of the criminal underclass.

137.2.1.2 Pathophysiology

The numerous connections between ADHD and SUD become far clearer once we understand the likely pathophysiology of ADHD. Awareness of the pathophysiology of ADHD will also give us hints and understanding not only of the core symptoms but the source of much of the dysfunction, associated symptoms, and comorbid risks of ADHD. Finally, it will also give us insights into what is most likely to be effective treatment strategies especially when we take into account the neurophysiological effects of treatment itself.

Familial and Genetic Risk

ADHD has long been known to be a familial disorder with much higher risks especially among first-degree family members (Cantwell 1972; Epstein et al. 2000). This of course begs the question of whether it is genetic or environmental risks which bring out the symptoms. Unfortunately, like many non-Mendelian polygenetic influences, it is unlikely to be totally the result of genes or environment but rather a combination of the two.

One of the methods to elucidate the role of genes versus environment is to compare the likelihood of the presence of a disorder in first-degree relatives in biological versus adoptive families. Results of this demonstrate a much higher likelihood of ADHD in biological first-degree relatives of a proband compared to adoptive relatives. It is also higher the closer related one is, for example, the risk of biological siblings having ADHD if the proband does is even greater than the risk for biological parents (Sprich et al. 2000). An even more precise method is to compare the differences between monozygotic versus dizygotic twins. As the twins share the environment similarly, including the in utero environment, differences in rates of ADHD are felt to be much more of a precise measurement of the relative risks of environment versus genes. A meta-analysis of the literature in this regard shows a *heritability index* of 0.76 (Faraone et al. 2005) (where 0 is no genetic influence, i.e., all environment, and 1 is all genes and no environmental influence). This compares with other medical disorders of around 0.4 for asthma and breast cancer and around 0.5 for depression and the very heritable psychiatric disorder of

schizophrenia of 0.7. Among heritable traits rather than disorders, height is very heritable at about 0.9.

Heritability is of course a measurement of overall genetic risk. As one would expect, we are not looking at a single but multiple genes (Faraone et al. 2005). Though none of the risk genes are able to give us a causal statistical threshold of 10^{-9}, as demanded by geneticist, they at least give us numerous clues to the pathophysiology and possible treatments. That most of the genes are connected with the well-functioning and intricate balance of the dopaminergic modulation system, and most effective treatments also are directed at this system, and, of course, that this system is implicated in addictive disorders all point in the same direction. One of the most interesting of these genes is the DRD4-7 repeat allele gene, which is also known as the *thrill-seeking gene*. People with this genetic variant have a lower dopaminergic tone and a much higher tendency to risk taking behaviorally. This may account for the associated thrill-seeking symptoms in many of those with ADHD as well as the very high comorbidity with oppositional defiant and conduct disorders. This may also account for the increased presence of substance abuse and criminality in ADHD individuals. One must be reminded, however, these risk genes do not mean the individual is going to be a criminal or drug addict, as there are very many modifiable psychosocial risk factors as well.

Perinatal Risk Factor

We are now beginning to understand how gene and environment interact to cause disorders. One of the most potent developmental periods when the environment may exert its maximum influence is in utero. As development is at its maximum at this point in the individual's life span, it becomes the point at which negative or positive environmental influences will exert its peak effect. In this perinatal period the key environmental influences that may negatively affect the fetus is the presence of maternal drinking of alcohol or of maternal tobacco smoking (Mick et al. 2002). Both of these in utero influences are risk factors for the development of ADHD. Alcohol especially can often result in fetal alcohol spectrum disorder (FASD), which, besides neurodevelopmental and physical sequelae, often also results in quite severe and intractable ADHD. There is even some evidence that paternal alcoholism can worsen and exacerbate the result of maternal in utero drinking (O'Malley 2007). There is also the observation that even in the absence of maternal drinking, the FASD parent may still pass on some of the disabilities and features of fetal alcohol in a phenomenon now labeled as epigenetics. As if all of these risks are not enough, nicotine exposure in utero further increases the risk for the development of ADHD (Milberger et al. 1996; Neuman et al. 2007). Tobacco use is also an independent variable for the development of SUD (Clark et al. 1998). We are also aware that ADHD individuals have a much higher risk of early onset of nicotine abuse (Milberger et al. 1997). This then predisposes to the early development of SUD due to the negative influences of like-minded peers, all of whom value independence from adults more than success (Marshall et al. 2003). These peers also tend to not being able to delay gratification, hence exacerbating risk-taking behaviors. So now we come full circle with ADHD individuals at

risk for SUD and the SUD worsening the next generation's outcome. This is especially the case with assortative mating which we know to be quite common clinically, i.e., both spouses being addicts and both with a much higher likelihood of having ADHD.

Psychosocial factors have also been shown to further increase the risk of ADHD. These include a combination of maternal psychopathology, paternal psychopathy, and early separation from family, e.g., apprehension by child welfare authorities, large sibship sizes, lower social class, and severe marital discord. These findings from the landmark *Isle of Wight Study* by Sir Michael Rutter et al. (1975) indicate just how potent are the psychosocial and genetic variables acting in concert, to the point that one can *predict* later psychopathology even in the young child. Together with our newfound knowledge of epigenetics and the *teratogenic* effects of alcohol and tobacco, we now have a very powerful breadth of knowledge to decrease the burden of psychiatric disorders. The good news as always is tapered by the bad news that effective prevention requires not only knowledge but wisdom in applying into public policy what we know to be true in science. Alas, this wisdom is not quite as easily gained as knowledge, so we remain unable to exploit much of what we know to minimize individual and family morbidity and, yes, mortality.

Neuroimaging/Neuropathophysiology

One of the biggest impediments to a better understanding of psychopathology until recently was the lack of tools to visualize not just structure but neuroreceptors, neuroconnections, and neurofunctioning in the living and working, active brain. Fortunately with the availability of MRI, fMRI, Diffusion Tensilar Tomography, SPECT and PET scanning, and on top of the old stalwart CT and EEG and with genetic techniques like the breeding of the *genetic knockout mice* animal models and Genome-Wide Association Studies, a wealth of new understanding of the workings of the normal and psychopathological brain has emerged. In fact, the first published PET scan for psychiatry was in ADHD, specifically parents of children with ADHD whom exhibit ADHD symptoms themselves (Zametkin et al. 1990). This prevented children from exposure to radiation but allows studies of the underlying ADHD in the functioning brain. As a result, we knew very early on that ADHD seemed to be related to a disconnect between the higher cortical centers which tended to be noradrenergic, with the lower striatal structure which were dopaminergic. Thus, this *noradrenaline-dopamine axis* was postulated to be the problem in ADHD. It was certainly backed up by the treatments already prevalent at the time, i.e., of stimulants that exerted its effect on both the noradrenergic and dopaminergic systems.

The other piece of knowledge needed was how the stimulant medications, in use for ADHD for more than 70 years, actually worked. Again with PET scanning we were able to use radioactive ligands to block the postsynaptic dopaminergic receptors (Matochik et al. 1993). Once a stimulant like methylphenidate was given, the level of dopamine or the dopaminergic tone was inferred to increase by the displacement of the radioactive ligand. This was via the action of methylphenidate

in blocking the presynaptic dopamine reuptake transporter. To close the loop, once the dopamine tone increased, symptoms of ADHD decreased clinically.

Further studies to visualize the anatomical effects on the brain of these microscopic neuroreceptor activities via fMRI were successful once the situational load on the brain was controlled. For example, when the brain was given an inhibitory task (Counting Stroop test), then those with untreated ADHD showed an inability to activate the anterior portion of the anterior cingulate cortex compared to normal controls (Bush et al. 1999). That effort was being exerted by the ADHD patients was obvious, as they activated a much larger portion of the brain than controls in an effort to complete the task but in a grossly inefficient and hence ineffective way neurologically. Once the ADHD patient was treated, this finding on fMRI disappeared indicating successful treatment of dysfunction and hence symptoms. This also dovetails very well with the associated symptoms of short temperedness. The posterior portion of the anterior cingulate is the emotional regulation center, thereby subjected to input from the anterior cingulate (Bush et al. 2000). It is for this reason that one of the best treatments for short temperedness is optimal treatment of the underlying ADHD and especially with stimulants.

In regard to SUD, one of the most intriguing findings was recently at the NIDA, where untreated ADHD individuals, so untainted by any possible medication effect, were found to have lower dopaminergic tone in the nucleus accumbens (Volkow et al. 2009). Since the nucleus accumbens is part of the primitive reward pathway that is implicated in addictions and activated not only by drugs of abuse but also by behaviorally addictive behaviors, this seems to connect neurophysiologically the observation of the heighten risk of addictions and thrill-seeking behaviors in the untreated ADHD individual.

Psychostimulants increases dopaminergic tone and hence increases saliency of a task for the individual. At the same time, if presented with a gradually increasing concentration of psychostimulants, such as via oral dosing, there is no euphoria, whereas if dosed with an IV bolus, then indeed euphoria was noted. This observation further brings us to a treatment strategy to minimize the risk of medication diversion and abuse by using the newer long-acting psychostimulants which has much lower abuse potential due to difficulty in the hands of the addict to defeat the slow release mechanism, hence preventing euphoria by not being able to load a large enough amount of stimulant, e.g., by snorting intranasally or using via IV means (Volkow and Swanson 2003; Volkow 2006). We will discuss these strategies in more detail later.

Finally, there are numerous studies (Bush et al. 2005) documenting volumetric decreases in various parts of the brain ranging from cerebellum to prefrontal cortex to inadequate connections via various nerve bundles and tracts and even decreased cortical thickness. There is even a very elegant developmental prospective study by the NIMH demonstrating developmental delay and immaturity in the untreated ADHD child brain compared to controls (Shaw et al. 2007). However with treatment, there is an acceleration of development to almost the level of controls. This is one of the first neurological evidences that ongoing treatment may be a very good

prophylactic and prevention strategy for the complications of untreated ADHD. It also backs up findings from clinical studies and demonstrates physically that there is risk of significant side effects to NO treatment and that the common strategy of "waiting to see if he grows out of it" may be causing much harm and has lifelong sequelae not only clinically but also neurologically.

Risks of No or Inadequate Treatment

In medicine, as in much of life, decisions are made by a balance of the risks and benefits of treatment versus no treatment. To take an extreme example, if one has been diagnosed with a condition like cancer, before embarking on tumor removal surgery, chemotherapy with cytotoxins, and radiation therapy with ionizing radiation with all of these concomitant side effects, one would want to know the risks of no treatment and the chances of success. We of course know the ultimate risk is death for no treatment in cancer. As a result one is willing to accept a far higher risk for treatment side effects than if the condition had a lower risk than death.

This is the same thinking behind the treatment of ADHD. Unfortunately much emphasis has been placed on possible side effects of treatment, which is present in all areas of medicine and not enough on the risks of no treatment (Shaw et al. 2004). The first most obvious risk is in school. Children with ADHD have been noted to have much higher rates of academic failures and underachievement once corrected for intelligence than controls (Barkley et al. 2008). This is easily understood in ADHD due to the effects of inattention and easy distractibility to one's academic performance. The presence of distractions especially in a classroom has a very deleterious effect on academic outcome to an ADHD child. The presence of hyperactivity and impulsivity that often is present further adds to academic risk. Furthermore, the presence of executive dysfunction, commonly present in ADHD, contributes greatly to academic underachievement especially in the more advanced grades like in high school. This includes skills like organization, planning, prioritizing, and inhibition, which take on more importance as one matures and expectations are increased from adults (teachers and parents) to take on more of these skills in one's own life. Finally, there is often the presence of problems in motivation, likely due to intrinsic deficient dopamine tone in the reward system (nucleus accumbens) (Volkow et al. 2009).

Though good academics are a very major portion of one's school success, it is by no means the only variable. Social peer interactions are widely accepted by educators as a very significant part of the school experience.

Children themselves also place a large premium on the effects of social interactions to their overall school success. Here as well, the ADHD child is in a significant disadvantage (Strine et al. 2006). The effects of impulsivity are felt most acutely here. Here the child often *acts without thinking*, hence inadvertently offends another child. Add the inattention and distractibility as well as often hyperactivity, and one can easily imagine how other children often perceive the ADHD child as unruly and unpredictable. Add to this the frequent presence of impatience and the poor ability to pick up nonverbal cues so essential to social interactions, and it is no wonder that ADHD children report less friends and less positive social interactions, not only with peers but even with family members.

The final functioning that predicts success at school is the ability to deal with authority relationships. The ability to work with teachers, lunch room supervisors, principals, and other adult *authority* figures is vital to a child successfully negotiating school. Here impulsivity and hyperactivity again contribute very greatly to a poor outcome. However, the worst characteristics with the authority figures are the very frequent presence of an oppositional defiant disorder (The MTA Co operative Group 1999). This habitual surliness, passive opposition, and active defiance of authority that is the top comorbid disorder to ADHD is a major contributor to the poor experience ADHD children have at school and also at home, since the same behaviors are directed at parental authority figures as well. It is no wonder then a major risk of untreated ADHD is the significantly increased rate of lack of completion of high school and lower college graduation rates (Barkley et al. 2008). This of course has major implications for the longer-term socioeconomic achievement of the ADHD child and later on by his or her own family.

Due very much to the same interactions of inattention and distractibility, impulsivity, restlessness, and impatience, together with passive opposition and active defiance, one of the other major risks of untreated ADHD into adulthood is the high frequency of being terminated at a job. This then results in the affected individual having to seek multiple jobs and careers. This is not only stressful and impacts one's emotional and relational health but, at a very basic level, results in a lower income, employment reduction, and increase in social assistance (Barkley et al. 2008; Fletcher 2013).

Given these significant consequences psychosocially of untreated ADHD, it is surprising to know that frank psychiatric comorbidities, e.g., mood disorders (both unipolar and bipolar), anxiety disorders, and personality disorders, are increased in those with untreated or poorly treated ADHD. In fact, one can actually make the statement that in a well-treated individual with ADHD, we can *prevent* or *decrease the risk* of development of psychiatric disorders as the individual develops over time (Beiderman et al. 2009).

Other risks very relevant to Addictions Professionals are the increasing awareness of the risk of addictions with untreated ADHD. In both prospective follow-up and meta-analysis, those with untreated ADHD are at significantly increased risk (2×) over a lifetime of developing a substance use disorder (Wilens et al. 2003). This is also part of the reason that patients with untreated ADHD are far overrepresented in prisons. Studies of the prison population have found about 15 % of prison inmates to have persisting ADHD and up to 50 % having a childhood history of ADHD (Young and Thome 2011). In fact, the cost of housing and providing for prison inmates is one of the biggest societal costs of untreated ADHD.

Costs of untreated ADHD are one of the major unrecognized consequences (Bernfort et al. 2008). That the costs are paid by every level from the individual to the family, to businesses, and to the overall society and government is even less recognized. Of course, the individual suffers from ADHD and its attendant comorbidities, e.g., depression, anxiety, and substance abuse. However, these

have cost businesses and the community to the tune of billions of dollars in the USA per year.

Families of those with ADHD also paid the cost (Cussen et al. 2012). The families have a higher rate of marital discord and separation; primary caregivers often change their work status upon diagnosis to help deal with the fallout of ADHD; there is more likelihood of unwed pregnancy and contracting STIs; children given up for adoptions are more often from a parent or parents with ADHD.

Driving is also increasingly recognized as a major societal cost of ADHD (Barkley et al. 1996). Untreated ADHD patients are noted to have more speeding tickets, motor vehicle accidents, and road rage and drive without a license. In some jurisdictions, physicians are obliged to report any patient with ADHD who drives while unmedicated. Driving studies in simulators have found untreated ADHD drivers to commit more errors both of omission and commission (speeding) especially in long boring and unstimulating roads. Interestingly, driving a manual transmission seems to be helpful, likely due to the increased involvement and hence saliency of one's actions to the untreated ADHD individual.

Given the costs of untreated ADHD, i.e., financially, socially, educationally, occupationally, familially, parentally, and psychiatrically, is it any wonder that untreated ADHD confers such a high risk for the development of a substance use disorder? Many of the risks of untreated ADHD are the same risk as for the development of substance use disorders. In this authors' program, the genogram is used as an agent of both neutral information gathering and engagement. We have noted this very strong familiarity of addictions over the generations. With the data present thus far, it is the considered opinion of this author that much of what is noted via a genogram for addictions is actually merely the development of consequences of untreated ADHD in vulnerable genetic populations. The genetic vulnerability is then activated by the very real psychosocial disadvantage and hence stressors that untreated ADHD confers.

137.2.1.3 Treatment

MTA Study

Fortunately, with the advent of the large multisite, multimodal treatment studies, so as to be able to study the relative contributions of various modalities of treatment, we now have a far better understanding of the merits of various treatments (1999). The first and still key study of this type in this field was the Multimodal Treatment of ADHD (MTA) study of the National Institute of Mental Health. This study firmly established the efficacy of treatment for ADHD and especially of medication treatment.

In this landmark study conducted under the vision and leadership of Dr. Peter Jensen of the NIMH in both Canada and the USA, children with ADHD were admitted to the study with very few exclusionary criteria especially in regard to other psychiatric disorders. This had the advantage of allowing a typical clinical population rather than the usual monodiagnostic homogenous study population. The children were then randomized to one of four treatment groups; these were as follows:

Usual Treatment

This meant what was usually done at the time, i.e., seeing a physician and being prescribed Ritalin b.i.d. and with long duration between follow-ups.

Psychosocial Treatment

This was using all empirically useful psychosocial treatments and combining them in such a way as to maximize their efficacy. These included such interventions as summer social skills camps, academic remediation and support, parent skills training, etc. This was the most expensive arm of treatment.

Intensive Medication Treatment

This arm consisted of each child being given the optimal dose of stimulant to not only improve but treat to remission all ADHD symptoms with full coverage medication throughout the waking hours. Given the medications available at the time, it was of t.i.d. use of stimulants. Symptoms were also followed systematically with a rating scale. Follow-up was also on a regular basis with a psychiatrist. Compliance was also ensured with regular contact.

Combination Treatment

This arm essentially combined the psychosocial and intensive medication treatments.

In total 579 children were enrolled and followed with treatment for a period of 14 months, which even for today is an uncommonly long duration of follow-up for any treatment. The outcomes of treatment were very telling. As one would expect, the best outcomes was in the ***combination treatment*** arm.

Also significantly improved was the ***intensive medication*** *group*. The worst outcome was in the ***treatment as usual*** *group*. The ***psychosocial only*** *group* was better than the ***treatment as usual*** *group* but not statistically significant. In other words, the only statistically improved group over the ***treatment as usual*** *group* were those that included medication either intensively on its own **or** in *combination with psychosocial treatment*. When the specific symptom measures were reviewed, approximately 90 % of the effect was from medication effect. While this may seem to indicate that *medication only treatment* is all that is required, especially once costs are also factored in, the patients and family prefer the *combination treatment*. This suggests the likelihood of better compliance to meds with *combination treatment* in real life, which unlike in the study does not have supports to ensure medication compliance.

There have since been several longitudinal follow-ups of the MTA study indicating no sustained improvements on medication. Various explanations have been given for this. Caution however is needed in interpreting these studies given that randomization was ended at 14 months of treatment, and so any treatment or no treatment combination can occur. The key learning from these longer-term follow-ups is in the differences in family variables of the children doing well. These tend to be from intact, functional, involved, and socioeconomically successful parents (Murry et al. 2008). This suggests an approach to improve parental capacity likely

to be helpful. This trend is not unlike other areas of medicine, where better outcomes tend to occur in those with better psychosocial and socioeconomic functioning. As such, minimizing psychosocial adversity has much promise as an intervention on top of the obvious and significant gains from pharmacological treatment.

Overall the key taken away point from the MTA study is the large effect size of pharmacological treatment for ADHD over and on top of the smaller effects of psychosocial treatments (The MTA Co operative Group 1999).

Risks of Treatment

The key modality of pharmacological treatment has historically been with the psychostimulants. These have been from the various formulations of both the methylphenidate and amphetamine class of stimulants (Canadian ADHD resource alliance practice guidelines 2013). More recently, non-stimulants have also become a much larger proportion of treatment especially with the advent of atomoxetine and long-acting guanfacine. Each group has their own advantages and disadvantages. Insofar as substance use disorders go, however, the major concern is with abusability and the risk of diversion of the psychostimulants. As a result, we will review this in some detail. As for other side effects and potential adverse effects, it is beyond the scope of this review to delve into with any detail, though we will try to cover the key concerns.

As one would expect, both classes of stimulants, i.e., methylphenidate and the amphetamines, have the same possible side effects, though not necessarily in the same individual. These are typically abdominal discomfort, decreasing appetite, dry mucosal membranes, headaches, slightly increased heart rate (4–5 beats per minute) and BP (4–5 mmHg), and, if taken too late in the day for the duration of the formulation, insomnia. On many occasions, however, it is ADHD itself that confers insomnia due to chronic motor and cognitive restlessness, and not the medication. The timing of the onset of the insomnia is important to distinguish this and is important in that long-acting stimulants can actually improve sleep by decreasing restlessness, if insomnia is due to ADHD symptomatology. There have also been concerns of cardiovascular events, e.g., possible sudden death. Upon closer review, however, it appears there is no significantly increased incidence of sudden death when compared to the background rates. Nonetheless, it is the opinion of electrocardiophysiologists that the main concern is possible arrhythmia due to congenital heart disease and especially channelopathies. These are congenital conduction anomalies stemming from abnormal microchannels of conduction. The recommendation is to screen for congenital heart disease in one's history. This includes screening for the presence of:

(a) Prior congenital heart disease diagnosis
(b) Severe syncopal episodes especially due to exertion
(c) Severe exercise intolerance, e.g., unable to climb one half flight of stairs or walk down a hallway without dyspnea
(d) Family history of sudden death before age 50
(e) Severe chest pains

If present, EKG and cardiology consultation are recommended prior to medication.

This is the case for *all* ADHD meds, both stimulants and non-stimulants. Other side effects generally are acclimatized to usually in less than 1 week. If these persist, a switch to the other class of stimulant often is all that is needed to improve side effects. The stimulants have some of the highest effect sizes of medications in both medicine and psychiatry, with Cohen's effect size of approximately 0.9–1.0. Hence, even taking into account side effects, it is uncommon indeed for a patient not to benefit from or be unable to tolerate a stimulant for his or her ADHD (Arnold 2000; Faraone and Buitelaar 2010).

In the area of substance abuse, a bigger cause for concern is the diversion and abuse of medical stimulants by the substance-abusing population. This is generally not abused by the ADHD patient, but, rather, diverted by them for money to buy other substances of abuse. Fortunately this issue is easily dealt with as it is usually the short-term immediate-acting medications that are abused. This is due to their ease in being abused parenterally, usually by grinding down and snorting intranasally or by IV routes. The NIDA has noted that both cocaine and medical stimulants are abusable and can result in intoxication, especially parenterally, due to the very rapid rate of rise of concentration of stimulant with both, hence the feeling of intoxication. Interestingly, if parenteral abuse is prevented, typically by the formulation of the medical stimulant, then oral use does not result in intoxication, due to the slow rate of rise of concentration of the stimulant (Volkow and Swanson 2003; Volkow 2006). This is one of the rationale for the recent inclusion of the *long-acting* stimulants as *1st line* for the treatment of ADHD (Canadian ADHD Resource Alliance Practice Guidelines 2013).

The other is the obviously advantageous effect on compliance due to once a day dosing versus the need for multiple dosing with immediate-release formulations (Farone 2009). The methods of ensuring prolonged delivery by the long-acting stimulants are also the same mechanism that prevents its parenteral use, hence minimizing the rapid rate of rise of the stimulant in the blood needed for the feeling of intoxication.

These mechanisms include beaded formulations with some beads immediate and some delayed release in various proportions, e.g., Adderall XR (Product Monographs). The OROS technology where a laser-drilled hole is made in one end of a rigid capsule and then filled with two portions of increasing concentration of stimulants to achieve an ascending profile of serum concentration. These are propelled by a *push* compartment in the far end of the capsule consisting of a polymer that expands with water, thereby *pushing* out the stimulant at a measured and predeterminate rate, e.g., Concerta (Product Monographs). There is also the new generation transdermal system where the glue and stimulant molecules are interlaced and cannot be separated easily physically and which only allows for *1 sticky episode*, i.e., cannot be transferred once applied – Daytrana patch (Product Monographs). Finally, the most elegant is the recent development of prodrug Vyvanse technology. Here the active stimulant

molecule is covalently bonded to a lysine amino acid molecule (Product Monographs). Once this occurs there are several advantages. Firstly, the new molecule is inert and so has no metabolic activity until the covalent bond is cleaved by a red blood cell membrane-bound enzyme. Secondly, the use of lysine allows the molecule to be recognized by gut cell transporters which actively transport the molecule into the blood stream.

Thirdly, once in the blood stream, most of the molecules are able to bypass the liver due to the inert properties of the molecule. Finally, once in the systemic circulation, the prodrug is cleaved at a fixed rate-limiting step, thereby resulting in a very long duration of action, up to 13–14 h. This technology is especially useful for the substance-abusing individual in that the prodrug is very hard to abuse. Cleaving the prodrug into its constituent stimulant is a very involved and time-consuming process, making the prodrug difficult to abuse or divert. This gives the prodrug stimulant (Vyvanse) an additional margin of safety over other long-acting technologies for stimulants.

The final option is with treatment with the non-stimulant, hence non-abusable anti-ADHD medication. At present there are two molecules available, i.e., atomoxetine (Strattera) and Guanfacine XR (Intuniv) that has formal regulatory body approval for the treatment of ADHD (Product Monographs). Despite its safety profile in substance-abusing populations, non-stimulants, while very effective, has a somewhat lower, though still impressive, effect size for the treatment of ADHD (better than the effect size of SSRI for depression as comparison). As a result, we need to keep all options open and available to ensure optimal treatment and outcomes (Canadian ADHD Resource Alliance Practice Guidelines 2013). This includes psychosocial, psychological, and of course a wide choice of pharmacological treatments. One of the most potent treatments for this rather large percentage of substance-abusing adolescents is in fact family therapy (Williams and Chang 2000; Waldron and Turner 2008), where treatments including pharmacological need to be done within the context of a family structure that supports pharmacological treatment in order for this to be successful.

137.2.2 Adolescent Substance Abuse

Substance abuse and misuse is present in all cultures. What is less well appreciated is the developmental perspective of this. It is very often assumed that SUDs are an adult problem. A review of epidemiological data reveals otherwise however. In the USA the Substance Abuse and Mental Health Services Administration has kept regular data on the epidemiology of substance abuse. Tellingly, the median age of peak use occurs in young adults in the 18–20-year-old age group. This then drops off to either side of this age with a long trailing arm into the elderly, like a bell curve (Substance Abuse and Mental Health Services Administration 2009). On the leading side the beginning of the onset of substance abuse seems to begin at about age 12 when measurement begins. This has significant implications for the prevention and treatment of SUD. It is especially so if we conceive of SUD as a *childhood*

disorder that persists into adulthood. The suggestions for this are immense as for many other chronic medical conditions now understood to have pediatric beginnings.

To begin with, we need to screen for family history. It is well known that adolescent substance abusers have much higher rates than controls of other members of their family also being substance abusers (Clark et al. 1998; Kaminer 1994). Although this has often been framed as environmental modeling, as our understanding of developmental psychopathology improves, we are also coming to appreciate the heritability of the underlying psychopathology, both in substance abuse and especially in other concurrent disorders. In fact, the common comorbidity of ADHD is also the most heritable. How does having the ADHD genotype lead to the development of an SUD? What are the multifactorial risk factors that lead to SUD in the ADHD individual?

We have already discussed that nicotine use is a key major risk for ADHD individuals. It is also a key risk for their parents. As a result, there is significant environmental risk from in utero exposure, on top of the role modeling as a child and adolescent (Milberger et al. 1996; Neuman et al. 2007). Nicotine is also often used by ADHD individuals to self-medicate their own ADHD symptoms. This is so well recognized that pharmaceutical companies are already involved in looking at the use of nicotinic agonist (both complete and partial) for their potential in ADHD treatment. These molecules have not as yet resulted in a new class of ADHD treatment due primarily to side effects.

Is it any surprise then to be aware that ADHD individuals tend to start smoking tobacco earlier, smoke more, and have a harder time stopping than those without ADHD (Milberger et al. 1997; Kollins et al. 2013)? Due to the very early age of onset of nicotine abuse (Substance Abuse and Mental Health Services Administration 2009) into late childhood and preadolescent ages, the youth is further put at risk by their exposure to other tobacco-using peers, often older and more troubled. This affiliation very easily leads into invitations to a "party" where they are further exposed to many other substances of abuse. This is very attractive for an ADHD child due to the profound psychosocial deprivation secondary to the negative effects of ADHD on socialization as discussed (Strine et al. 2006). The ADHD child often has no *real* friends nor even any experience at going to a *party* as they have often never been invited to classmates' birthday parties and the like due to their perceived lack of *likability* and poor social skills (Strine et al. 2006). They therefore take to the newfound *friends*, negative as they are, like drowning individuals to life buoys. We have often observed that once substance-abusing ADHD adolescents give up their substances of abuse, they no longer have any friends as substance abuse was their only successful strategy to friendships. No wonder untreated ADHD individuals have an even harder time giving up their substance abuse than those without ADHD.

A particularly vulnerable group is the females with ADHD and SUD. This is no surprise as ADHD is present epidemiologically in approximately equal amounts in both males and females. However, males are treated more than females, as clinical populations often show a male to female ratio of 4–5:1 (The MTA Co operative Group 1999). This is due to the peculiarities of psychiatric presentations

in children. Children are identified by the adults in their lives and do not come to medical attention as a result of self-report, unlike other medical symptoms. Boys with ADHD tend to have more behavioral problems and so more frequently are identified by teachers as needing intervention. Girls are more socially savvy and less behaviorally troubled, which has led to their lower rates of clinical presentations. Once they are an adult, males and females present at the same rate, as they can self-present with their now better self-awareness of their personal problems. As discussed, untreated ADHD individuals, males or females, have a much greater risk of SUD. No wonder the higher untreated ADHD population of females now presents with SUD, one of the complications of untreated ADHD. This is a big concern, as females with SUD, especially young females, are at a much higher risk of traumas and, in particular, sexual traumas. Once traumatized, the development trajectory is often permanently altered resulting in personality and other psychiatric problems. We need to ensure that young girls with ADHD, who often act well, perform well (though well below their potential), but has significant residual ADHD symptoms with its functional and psychosocial sequelae, are identified and treated early to prevent development of complications, like SUD, which affects her to a much greater degree than males (Davis and DiNitto 1996).

Once substance abuse begins, the ADHD individual often gravitates to specific substances of abuse. These often are those that seem best at self-medicating the underlying ADHD symptoms. In our experience, as well as those in recent NIDA studies, the most commonly abused substance in the ADHD adolescent is cannabis (Riggs et al. 2011). The adolescent often informs clinical staff that the use of cannabis:

(a) Helps them to calm down
(b) Helps them to fall asleep at night
(c) In low doses seems to improve attention

These are profound insights into ADHD symptoms, since these are often the cardinal symptoms of untreated ADHD. This also makes sense neurophysiologically (Castle and Murray 2004). The active ingredient in cannabis is Δ9 tetrahydrocannabinoid (THC). This mimics an endogenous cannabinoid (anandamide) which binds at the CB 1 receptor. Interestingly, these neurons often terminate on dopaminergic neurons, postulated as the source of difficulties in ADHD. It is also the site of action of medications for the treatment of ADHD. Thus, cannabinoid abuse makes pharmacological sense in self-medication, at least initially.

Unfortunately, like other drugs of abuse, another mechanism results in difficulties over time. This is the principle of TOLERANCE. As this builds, the increased consumption then results in deteriorations in the very areas of functioning the self-medication initially improves on. With cannabis, there are also two other factors to consider. The first is the trend toward higher and higher-potency cannabis. This trend in Canada began in the 1980s. This was due to several high-profile cases of toxicity due to residual pesticides sprayed on the cannabis plant. The serious injury and deaths resulted in an attempt to *grow your own*. Unfortunately, the Canadian climate, i.e., severe cold, resulted in very high

and uncompetitive costs due to the heating and lighting costs. In a bid to compete, genetic engineering was used to increase the potency from 2 % to 3 % THC by weight, up to a maximum tested of 29 % THC by weight, i.e., compete on quality versus cost. This had two implications that are related. Firstly is the finding in several cohort studies that the earlier the onset of use in adolescents and the greater the amount of use (a given with high-potency cannabis), the higher the risk of development of psychosis (Castle and Murray 2004; Englund et al. 2013). Secondly, despite the ability to increase the amount of Δ9 THC, we have not increased appreciably the concentration of cannabidiol which has properties as an atypical antipsychotic (Englund et al. 2013). The combination of these two factors has resulted in a large increase in Canadian admissions to psychiatric inpatient and early psychosis programs with youth and young adults with first-onset psychosis. The vast majority of these patients invariably have positive urine drug abuse screens for cannabinoids at the time of admission. As if this was not enough, there are the usual well-described cannabis-induced mood and anxiety disorders that, if onset early and if poorly treated, can again change the developmental trajectory of the afflicted individual and set off into action chronic mood and anxiety disorders.

Even if the youth escapes the psychotogenic, mood, and anxiety effects of the high-potency cannabis, there is the usual psychosocial and functional deleterious effects of cannabis that often potentiate the very psychosocial and functional deleterious effects of untreated ADHD (Von Polier et al. 2012). These include the poor social skills and socialization made worse by the use of substances as a socialization tool. The substance-abusing lifestyle also increases the risk in ADHD individuals for risk taking and criminality. The withdrawal effects of cannabis, in particular irritability, worsen the often coexisting oppositional and defiant attitudes and behaviors. This reinforces the alienation from authority figures, family members, and sources of real support, for like-minded peers and the using community. These all combine to result in functional deterioration in the areas of academics and school, occupation, and premature emancipation from family and often result in homelessness and becoming esconded in a permanent underclass of crime, drugs, prison, and poverty with concomitant poor physical and mental health with real and permanent premature morbidity and even mortality.

137.2.3 Treatment

As in any medical discipline, the key to treatment begins with assessment. This is not only to make a differential diagnosis and diagnosis but also to focus on the areas of functional strength to be built onto and the areas of functional weaknesses that will require remediation. As important in an often complex interrelated environmental and genetic interaction is to intervene in many areas of need with various modalities of treatment, all of which are individualized for each particular patient and their family. Families are an extremely important site for intervention and are in fact the anchor to allow for successful integration of treatment modalities for any

adolescent. Even those without families such as those which are in custody of the state, family members still involved, and surrogate families are potent targets for intervention. The determination of how to proceed in all of these areas is only possible with optimal assessment.

137.2.3.1 Assessment

The ideal is for a concurrent disorder assessment to occur at the very start. This is due to the very high comorbidity of adolescent substance abuse with psychiatric disorders. At the same time, we do recognize that the availability of the ideal concurrent enhanced program by the definitions of the American Society of Addiction Medicine is not available in every community/treatment program regardless of whether the primary focus is on substance abuse or psychiatric disorders. Nevertheless, a very high index of suspicion needs to be present with both groups of disorders and, in particular, with the top comorbidities of ADHD ± L.D., oppositional defiant/conduct disorder, mood disorders, and anxiety disorder. The use of well-validated rating scales for these disorders is recommended if symptoms are present and has been the key innovation after years of clinical research. Many of these are in the public domain and so do not require the use of precious resources to acquire (see previous tables), and scoring has been discussed.

The other recommendation is that the assessment process be seen not only as a chance to gather information but as an engagement tool with both patients and families. Although there are many ways of doing so, we at the Addiction Centre, in Calgary, have for over two decades now involved both parents and adolescent patients concurrently for the assessment process including for the substance use history. This process seems to confront the denial and minimization by both adolescents and their families. In this situation, substance abuse is perpetuated by adolescents minimizing and denying the consequences of their use, whereas parents are very aware of the consequences but minimize and deny the extent of the adolescent's use, e.g., *all adolescents experiment and I did it at that age too*. This often blinds them to the rapid development of a SUD especially those at high risk like ADHD. It is also a very good time for education, e.g., younger siblings of the proband with ADHD often also have ADHD and are at risk of using if ADHD is not well treated or not even diagnosed. They also need to be very vigilant for any use of tobacco in the younger siblings as a risk factor to SUD. Finally, parents often are not treated or even diagnosed for their own ADHD, thereby making them a much less effective ally than they are capable of being, if parental ADHD are diagnosed and well treated.

Once the assessment is completed, it is also extremely important that all are informed of the diagnosis and a treatment plan elucidated with the patient and their families. This level of clarity is often not done in favor of offering generic *counseling* or *therapy*. Clinical trials have demonstrated the evidence base of specific therapies versus unfocused *counseling*. Having a diagnosis also holds the patients, families, and the treatment team accountable for the specific interventions and treatments needed to ensure remission of symptoms. The use of very structured written diagnosis and treatment recommendations is suggested due to the presence of parental ADHD and as a result poorer executive functioning that the structure will support. This also helps

the often blended families to communicate with each other and to increase the level of buy-in of various parents and stepparents. In fact, the buy-in of the adolescent is often less important than the buy-in and commitment of families to the successful outcome of treatment (Williams and Chang 2000; Waldron and Turner 2008).

137.2.3.2 Treatment Modalities

The most effective treatment is multimodal (The MTA Co operative Group 1999; Canadian ADHD Resource Alliance Practice Guidelines 2013). This includes family, group, individual, and pharmacotherapy with long-acting ADHD medications. The family therapy includes not only therapy but specific parent skills training. If parents have ADHD or symptoms thereof, assessment and treatment greatly improve their parenting effectiveness. Individual therapy includes the use of cognitive behavioral therapy with more recently a major increase in popularity and use of Motivation Enhancement Therapy. While it is beyond the scope of this review to go in depth into these therapies, all are enhanced by the use of contingency management, or the use of rewards for gains (Carroll et al. 2006). This is also an excellent way to work parental involvement into treatment, as they are then seen as instruments not only of consequences but of rewards thereby further improving the often severe parent-child conflict so often present. Many of these therapies can also be delivered in groups for cost-effectiveness. Unfortunately, group members need to be carefully selected to avoid the often present "contagion" effect, as the negative, acting-out, risk-taking behaviors often have more overt and acute appeal than the hard work of reordering one's life and relationships.

137.2.3.3 Pharmacological Treatment

This was an area of intense discussion and disagreement for some time. On one hand, it was felt ADHD individuals needed anti-ADHD treatment in order to develop the cognitive and follow-up behavioral skills for sobriety. The intense craving for risks and novelty, the surly oppositional and defiant stance and attitude, the impulsivity, the forgetfulness and inattention and lack of follow through, the internal restlessness, and even insomnia and poor sleep of ADHD all conspire to decrease success toward sobriety even if motivated. On the other hand, there were concerns for stimulant abuse and diversion in a substance-abusing population, the risk of medication/street drug interactions in actively abusing individuals, and even the added conflicts to take medications in an already conflicted and discord filled parent-adolescent relationship. Two schools of thought emerged through this:

(a) Concurrent treatment for ADHD and SUD from the beginning
(b) Waiting for sobriety before treatment initiated for ADHD

This was felt to be such an important need that the NIDA funded a study to look just at this issue (Riggs et al. 2011). In this study 303 adolescent participants were randomly assigned to either PBO and CBT or OROS methylphenidate and CBT for their concurrent ADHD and SUD diagnoses, respectively. In terms of efficacy, the primary measures, i.e., adolescent self-reports of both ADHD symptoms and substance abuse, did not show any difference between groups. Yet, the secondary

measures, i.e., objective measures of ADHD by parental rating scale and of substance abuse by urine drug abuse screening, both showed improvements. ADHD with decreasing ADHD R.S. PARENT'S rating scale scores and substance abuse with the number of negative urine drug abuse screens. As far as safety of this strategy goes, (a) there was no increase in medication abuse and diversion and (b) both study groups mixed medication or placebo with drugs and alcohol, but there were very few adverse interactions.

These findings were interpreted by the authors as a negative study based on the negative outcomes on the primary measures. Many of us however who work with this population very regularly make the following observations of the differences between the primary and secondary measures in this study:

(a) Most children are not capable of the insight and awareness to judge changes in ADHD symptoms with treatment. This is why most studies use observer, i.e., parents/teachers rating scales. Adults are more capable of this, with adolescents in the middle.
(b) While it is true that with a good therapeutic relationship adolescents are often very truthful around their use, in others, objective urine screenings are very important. The fact that the numbers of negative screens are different is especially important as most of the adolescents in the study used cannabis. Given the lipophilic nature of the Δ9 THC and its long half-life, this means a very significantly decreased amount of use as it takes the cannabinoid so long to clear the body to result in even one negative urine drug abuse screen.

Practically speaking, then how does one incorporate these findings into clinical practice? To begin with, engagement to treatment is very important. This includes especially the engagement of parents (Williams and Chang 2000; Waldron and Turner 2008). Most often, adolescents even when willing have difficulty following through over time. Yet this is precisely what we are needing, as both SUD and ADHD are chronic disorders requiring longer-term treatment and interventions. Together with engagement, regular urine drug abuse screening is very important to at least see some gains in SUD treatment to demonstrate at minimum some patient motivation. If these conditions are met, then integrated concurrent treatment may begin with one of the long-acting and harder to abuse and divert stimulants or alternative with non-stimulants like atomoxetine. Safety can be boosted further by informed consent as to the risk of concurrent use of street drugs and medication, as well as a strategy to have parents be in charge of giving out the medication while there is active substance abuse happening. This is in fact the recommendation in some national guidelines including our own Canadian guidelines that may be accessed in English or French via the Canadian ADD/ADHD Resource Alliance website, i.e., CADDRA.ca (Canadian ADHD Resource Alliance Practice Guidelines 2013). This website also includes the public domain rating scales for not only child and adolescent but adult ADHD. There are also scales for functioning and even history and physical forms if desired. All are available free for downloads and for members, even an A*sk the Expert* service.

137.3 Conclusion

In conclusion, ADHD and SUD are one of the most common presentations and complications of undertreated or undiagnosed and hence untreated ADHD. This being a very heritable disorder, there is often many other family members with the same condition, including parents, thereby complicating treatment and necessitating very regular family involvement. Treatment of ADHD is absolutely essential to minimize the cost of psychiatric and psychosocial comorbidity for both the patient and their families and for society. It is a significant public health issue as a result. Multimodal treatment is noted to be safe even in the presence of SUD and ongoing substance use and despite being on long-acting stimulant. Outcomes are also noted to be generally positive for both ADHD and SUD with treatment.

Contents

Abstract

The use and abuse of psychoactive substances by women of childbearing age is an important public health problem. Its prevalence is high and for some substances has increased in the past decade, with resultant increases in neonatal morbidity. With advances in fields such as genetics, epigenetics, and neuroimaging as well as improved research methodologies, it has been established that in utero exposure to psychoactive substances is one of the major preventable causes of disorders of fetal and infant/child growth and neurodevelopment. The effects of these neurodevelopmental alterations can appear at any time of the individual's life and can affect a variety of domains including developmental, behavioral, cognitive, and adaptive functioning. Moreover, maternal chronic substance use can compromise the maternal neural circuitries that subserve executive functioning and the regulation of stress response and consequently the ability to appropriately parent children. Expression of the teratogenic effects

of perinatal exposure to substances can be exacerbated by a toxic or unstable prenatal and/or postnatal environment and ameliorated by a nurturing and stable one. Health-care providers play an important role in the prevention, early detection, and intervention for perinatal addiction. This chapter will describe the effects of maternal addiction on the mother, child, and maternal/child functioning and provide recommendations for screening and therapeutic interventions for families affected by perinatal addiction.

138.1 Introduction

The use and misuse of psychoactive substances among pregnant and recently postpartum women is a cause of great concern among health professionals and policy makers. Intrauterine substance exposure affects more newborns than many other common medical conditions and is linked to a variety of adverse outcomes for the pregnancy, the fetus/child, and/or the mother (Lester and Lagasse 2010). Furthermore, addiction can compromise maternal neural circuitries regulating stress responses and behavior, affecting her ability to care for the infant (Rutherford et al. 2011) which can lead to child abuse and neglect. The physiological, behavioral, and neurodevelopmental problems associated with prenatal substance exposure can appear in the fetus, at birth, or at any age and can be transient or persist throughout life causing serious emotional and financial burdens to individuals, families, and society. The management of pregnant women with substance use disorder (PWSUD) and their children is an opportunity and a challenge for both the patients and the health providers. Their identification, assessment, and successful intervention require the knowledge of the particular needs of the mother/infant dyad in the context of their community; the consequences for failing to identify and treat these mothers and children comprehensively may bring undesirable consequences for the dyad and society in general. It is the purpose of this chapter to review the (1) overall scope of the problem, (2) challenges faced by PWSUD, (3) effects of drugs on fetal/infant brain and neurodevelopment, (4) identification of PWSUD and their children, and (5) interventions to help this population of women and children.

138.2 The Problem of Substance Use During Pregnancy

138.2.1 Magnitude of the Problem

The use and misuse of licit and illicit substances is a major cause of preventable disorders of fetal growth and neurodevelopment (Floyd et al. 2009). Concerns about these known effects should lead to increased awareness among health-care providers and communities to the problems of gestational drug use, improvements in care being delivered to at-risk populations, and reductions in the prevalence of toxic exposures during the preconceptional and prenatal periods. Despite this fact,

the incidence of neonatal morbidity associated with maternal substance use has been increasing (Patrick et al. 2012), and the danger of substance use by pregnant women remains an undiminished challenge for the perinatal care provider in the twenty-first century.

138.2.1.1 Preconceptional Period

In the United States, 55 % of childbearing-age women report alcohol use, with 24.5 % reporting binge drinking in the past month (SAHMSA 2012). Women who binge drink in the preconception period are more likely than non-binge drinkers to continue drinking, even after becoming pregnant (Naimi et al. 2003). The use of tobacco among nonpregnant women aged 15–44 is 25.4 % and the use of illicit drugs is 10.8 % (SAHMSA 2012). Although pregnancy is a motivation for many women to stop drug use and to limit or cease smoking or drinking, approximately half of the pregnancies in the United States are unplanned (Henshaw 1998) and unrecognized for weeks or months after conception, putting the fetus at risk during the vulnerable period of early brain development.

In contrast to the attention dedicated to the influence of maternal factors on pregnancy outcome, the role of paternal factors on the developing fetus remains under-researched. The few epidemiological and animal studies that have explored these factors support the idea that paternal substance abuse may have a negative impact on development and that this impact could be caused by chronic substance use prior to conception (Abel 2004). Paternal alcohol use has been found to have influence on infant birth weight, congenital malformations, and cognitive functioning (Ramsay 2010). Paternal smoking has been associated with fetal growth retardation (Davis 1991). Preliminary studies suggest that paternal preconceptional substance abuse can produce heritable changes in genomic expression and phenotype in offspring via epigenetic transmission. However, the mechanisms underlying the role of the paternal substance use on physical and developmental outcomes of the offspring is unclear.

138.2.1.2 Prenatal Period

Tobacco, ethanol, marijuana, cocaine, amphetamines, opioids, and benzodiazepines are the most commonly abused substances, and polysubstance abuse is more common than monosubstance abuse. The prevalence of disorders related to prenatal substance exposure varies by ethnicity, geographic location, and population factors. Among pregnant women in the United States, it is estimated that between 16 % and 30 % smoke tobacco and 7.6–15 % use alcohol regularly with binge alcohol drinking reported in 2.6 %. Five percent of pregnant women report current illicit drug use (Lamy and Thibaut 2010; SAHMSA 2012). Adolescents are a particular concern; in 2010–2011, among young pregnant women between 15 and 17 years, the rate of illicit drug use was 20.9 % and smoking rates are higher in pregnant vs. nonpregnant teens in this group.

Despite its classification as legal in certain areas, marijuana continues to be the most commonly used illegal substance among pregnant women in the United States, with use in the last month figures ranging from 3.6 % in the general

population (SAMHSA 2005) to 23–30 % in urban samples (Fried 2011). This high consumption of cannabis during pregnancy may result from a generalized opinion that marijuana is relatively harmless. However, cannabis use during pregnancy has known harmful effects on the offspring (Campolongo et al. 2009). Between 0.5 % and 3 % of pregnant women use cocaine (Lamy and Thibaut 2010; SAMHSA 2005), and in recent years there has been a marked increase in the use of opioid analgesics in the United States, with prevalence among pregnant women in some communities of up to 17 % based on tests of neonatal meconium (Moller et al. 2010). During the last decade the overprescription, diversion, and misuse of prescription opioid medications have become a major public health burden for maternal and child health (Kellogg et al. 2011). Such an increase is especially concerning because 55–94 % of newborns exposed to opioids prenatally develop neonatal abstinence syndrome (NAS), which can predispose the infant to prolonged hospitalization, significant morbidity, and protracted developmental concerns, all of which are costly to the child, the family, and the health-care system.

138.2.1.3 Postnatal Period

Resumption of substance use following delivery is an additional concern; it has been reported that cigarette, alcohol, binge alcohol, and marijuana use rates were higher in women with a child younger than 3 months of age (20.4 %, 31.9 %, 10.0 %, and 3.8 %, respectively) compared with rates of use in the third trimester of pregnancy (13.9 %, 6.2 %, 1.0 %, and 1.4 %, respectively) (SAHMSA 2007).

138.2.1.4 Children of PWSUD

Although the exact prevalence of individuals affected by prenatal substance exposure is impossible to estimate, there is some data regarding negative consequences of prenatal substance exposure that illustrates the magnitude of the problem. Prenatal smoking is one of the most common preventable causes of infant morbidity and mortality and is associated with 30 % of small-for-gestational-age infants, 10 % of preterm births, and 5 % of infant deaths (CDC 2009). Maternal tobacco use during pregnancy doubles the likelihood of sudden infant death syndrome (Salihu and Wilson 2007). A recent report cites the tripling in the incidence of NAS in the United States between 2000 and 2009 (Patrick et al. 2012). Fetal alcohol spectrum disorders (FASD) are estimated to occur in 1 % of births (Sampson et al. 1997), although some suggest that the rate is much higher. Reporting figures for fetal alcohol syndrome (FAS) range from 0.5 to 2 cases per 1,000 in the United States (Abel 1995; May and Gossage 2001); the risk of FAS is higher in disadvantaged groups (e.g., Native Americans) in the United States with rates of 3–5 FAS affected children per 1,000 live births and up to 68.0–89.2 per 1,000 in the wine-producing regions of South Africa (May et al. 2007).

138.2.1.5 Financial Burden Imposed by Prenatal Substance Exposure

The financial burden of the problems related to maternal substance abuse during pregnancy is multifactorial. For mothers, medical costs are substantial but can be decreased by providing assessment and intervention (Goler et al. 2012). Mean

hospital charges for newborns affected with NAS increased from $39,400 to $53,400 between 2000 and 2009 (Patrick et al. 2012). Studies in the United States and Canada have indicated that the increase in cost of neonatal care for infants born to a cigarette-smoking mother is approximately $700 and the increase in cost for those exposed to cocaine is $5,110 per patient (Chiu et al. 1990; Hutson 2006). The lifetime cost of the care of individuals with FASD is approximately $2 million to $2.8 million across the United States and Canada (Lupton et al. 2004; Thanh and Jonsson 2009). A study by Credé et al. (2011) reported that in the Western Cape (South Africa), $70, 960,053 are spent annually on managing health-care needs of children with fetal alcohol syndrome/partial fetal alcohol syndrome.

138.2.2 Problems Faced by the PWSUD

The neurobiology of addiction and maternal behaviors indicates that the chronic use of drugs by women can lead to morphological and functional changes in the brain that produce a compulsive craving and drug seeking that impairs the woman's daily functioning and may affect mother/infant interaction. Addiction has been conceptualized as a dysregulation of the balance between reward systems and stress response. These two systems need to be organized and regulated to support the demands of adequate parenting practices, self-care, and decision making. Chronic use of drugs has been associated with impairment of memory and attention, executive function and inhibitory control, interoception, and self-awareness (Volkow 2005). Compromise of these functions in a pregnant/postpartum woman may explain how addiction leads to relapse and other unhealthy behaviors that affect the mother's ability to take care of herself, the pregnancy, and the infant. In the addicted mother, substance-induced brain changes can result in heightened stress reactivity as opposed to reward salience to parent–infant interaction, which may amplify negative affect state and increase drug seeking and neglectful parenting behavior, which may in turn lead to child abuse or neglect (Rutherford et al. 2011).

Addiction during pregnancy has been associated with perinatal complications related to the direct effects of the drugs or, secondarily, due to the lifestyle associated with compulsive drug use and seeking, all of which can negatively impact both the health of the mother and the pregnancy. Medical and obstetrical complications include miscarriage, premature rupture of membranes and preterm delivery, placental abruption, intrauterine growth restriction, chorioamnionitis, stillbirth, hypertension, and increased rate of infectious illnesses. Injection of drugs carries the risk of cellulitis and abscess formation, sepsis, endocarditis, hepatitis B, hepatitis C, and human immunodeficiency virus (HIV) infection. Sexually transmitted diseases are not uncommon due to unsafe sex and prostitution (Jansson et al. 1996). Poor decision-making skills can lead to risky sex, violence exposure, high levels of stress, and homelessness. Many pregnant women with substance use disorders seek prenatal care late or not at all even if they have chronic medical problems (e.g., asthma, diabetes, hypertension, seizure disorders) that increase the risk of poor perinatal outcomes. Dental problems are very common due to poor dental hygiene and inadequate nutrition.

A significant proportion of PWSUD have one or more psychiatric diagnoses (Fitzsimons et al. 2007; Wouldes et al. 2013), with this incidence ranging from 45 % to 75 %, depending on the sample. Personality disorders are also common. Psychiatric comorbidity during pregnancy has been associated with delayed prenatal care and unhealthy behaviors such as smoking, poor nutrition, and poor compliance with medical recommendations. Unaddressed maternal psychological symptoms may lead to difficulty managing emotions and stress that can contribute to communication/dyadic interaction problems after delivery and dysregulation of the newborn, making postpartum adaptation difficult for the dyad. Postpartum depression is prevalent among women receiving substance abuse treatment (Holbrook and Kaltenbach 2012). Of particular concern is the evidence that links maternal psychopathology, substance use disorders, and other psychosocial problems with negative parenting behaviors and poor developmental outcomes for children (Wan and Green 2009).

PWSUD very often have a history of traumatic experiences. A past and/or current history of abuse (physical, sexual, or emotional), neglect, abandonment, and family violence are common conditions (Velez et al. 2006). Many women grow up in multigenerational drug-using families, families with significant mental health problems, or environments where chaos, inconsistency, mistrust, and aggression are the norm. All of these situations have a significant impact on how women perceive their pregnancy, the fetus, and the child and contribute to high levels of stress. The perceptual, cognitive, and emotional capabilities of the mother and her parenting skills are built upon the scaffolding provided by her earlier life experiences. In PWSUD, this frequently leads to maladaptive and recurring unhealthy behaviors which originate as a consequence of those traumatic experiences. These maladaptive behaviors can have a negative impact on their general functioning and the well-being of their pregnancy. Inability to appropriately manage stress can lead to increased drug use or relapse to active drug use, violence, and deleterious prenatal practices that increase risks for the mother, her pregnancy, and the developing fetus.

138.2.3 The Effects of Drugs on Fetal/Infant Brain and Neurodevelopment

Negative effects of substance use during pregnancy on the fetus have been presumed since ancient times, with biblical texts and ancient Greek and Roman warnings about infant effects of maternal alcohol use during pregnancy. First described by Paul Lemoine et al. (1968), fetal alcohol syndrome (FAS) was defined as a cluster of serious physical and neurological problems due to prenatal exposure to alcohol in 1973 (Jones and Smith 1973). Beginning in the 1960s, clinicians and researchers described the effects of opioids on neonates exposed to heroin or methadone and defined criteria for identifying and treating infants with “narcotic neonatal abstinence syndrome” (Rosenthal et al. 1964). Teratologic theories of prenatal harm due to individual substances used or abused by pregnant women as the cause of problems encountered in children of PWSD continued into the 1980s.

During the cocaine epidemic in the United States, several studies based on case reports or small samples created the prejudiced portrayal of "crack children" as a harbinger of profound negative effects on the educational, legal, and medical systems (Toufexis 1991). The media attention generated by these reports gave origin to several well-designed, longitudinal studies controlling for environmental and social issues that could influence the neurobiological effects of drug exposure during development. Results of studies carried out in the 1990s indicated that the consequences of prenatal drug exposure on the fetus and child are multifactorial and complex and should be attributed not only to direct effects of the drug on fetal development but to the interaction between genetic, epigenetic, and environmental factors before and after birth (Bandstra et al. 2010; Salisbury et al. 2009).

Most psychoactive substances taken by pregnant women cross the placenta, have a longer half-life in the fetus than in adults, and have higher concentrations in fetal blood than in maternal blood (Finnegan et al. 1992). The psychoactive substance may affect biologic functions either through the binding of the active components of the drug's receptors in the central nervous system or by affecting the release and reuptake of neurotransmitters. Neurotransmitters and neuromodulators appear early during embryogenesis and their signaling serves key functions during neurodevelopment; they are involved in the control of neurodevelopmental processes such as neurogenesis, neural progenitor proliferation, lineage segregation, and the migration and phenotypic specification of immature neurons. Alterations in these processes can change neurodevelopmental trajectories via a variety of actions depending on the substance, the timing of exposure, and the system affected. As an example, prenatal alcohol exposure may disrupt neural development by interfering with myelination, synaptogenesis, and cell migration and by enhancing cell death (Bonthius and West 1991; Chen et al. 1999; Miller et al. 2006; Maier and West 2001). Developmental effects secondary to disruptions in brain development may not become clinically apparent until later in life and may be produced in the fetus at dose levels that are relatively harmless for adults (Frederick and Stanwood 2009; Thompson et al. 2009).

The foundations of brain architecture and function are established early in pregnancy through dynamic interactions between genetic influences and the prenatal environment and experiences (Shonkoff 2012). Though it was previously believed that genetic mechanisms are unchallengeable, expression of early gene networks can be disturbed not only by maladaptive genetic mutations that disrupt important regulatory genes but also by prenatal environmental influences, such as drugs, alcohol, toxins, and inflammatory responses. The effects of the drugs depend on factors such as fetal developmental stage of exposure (critical periods), drug type, dose and use patterns, use of more than one substance, as well as other uterine stressors that are frequently seen in women with addictions. Prenatal substance abuse often occurs in the context of risk factors such as maternal psychiatric comorbidities, toxic stress, exposure to violence, homelessness, poor nutrition, sporadic or absent prenatal and medical care, and lack of social support which can alter the prenatal environment independently of drug exposures per se. Postnatal factors such as nutrition, socioeconomic conditions, parenting practices, and exposure to early adversity can also alter gene expression and modify the processes of brain development in the infant.

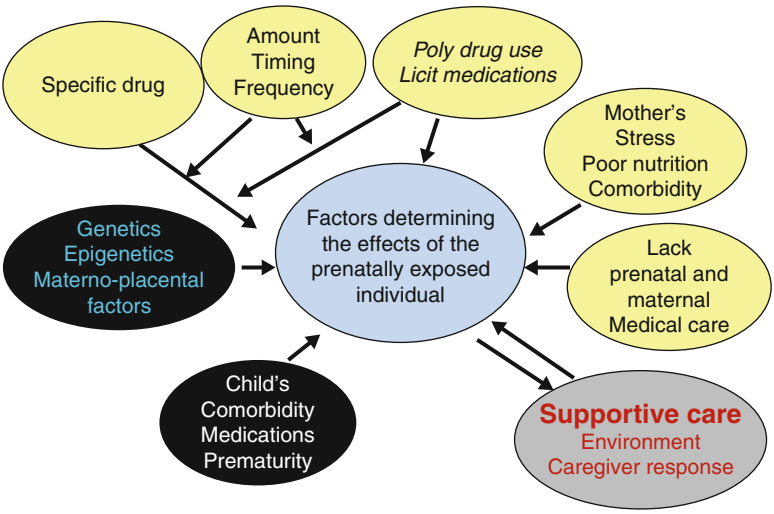

Fig. 138.1 Factors determining the effects of the prenatally exposed individual. These include maternal factors (drug use, medical care, stress), infant factors (including NAS and comorbid pediatric conditions such as preterm birth), and genetic/epigenetic and placental factors

The environment encountered in fetal and neonatal life exerts a profound influence on physiological function and risk of disease in adult life, and multiple risk and protective factors have been investigated for their roles as mediators or moderators of the effects of maternal drug use on the developing child. Recent advances have identified specific genes that appear protective for the development of NAS in opioid-exposed infants (Wachman et al. 2013). In contrast, adverse prenatal environments, including those created by prenatal substance exposure, may result in epigenetic modifications, altered hypothalamic–pituitary–adrenal (HPA) axis activity, and elevated corticosteroid levels in the mother and fetus. These changes, which have been found to occur with cocaine and alcohol (Weinberg et al. 2008; Salisbury et al. 2009; Hellemans et al. 2010), may alter the programming of the fetal neuroendocrine environment, causing the fetus to "reset" or adapt his/her biologic functioning and predispose the child to having an altered expression of key candidate genes leading to problems with behavioral and emotional dysregulation that can impact physical and mental health and developmental trajectory (Lester and Padbury 2009; Lester and Lagasse 2010). Regardless of mechanisms of harm and confounding by other risk factors, it is accepted that children exposed to substances during pregnancy are at increased risk for a variety of conditions that portend future neurodevelopmental and other difficulties. These effects can be seen during the neonatal period or at later stages of development. It is easy to comprehend the wide variation in infant outcome in substance-exposed pregnancies with the myriad factors at play in these pregnancies (Fig. 138.1).

138.2.3.1 Neonatal Period

Neonates exposed to substances during pregnancy are at increased risk for a variety of conditions that can make adaptation to extrauterine life a challenge for the neonate and his/her caregivers and can negatively alter mother/infant interaction and/or the trajectory of development if not recognized and properly treated. The following are the most widely recognized clinical conditions associated with in utero substance exposure during the neonatal period.

Substance-Related Adverse Birth Outcomes

Almost all drugs of abuse have been associated with drug-related adverse outcomes such as preterm birth (e.g., nicotine, alcohol, cocaine, benzodiazepines), low birth weight, and intrauterine growth restriction (e.g., nicotine, alcohol, cocaine, methamphetamine) (Wikner et al. 2007; Plessinger 1998). Many substances used by PWSUD can shorten gestation and impair fetal growth without resulting in preterm deliveries or LBW, as traditionally defined. Small-for-gestational age rather than preterm birth is the main mechanism through which smoking causes excess infant mortality. Epidemiological studies have associated low birth weight with insulin resistance, hypertension, coronary artery disease, and non-insulin-dependent diabetes in later life. A suggested explanation for this association is intrauterine programming in response to alteration in the maternal placenta–fetus unit (Barker 1995). Some studies suggest that about 5 % of infant deaths in the United States are attributable to maternal smoking while pregnant, with variations by race/ethnicity (Salihu and Wilson 2007). Additionally, substance-exposed infants are at higher risk than the general population for maloutcomes due to maternal sexually transmitted diseases or other infections such as TORCH and HIV infections.

Neonatal Abstinence Syndrome (NAS)

Neonatal withdrawal is a group of signs and neurobehaviors experienced by the infant that occur after discontinuation of gestational exposure to psychoactive substances taken by the mother. The symptoms associated with NAS include high-pitched cry/irritability, sleep–wake disturbances, alterations in infant tone and movement (hyperactive primitive reflexes, hypertonicity, and tremors with resultant skin excoriations), feeding difficulties, gastrointestinal disturbances (vomiting and loose stools), autonomic dysfunction (sweating, sneezing, fever, nasal stuffiness, and yawning), and failure to thrive. Opioid-induced NAS symptoms usually begin during the first 4 days of life with the clinical signs escalating over time as the drug is metabolized and eliminated by the newborn. NAS is variable in its presentation in severity of infant display, amount and types of symptoms presented, and onset of symptoms. The Finnegan scoring system was developed as a clinical tool to measure withdrawal in newborns exposed to opiates (Finnegan 1975).

Although the Finnegan scoring system was developed to evaluate symptoms of withdrawal among opioid-exposed infants, this scale has been used in children exposed to other substances. Neonatal withdrawal signs have been reported when

using the Finnegan score in infants exposed to benzodiazepines and alcohol and heavily nicotine-exposed neonates (Godding et al. 2004; Pichini and Garcia-Algar 2006; Coles et al. 1984). Signs of benzodiazepine withdrawal include hypoventilation, irritability, hypertonicity, and "floppy infant syndrome," particularly after use in late gestation. These symptoms can appear within a few days to 3 weeks after birth and can last for several months. A neonatal alcohol withdrawal phenomenon has been described in children born to alcoholic mothers and includes jitteriness, irritability, seizures, opisthotonus, abdominal distention, excessive mouthing movements, and reflex abnormalities (Pierog et al. 1977; Robe et al. 1981). A NAS has been described and disputed for PCP-, cocaine-, and methamphetamine-exposed infants (Behnke and Smith 2013).

Most children exposed to opioids undergo NAS. However, only a portion will require medication for more severe presentations and symptoms that impair adequate functioning of the baby in the areas of feeding, sleeping, growth, and interaction. Evaluation of the infant to determine the need for NAS pharmacotherapy and determination of dosage of medication is usually done using the Finnegan scoring system or a variant of it (Jansson et al. 2009). Opioid medications, such as morphine sulfate and methadone, are recommended for the treatment of opioid-induced (i.e., exposure to heroin, morphine, methadone, prescription opioids, and buprenorphine) NAS (Hudak and Tan 2012). The infant's display of NAS can profoundly affect maternal functioning due to feelings of guilt and subsequently her interactions with the newborn, further compounding the threat to the problematic mother/dyad interaction and the resultant developmental trajectory of the newborn. Non-pharmacologic care (i.e., comforting techniques, modification of environment according to the newborn's needs, education to the parents) should be used with all newborns to support their functioning and development and prevent disruptions in the mother/infant dyad (Velez and Jansson 2008).

Neurobehavioral and Regulatory Problems

Each newborn has a particular repertoire of physiological and behavioral characteristics that depend on the maturation, organization, and regulation of different interactive systems: state control and attention, sensory integration, motor/tone performance, and autonomic control (Als 1982). The direct and/or indirect effects of drugs in the fetus can negatively impact the newborn's functioning in one or more of these domains affecting the newborn's neurobehavioral display and capacity for interaction in an individualized way. These regulatory difficulties experienced by the neonates that are not directly attributed to NAS have been studied for various substances using the Neonatal Behavioral Assessment Scale (NBAS) (Brazelton 1973) or the NICU Network Neurobehavioral Scale (NNNS) (Lester and Tronick 2001). These scales, developed as neurobehavioral assessment tools for normal and at-risk infants, respectively, have been used to evaluate how stressors, such as in utero substance exposure, affect infant self-organizing neurobehavioral capacities and to describe the neurobehavioral effects of in utero exposure to cocaine (Lester et al. 2002), nicotine (Law et al. 2003), marijuana (de Moraes Barros et al. 2006), alcohol (Chiriboga 2003), methamphetamine

(Smith et al. 2008), and methadone (Velez et al. 2009). Using the NNNS, cocaine exposure was associated with lower arousal, poorer quality of movement and self-regulation, higher excitability, hypertonia, and nonoptimal reflexes, with most effects maintained after adjustment for covariates (Lester et al. 2002). Neurobehavioral symptoms described in neonates exposed to nicotine include impairment of arousal, irritability and hyperexcitability, hypertonicity, and signs of stress/abstinence (Law et al. 2003). Neurobehavioral effects of in utero cannabis exposure range from mild deficits in visual functioning, heightened tremors, startling, jitteriness, hypotonia, and lethargy to difficulties with arousal, regulation, and excitability (Fried 1991; de Moraes Barros et al. 2006). Neurobehavioral signs associated to phencyclidine (PCP) after delivery consist of decreased attention, high-pitched cry, poor visual tracking, coarse flapping tremors, lethargy, nystagmus/roving eye movements, poor feeding, and altered newborn reflexes (Strauss et al. 1981; Golden et al. 1987). Poor habituation, low levels of arousal, and motor abnormalities have been identified in infants of heavy alcohol drinking women (Chiriboga 2003). Prenatal methamphetamine exposure has been associated with decreased arousal, increased stress, and poor quality of movement (Smith et al. 2008).

Congenital Malformations

Aside from alcohol, which has a clearly defined pattern of birth defects, studies evaluating the correlation between congenital anomalies and periconceptional drug use generally find inconsistent or no associations (Evans et al. 1979; van Gelder et al. 2009). While a few case reports, retrospective studies, and studies with small samples describe associations of some drugs with particular anomalies, large-scale and prospective studies do not generally confirm these associations (Behnke et al. 2001, 2013). A systematic literature review of studies carried out between 1959 and 2010 found a significant positive association between maternal prenatal smoking and congenital malformations including cardiovascular/heart defects, musculoskeletal defects, limb reduction defects, missing/extra digits, clubfoot, craniosynostosis, facial defects, eye defects, orofacial clefts, gastrointestinal defects, and undescended testicles (Hackshaw et al. 2011). However, these associations have not been found by others (Evans et al. 1979). Minor physical anomalies such as true ocular hypertelorism and severe epicanthus have been reported in heavy users of cannabis (O'Connell and Fried 1984), but there is a lack of a definitive convincing relationship between physical anomalies and prenatal cannabis exposure in general (Astley et al. 1992). Congenital anomalies had been reported in cocaine-exposed infants, but larger recent studies have not documented those associations (Behnke et al. 2001). Infants exposed in utero to phencyclidine (PCP) have been reported to display dysmorphologic features that consist of microcephaly (Strauss et al. 1981) and alterations in facial features (Golden et al. 1980). Isolated cases of cardiac defects, cleft lip, and biliary atresia have been reported in neonates exposed to methamphetamine (Plessinger 1998), but these findings have not been found in other samples (Little et al. 1988). There has been inconstant reporting on the relative risk of congenital anomalies (orofacial clefts) among infants exposed to benzodiazepines (Dolovich et al. 1998; Iqbal et al. 2002).

Malformations associated with alcohol abuse include the dysmorphic facial features seen in fetal alcohol syndrome (FAS) or partial fetal alcohol syndrome (pFAS) (short palpebral fissures, smooth philtrum, and thin vermillion border) and the congenital malformations seen in the alcohol-related birth defects (ARBD) (cardiac defects, eyesight and hearing issues, urinary problems, joint abnormalities, and skeletal problems) (Jones and Smith1973; Stratton et al. 1996). Reports from autopsies of infants with FAS and human imaging studies demonstrate abnormalities in overall brain size and shape particularly in the cerebellum, basal ganglia, and corpus callosum (Clarren 1977; Mattson and Riley1996; Lebel et al. 2011).

138.2.3.2 Problems Related to Individual Substance Exposures

Illicit drugs and licit drugs that are misused are considered neuroteratogens that can compromise critical neural pathways in the developing brain. Although the number and severity of negative effects of alcohol and drugs can range from subtle to serious, they can be lifelong.

Alcohol

Alcohol is generally acknowledged as the leading human teratogen and is the top known cause of preventable neurodevelopmental disorders in Western society (Abel and Sokol 1991; Caetano et al. 2006). The effects of prenatal alcohol exposure vary depending upon timing of exposure, blood alcohol concentration, and patterns of maternal use. Although a dose-related severity of effects has been found, there are no evidence-based studies to suggest that any particular amount of alcohol use is safe during pregnancy. Furthermore, only a percentage (perhaps only 5 %) of women classified as "heavy drinkers" during pregnancy give birth to children who meet diagnostic criteria of FAS (Abel 1995). However, which children will be affected by maternal alcohol use is not predictable, so women should be advised to abstain from drinking during pregnancy or while attempting to conceive.

Alcohol-induced effects on pregnancy and the fetus/infant include prenatal loss, fetal growth retardation, congenital malformations, and neurodevelopmental problems. The different categories of effects related to prenatal alcohol exposure are grouped under the nondiagnostic umbrella term fetal alcohol spectrum disorders (FASD). Four different groups of symptoms constitute FASD: fetal alcohol syndrome (FAS), partial FAS (pFAS), alcohol-related birth defects (ARBD), and alcohol-related neurodevelopmental disorder (ARND).

Fetal alcohol syndrome is characterized by a combination of (1) a specific facial phenotype (short palpebral fissures, a thin upper vermillion, and a poorly formed philtrum), (2) prenatal and/or postnatal growth deficiency (prenatal and/or postnatal height and/or weight at or below the tenth percentile for age), and (3) a range of neurostructural and/or neurodevelopmental defects (Jones and Smith 1973; Hoyme et al. 2005; Astley 2006). Prenatal alcohol exposure may or may not be confirmed in FAS.

Partial fetal alcohol syndrome (pFAS) refers to a less severe FASD in which a child presents with less than three characteristic facial dysmorphic features and

fewer abnormalities in growth or central nervous system structure and function than a child with FAS (Hoyme et al. 2005). Children with pFAS have a confirmed history of prenatal exposure to significant amounts of alcohol but do not meet all of the criteria to qualify for the FAS diagnosis.

Alcohol-related birth defects (ARBD) is a term referring more specifically to physical anomalies associated with prenatal alcohol exposure including malformations and dysplasia (e.g., dysplastic kidneys, ptosis, atrial and ventricular septal defects, neurosensory loss) (Stratton et al. 1996; Jones et al. 2013). Confirmation of prenatal alcohol exposure is required.

Children with *alcohol-related neurodevelopmental disorder* (ARND) have a confirmed maternal history of use of alcohol during pregnancy and normal growth, lack the facial features seen in FAS, and display a pattern of behavioral, developmental, and/or cognitive problems that are inconsistent with the developmental level of the individual. The neurodevelopmental problems cannot be explained by the genetic contribution of the biologic parents or abnormalities in brain maturation related to toxic environmental factors. Neonates affected by ARND can be challenging to care for, due to regulatory problems causing irritability, disordered sleep, and feeding problems (Coles et al. 1984). Infants may have deficits in language and motor skills and attention and impulse control deficits during the toddler and preschool years (Kable and Coles 2004). At school age they can have learning disabilities, social skills deficits, attention and memory problems, and sensory integration disorders (Streissguth et al. 1990). Deficits in attention and arithmetic skills seem to be especially marked and persistent. There are many studies documenting cognitive deficits and behavioral–emotional difficulties in children with FASD (Kodituwakku 2007; Riley and McGee 2005). Deficient adaptive behaviors, with social deficits becoming pronounced as they grow older, have been described. If early detection and intervention for these problems are not provided, secondary disabilities may arise during adolescence and adult life. In affected adults, the implications and effects of the disabilities may involve troubles with the law, mental health problems, inappropriate sexual behaviors, alcohol and drug problems, and problems with employment and dependent living (Streissguth et al. 1996). However, while FASD is a leading and preventable cause of mental retardation, not all people with FASD have cognitive limitations. This fact has important implications, because alcohol-exposed individuals with IQ scores of $\geq$70 (i.e., those not defined as mentally retarded according to current standards) may not qualify for supportive services, despite evidence that these individuals perform poorly on tests of complex attention, verbal learning, and executive functioning. Adaptive functioning is also affected in this population and many individuals identified as having FASD are unable to live or work independently. Therefore, general cognitive ability alone may not be an effective indicator of special service needs in the FASD population.

The magnitude of the health burden (Lupton et al. 2004) combined with the unchanging incidence of FASD, despite efforts to educate the public about the risk of alcohol use during pregnancy, make the early diagnosis of and intervention for maternal alcohol abuse in an effort to prevent damage to the developing brain a high research and public health priority.

Nicotine

Smoking during pregnancy is harmful for the mother and child, with increased risk of prenatal complications such as abruption, placenta previa, perinatal mortality, impaired fetal growth, higher neonatal stress and irritability, neonatal hearing loss, and respiratory problems (Cornelius and Day 2000). Prenatal nicotine exposure has been associated with neurobehavioral deficits manifested as irritability and difficult temperament during infancy and poor self-regulation during childhood. Externalizing behavior problems (Wakschlag et al. 2006) and difficulties in self-regulation, such as aggressive behavior and a higher risk of smoking in later childhood and adolescence (Goldschmidt et al. 2012), have been consistently associated with prenatal nicotine exposure.

Marijuana

Due to improved greenhouse technologies for the growth of cannabis, concentration in marijuana and hashish of delta-9-tetrahydrocannabinol (THC) – the main psychoactive ingredient of marijuana – has significantly increased during the past decades. Cannabis is the world's third most popular recreational drug used during pregnancy after alcohol and tobacco, and it is the most frequently used illegal substance during pregnancy in the Western world (SAHMSA 2009). Despite its popular use, there are few studies exploring the long-term effects of THC on the developing brain. Recent research has found that the endocannabinoid system plays a key role in prenatal and postnatal brain development, and its activation by exogenous agonists may cause alterations in the brain development that can have long-term neurofunctional alterations (Fried and Smith 2001; Campolongo et al. 2009). In utero THC-exposed infants exhibit an exaggerated startle response, tremors, sleep disturbances, poor habituation to visual stimuli, and irritability in neonates (Fried and Makin 1987). During the preschool years, deficits in verbal reasoning and short-term memory have been reported (Day et al. 1994). Adolescents that were prenatally exposed to THC may have impaired executive functioning in two domains: (1) problem-solving tasks that require complex visuoperceptual integration and (2) attention/impulsivity (Fried et al. 2003).

Cocaine

There is a large body of literature describing the effects of cocaine exposure in the developing child. During the neonatal period, cocaine-exposed neonates display signs of altered neurobehavioral regulation including state lability, altered sleep patterns, deficits in orienting and attention, and increased irritability (Chasnoff et al. 1989). Beyond the neonatal period, deficits in arousal regulation during cognitive tasks (Mayes 2002), greater reactivity, and reduced ability to modulate emotional and physiological responses to environmental stimulation during challenging tasks have been noted in cocaine-exposed infants. Other studies have reported behavior problems (Bada et. al. 2007; Bendersky et al. 2006), language (Beeghly et al. 2006), cognition (including poor sustained attention), and motor function problems. Some studies associate prenatal exposure and psychopathology (ADHD and oppositional defiance disorder) as well as substance use (Delaney-Black et al. 2011) in cocaine-exposed offspring.

Benzodiazepines

One of the most frequently prescribed class of drugs during pregnancy, despite the absence of complete knowledge of their potential adverse effects, benzodiazepines also are commonly abused licit drugs, and exposure often is unrecognized or ignored due to inconsistent screening policies. Studies evaluating the neurodevelopmental effects on exposed children have yielded mixed results, with some reporting delayed motor development and neuropsychological symptoms (Gentile 2010).

Methamphetamine

Methamphetamine is a popular illicit drug used recreationally worldwide, particularly among young adults in the United States, Europe, and Australia as part of the dance club culture. There is a limited amount of research regarding the long-term effects of methamphetamine exposure in utero (Lester and Lagasse 2010). However, there is a growing evidence from ongoing longitudinal studies that children at 3 and 5 years of age display more behavioral and emotional problems, including emotional reactivity, anxiety, depression, and social withdrawal. Five-year-old children had more attention–hyperactivity and externalizing behaviors (Lagasse et al. 2012).

Opioids

Long-term studies of children exposed to opioids are scarce, and most lack adequate control groups and have small sample sizes which preclude statistical adjustment for confounding variables, are cross-sectional, and evaluate global functions. Hyperactivity and short attention span have been noted in toddlers prenatally exposed to opiates (Rosen and Johnson 1985), and preschool children exposed to heroin demonstrated memory and perceptual problems (Wilson et al. 1979). There is no consensus from available studies about the effects of opioids on cognition. Some studies showed associations between exposure to methadone (Hans 1996) and heroin (Orney et al. 2001) and ADHD.

138.2.4 Identification of PWSUD and Their Children

138.2.4.1 Identification of Women with SUD

There is general agreement that the universal use of screening tools for alcohol/drug use among women of childbearing age will significantly decrease the incidence of problems related to substance exposure. This population of women are stigmatized by society and are perceived (and often view themselves) as having deviated from the traditional societal norms expected of women in their suitability as mothers and caregivers (Beckman and Amaro 1986; Toner et al. 2008). Women often have difficulty acknowledging their problems with substance use, and professionals are reluctant to ask women about drug and alcohol use. Health-care providers may be explicitly or passively judgmental toward the woman causing her to be unreceptive to needed health care. Therefore, women of childbearing age often enter the health-care provider/patient relationship with a feeling of shame and distrust. Such fears

are often justified in the United States, because many states have punitive laws in place for pregnant women who use drugs. Such policies often contribute to patient unwillingness to admit substance use and missed opportunities for education, support, and intervention. The result is that such women are likely to continue to use alcohol and drugs for the remainder of their pregnancy, arriving at labor and delivery unregistered, with an increased risk of adverse maternal and infant consequences (Svikis and Reid-Quiñones 2003). Even when they do seek treatment, women face practical and financial barriers to access treatment that is gender specific.

138.2.4.2 Identification of Women at Risk for SUD During Preconception

Despite a steady increase in the incidence and problems related to in utero substance exposure, use of substances during pregnancy remains underdiagnosed. Therefore, the preconception period is an important time to identify women at risk. Improving preconception health and health care can improve pregnancy outcomes by improving the overall health of women. A high proportion of pregnancies are unintended (86 % in one study of postpartum women in substance abuse treatment program), and WSUD frequently have menstrual irregularities and chaotic lifestyles making pregnancy detection difficult (Elko and Jansson 2011). In addition, conception frequently occurs during times of active alcohol/drug use/abuse, and use can continue during the early and critical stages of fetal development. Therefore, increasing universal screening and counseling during the preconception period is an important aim to improve perinatal outcomes and prevent neurodevelopmental problems. There are essentially two methods of screening for substance use disorders that can be used during the preconception and prenatal periods: maternal interview/report and biologic specimens.

Maternal Interview Screening

The US Preventive Services Task Force, the American College of Obstetrics and Gynecology, and the American Academy of Pediatrics recommend that universal screening for substance use become a routine at any preconception, prenatal, or any encounter with sexually active women and men of childbearing age. All pregnant women, regardless of socioeconomic status and/or any perceived risk, should be asked about past and current licit and illicit substance use. Maternal self-report has been commonly used but has been found to be unsatisfactory to detect exposure when compared to biologic markers. A high index of suspicion and sensitivity for substance use combined with an open-ended, nonjudgmental, and repeated questioning of pregnant women is therefore necessary to reduce reluctance to admission to use. There are several structured questionnaires that can be used. Tools that have been used in pregnant women include AUDIT-C (Alcohol Use Disorders Identification Test), T-ACE (Tolerance, Annoyance, Cut down, Eye-opener), and TWEAK (Tolerance, Worry about drinking, Eye-opener, Amnesia, K/Cut down). Other screening tools used are 4Ps plus (Parents, Partner, Past, Pregnancy), TQDH (Ten Question Drinking History), CAGE (Cut down,

Annoyed, Guilty, Eye-opener), MAST (Michigan Alcohol Screening Test) and DAST (Drug Abuse Screening Test). The full AUDIT instrument, the abbreviated AUDIT-C, and single-question screening ("How many times in the past year have you had five [for men] or four [for women] or more drinks in a day?") have the best performance characteristics for detecting the full spectrum of alcohol misuse (Jonas et al. 2012). Screening, Brief Intervention, and Referral to Treatment (SBIRT) is an evidence-based practice used to identify, reduce, and prevent substance use disorders in different health-care settings. SBIRT gives health-care providers skills to discuss health behavior changes with their patients and has proven particularly effective at motivating individuals to change harmful substance use. SBIRT has three components: (1) screening to determine the severity of substance use; (2) brief intervention to build motivation through supportive conversation, and (3) referral to treatment directly linking the patient with needed services (SAHMSA 2009).

Documentation of the interview and confirmation or not of maternal substance use should be recorded and information regarding maternal substance use transferred to appropriate health-care providers (i.e., obstetrician, anesthesiologist, pediatrician) to ensure a continuum of care (Sarkar 2009).

Biologic Specimens

The use of biologic specimens to screen for substance use has inherent difficulties. It does not give information about use patterns, is variably accurate depending on substances screened for and testing used, and can cause unintended legal consequences. Maternal and neonatal urine screening are most commonly used and have the lowest cost but only provide information about use in the last part of gestation (exceptions to this are marijuana, the metabolites of which can be excreted for as long as 10 days in the urine of regular users and 15 or up to 30 days in chronic, heavy users, and benzodiazepines, which can be present in urine up to 30 days) and have low sensitivity (high false-negative rates). Meconium analysis is more sensitive and supplies information about use in the second and third trimesters when meconium is formed, but does not reflect periods of drug abstinence closer to delivery. Meconium may be difficult to collect (before contamination by transitional stool) and its passage may be delayed, particularly in preterms, delaying the diagnosis. Meconium testing has high false-positive rates; for example, for opiates, only 59 % of positives are confirmed by GC/MS (Brahm et al. 2010). Prior to testing, clinicians must be aware of legal requirements and the need for consent, which vary by state in the United States. Hospital policies should comply with local laws and avoid discriminatory practices.

138.2.4.3 Identification of the Individual Exposed Prenatally to Substances

In order to provide prevention and intervention programs to reduce the incidence of problems related to maternal substance use, it must be identified as early as possible. Obtaining an accurate history of prenatal exposure to alcohol and/or

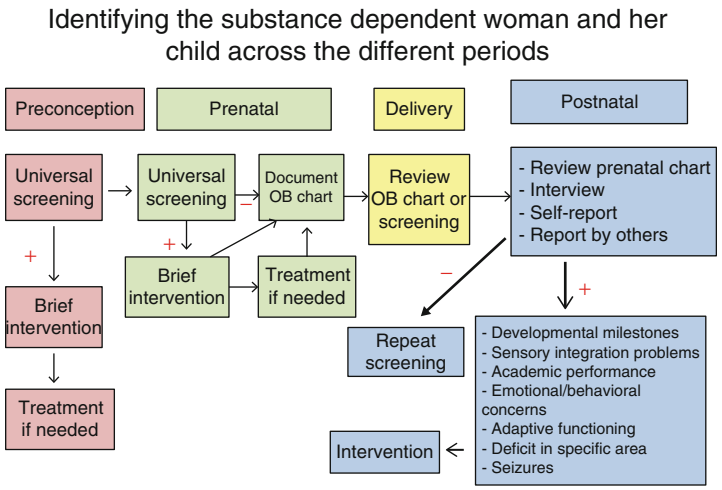

Fig. 138.2 Identification of the childbearing woman who uses/abuses substances should occur at several points during preconception and gestation and be multipronged, to include universal screening, review of the medical and social history, and maternal interview screening, as well as evaluation of the infant/child

other drugs is regarded as crucial for arriving at a diagnosis (Douzgou et al. 2012). Risk factors suggesting substance abuse during pregnancy include lack of prenatal care or late prenatal care, poor compliance with obstetric appointments, poor weight gain, cigarette smoking, skin infections, marks of injection (tracks), and preterm labor.

To date, there are no biologic markers to confirm or refute with certainty a syndrome or phenotype of children with problems related to prenatal drug exposure. This is a diagnosis of exclusion based on medical and alcohol/drug exposure history together with suggestive clinical signs. Infants with a suspected diagnosis of substance exposure or NAS should be evaluated using a scoring system such as the Finnegan. For children beyond the neonatal period, there are several nonspecific situations that can indicate suspicion of prenatal substance exposure in the absence of known causes, which include developmental delays, sensory integration problems, emotional and behavioral problems, poor academic performance, seizures, or deficits in specific functioning of the child (Fig. 138.2). The diagnosis of problems related to prenatal substance exposure is complex. Because it carries lifelong consequences, early recognition and treatment can result in a better outcome for the child that receives a diagnosis.

Underdiagnoses or overdiagnoses are not beneficial for the child or the family. The most important role of the clinician in the assessment of children with suspected problems related to prenatal substance exposure is to rule out alternative or coexisting diagnoses. Metabolic testing of urine or blood for other conditions and

imaging and/or chromosomal or SNP studies are a decisive approach in eliminating other causative factors including genetic abnormalities.

A history of prenatal alcohol exposure, necessary for a diagnosis of pFAS, ARND, or ARBD may be difficult or impossible to obtain. As a result, several scoring systems have been proposed, of which the 4-Digit Code (Astley 2006) and the Revised Institute of Medicine criteria (Hoyme et al. 2005) are the most widely used. The differential diagnosis includes only a small number of other dysmorphic syndromes, which can be excluded by a clinical geneticist. The American Academy of Pediatrics in concert with the Centers for Disease Control and Prevention created a schema to guide medical home providers through effective FAS/FASD screening, early identification, management, and referral (AAP and CDC 2006).

138.2.5 Interventions for PWSUD and Their Children

138.2.5.1 Preconception and Prenatal Counseling

Perinatal care providers have several opportunities during the preconception period and pregnancy to identify and assist women who have substance use problems. Those women found to have a positive screening for substance use can receive a brief intervention or be referred to receive a comprehensive diagnostic evaluation and intervention. This process can be facilitated by using the principles of motivational interviewing. Brief interventions that address substance use in a nonspecific way, in the context of several other potential health risks, may be useful. Brief interventions include short counseling sessions, feedback, advice, and goal-setting conducted by health-care providers. Even brief counseling has demonstrated effective in reducing the amount of drinking in pregnant women and the rate of morbidity in their offspring.

Pregnant women who are identified as having a substance use disorder should receive a multistep management approach that includes comprehensive individual and or group therapy concerning the adverse maternal and fetal/newborn impact of continued use and comprehensive prenatal care with identification of and intervention for medical and obstetric problems associated to substance use. Referral to a multidisciplinary team for drug rehabilitation and a high-risk pregnancy specialist for ongoing fetal surveillance should occur; appropriate additional referrals may include counseling to deal with preexisting trauma and or psychiatric comorbidity and assistance with other social determinants of health (e.g., food and housing) (Fig. 138.3), as women with fewer social supports are less likely to seek or remain in treatment. Additionally, partner participation in prenatal care and addiction treatment is very important to the woman's recovery; partner's active drug use has been associated with delayed treatment time for pregnant women seeking care. Comprehensive care, including health care and developmental and behavioral assessment, for existing children who may have suffered through the darkest days of their parent's addiction prior to their entry into medical care should additionally be incorporated into the care plan for any parenting woman.

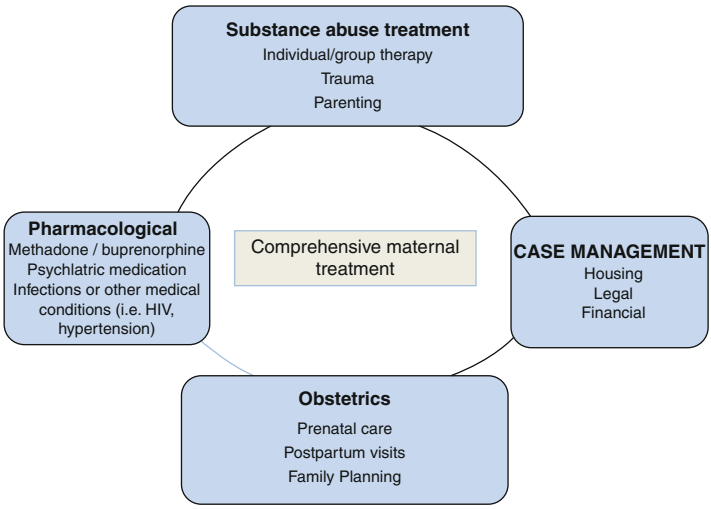

Fig. 138.3 Comprehensive treatment of the substance-dependent pregnant woman. Treatment of the pregnant woman who uses/abuses substances should be comprehensive in nature and incorporate behavioral treatment; medical/obstetric/psychiatric care with pharmacologic treatment, including methadone or buprenorphine maintenance, as warranted; and the identification and provision of social support structures

138.2.5.2 Pharmacologic Treatment During Pregnancy

Any pharmacologic treatment during pregnancy requires a clear and thorough discussion of the risk–benefits of the medication between the health-care provider, the mother, and the significant other when appropriate. Pharmacologic treatment for PWSUD includes medications for medical problems (i.e., HIV, hypertension), psychiatric comorbidities, and maintenance medications for the treatment of drug dependencies, such as in opioid-assisted therapy (Jones 2013). Daily maintenance with methadone or buprenorphine reduces the risk of relapse, increases retention in obstetric and substance abuse treatment, and may improve lifestyle for women addicted to opioids by reducing criminal activity and avoiding risks to the patient of association with a drug culture. Both medications must be viewed as a central aspect to treatment but should be given as part of a comprehensive treatment approach that also includes obstetrical care, medical care, case management, life and parenting skills, and counseling. These other components of care are needed to help empower women with opioid-use disorders to overcome the many complex, intertwining factors that served to set the context for their initial and/or continuing use of opioids. Although the benefits of treatment with methadone and buprenorphine are well known, a large number of infants exposed to these medications develop NAS. A study comparing the effects of these two drugs suggests that infants exposed to buprenorphine need less morphine for treatment of NAS and shorter duration of treatment and have shorter periods of hospitalization than children of mothers treated with methadone (Jones et al. 2010). The rationale for opioid-assisted therapy during pregnancy is to

prevent complications of illicit opioid use/licit opioid misuse and cycles of narcotic overdose and withdrawal in the mother.

138.2.5.3 Postpartum Care of the PWSUD

Comprehensive postpartum follow-up for PWSUD is necessary, with appropriate referrals to a primary care provider, a psychiatrist if needed, and social services when warranted to ensure that the newborn has a safe home environment. Working to ensure that women with substance abuse disorders engage in safe sex practices and family planning is a constant challenge; these women are disproportionately overrepresented among women with unplanned pregnancies and sexual violence.

138.2.5.4 The Mother/Child Dyad: Postnatal Period

Both maternal substance use and many of the medications used to manage the addiction and/or psychiatric symptoms have been associated with negative effects on the neonate (i.e., low birth weight, prematurity), NAS, and/or difficult adaptation of the newborn. Challenging neonatal behaviors such as irritability, uncoordinated movements, dysregulated sleep–wake patterns, hypertonicity, and autonomic signs of stress, frequently displayed by a neonate affected by prenatal substance exposure, can initiate altered caregiver behaviors, which have been considered an additional teratogenic effect of prenatal substance exposure. Children exposed to substances frequently have dysregulated nervous system functioning. They may have spontaneous or provoked changes in body tone, disorganized movements, and/or tremors that create great anxiety in the caregivers. They can have alterations in autonomic functioning and exhibit skin color changes (mottling, perioral cyanosis), tachypnea, fevers, or yawning/hiccuping. They can have difficulty managing a smooth transition between wake and sleep states and move rapidly from one extreme to the other without managing to achieve a quiet alert state, which is the state that infants use to provide cues to their caretakers. They can become overwhelmed by seemingly minimal sensory input, such as sights, sounds, touch, and/or movement, or display hyposensitivity to stimulation. They struggle with processing sensory information and either cannot process certain sensory inputs or they may react in adverse ways to even minimal sensory information. Learning to tolerate the early sensory experiences (i.e., touch, sound) is one aspect of developing early self-regulation. Problems with sensory integration are found in children that later present with learning disabilities and mood and behavioral problems. Infants with these difficulties require early recognition and appropriate interventions in order to facilitate a developmental trajectory toward more regulated, adaptive, and integrated responses that facilitate basic functions such as feeding, organized sleep–wake patterns, growth, and healthy child/caregiver interactions. Perinatal health providers should be trained in the special needs of these children to be able to help the infant and educate the parents.

All substance-exposed infants should receive non-pharmacologic supportive management of any symptoms beginning at birth regardless of the need for

medication for NAS. These interventions are designed to (1) individualize the care of the infant, based on behavioral observations, with the goal of promoting organization, physiological stability, and competence; (2) modify the environment to support autonomic, sensory, motor, and attention/interactive development; and (3) encourage parental involvement with their infant (Velez and Jansson 2008).

A child suspected of having NAS should be hospitalized for a minimum of 72 h for evaluation and identification of symptoms that may need pharmacologic treatment. This evaluation can be done using the Finnegan scoring system (Finnegan 1975) or a variant of it (Jansson et al. 2009). These tools are applied every 3–4 h for the infant's entire hospitalization. When the infant reaches a threshold score that indicates difficulties in feeding, sleeping, or interacting with their environment, medication is used. Medications most frequently used to treat the opioid-exposed infant are morphine sulfate and methadone (AAP 2012). Breastfeeding is not contraindicated in many substance-dependent women who are able to access treatment, which may include methadone or buprenorphine maintenance, and achieve sobriety and have no other medical contraindications to lactation, but each dyad should be individually assessed regarding their suitability for this practice (Jansson 2009).

The primary care pediatrician has an important role in addressing prenatal substance exposure, which includes ongoing assessment of the infant, his caregivers, and his environment (Jansson and Velez 2012). This includes (1) assistance with maternal difficulties surrounding her substance use/abuse (i.e., referrals to appropriate social services that can provide assistance with substance abuse treatment, psychiatric care, and contraceptive services) and awareness of how those difficulties impact the health and development of the child, (2) identification of infant/child difficulties related to exposures or parenting difficulties, (3) evaluation of his/her ongoing protection from situations related to drug dependence in his/her parents (i.e., violence exposure, safety issues surrounding maternal or paternal relapse to drug use, parental psychiatric issues), and (4) careful medical and developmental follow-up of the exposed infant (Behnke et al. 2013). Mothers of substance-exposed children may be afraid to seek evaluations and interventions (i.e., assessment for problems related to FASD) for fear of being labeled a "bad" or incompetent parent or due to her own difficulties dealing with the guilt for causing the problems in the child. Judgmental or punitive health-care provider attitudes will cause further reluctance on the mother's part to engage in necessary health care. Neurodevelopmental, behavioral, academic, and emotional problems in childhood related to prenatal substance exposure can have both lifelong and intergenerational effects. Identifying and addressing these concerns early in life is essential, not only for the individual child and his/her parent(s) but to break the multigenerational cycle of addiction and victimization that often exists in substance-using families. In these cases, pediatricians must be able to step out of their traditional role as health-care provider to the child only to recognize and address the issues that are of critical importance to pediatric health, namely, issues that involve principally the parent and the environment created by parental difficulties with addictions.

Substance-exposed children and their mothers may have CNS disabilities (either preexisting or due to drug use) that can range from subtle to serious, with affected individuals presenting variable combinations of emotional regulatory deficits, deficits in memory, information processing, social skills (including pragmatic language and social communication skills), attention, and executive functioning, as well as significant behavioral and mental health issues. As a result, the interventions for a child, adolescent, or adult affected by prenatal exposure and his/her family vary according to these factors. Interventions designed to address neurodevelopmental problems associated with substance exposure require multidisciplinary assessment and care that is individualized and unique to the dyad, coordinated, compassionate, and comprehensive.

138.2.5.5 Parenting in the Substance-Dependent Mother

Mothers of children prenatally exposed to drugs or alcohol may themselves have neuropsychological impairments that can affect their abilities to parent their children properly. These impairments can be caused by chronic substance abuse, psychiatric comorbidity, poor parental models and childhood adversities, and/or their own prenatal substance exposure (Rutherford et al. 2011). Substance-dependent women often have compromised judgment and difficulties with communication and conflict resolution and struggle to navigate their own personal relationships and safety issues while attending to their children's safety, attachment issues, and emotional dysregulation, all of which increase their vulnerability to maladaptive parenting (Hume et al. 2006) and continued drug use or relapse to drug use. Other frequent conditions such as lack of social support, abusive domestic relationships, involvement with the criminal legal system, homelessness, and poverty are major factors that, if not addressed, may contribute to dysfunctional parenting, child neglect, and maltreatment and to the cycle of intergenerational substance abuse, violence, and mental health problems. At a program level, parenting education for substance-dependent adults is essential in the treatment of themselves and their children. However, while the provision of information and support is necessary, it is not enough (Shonkoff 2012). The promotion of resilience in a substance-exposed child faced with the biologic vulnerability created by prenatal exposures depends upon the availability of parenting adults who can help children develop effective coping skills necessary to restore physiological and behavioral homeostasis and reduce disruptions in their developing brain circuitries. Essential to this process is the capacity of the parent to provide buffering protection for the children's developmental progress through their own skills which include parental self-awareness, self-control, problem solving, planning, monitoring, and self-regulation (Shonkoff 2011). These skills areas are frequently underdeveloped or altered in one or both parents. The likelihood is, therefore, relatively low that these skills will be sufficiently strengthened by the simple education about child development or parenting recommendations. Training or coaching strategies that center on the parental skill set that includes executive functioning, emotion regulation, and social skills offer a promising new direction that is worthy of investigation, especially for

parents whose needs are not sufficiently addressed by existing support. An example of this mother/child model may be found in the "Mothering from the Inside Out" program. In this model, substance-using mothers struggling to manage their addiction as they also parent their children participate in therapy focusing on problem solving and coping emotionally with the everyday stresses of being a mother. This program is based on an attachment-based intervention that focuses on building in the mother reflective functioning and the capacity to attend to her own and her child's mental states in order to promote secure attachment and emotional development in the dyad. These services are offered in conjunction with outpatient substance abuse treatment for the mother. Mother/child interaction is facilitated by a developmentally trained child care team, and the treatment center functions as a milieu that facilitates the dyad's regulatory functions (Suchman et al. 2011; Mayes et al. 2012).

In summary, the prevalence of use/abuse of psychoactive substances among women before, during, and after pregnancy remains high and constitutes one of the most common preventable causes of child morbidity. Studies looking at the costs of children affected by prenatal substance exposure show that the burden of care seems disproportionately high compared to the resources spent on education, prevention, and specific treatment. Prenatal substance exposure can disrupt fetal neurotransmitter systems, brain circuitry, and other important regulatory systems in ways that continue to influence physiology, behavior, and health at birth or decades later. Any health-care professional in contact with a childbearing-age or parenting woman and/or her child plays a critical role in screening women for substance use during pregnancy and initiating appropriate interventions, as well as in the early diagnosis and ongoing treatment of children affected by prenatal substance exposure both biologically and environmentally. Although identification and intervention for women and children affected by prenatal substance use is critical, primary prevention (reducing the number of women of childbearing age who abuse legal and illegal drugs) and secondary prevention (recognizing and reducing the use of drugs among pregnant women) are also necessary. Inclusion of repetitive counseling to abstain from alcohol and drug intake for women in the perinatal (preconception, pregnancy, parenting mother) health examination is essential. Men and women of childbearing age and the general population must be informed that no safe level of alcohol or drug consumption during pregnancy has been established. Services that enhance the mental health, executive function skills, and self-regulation capacities of vulnerable mothers, beginning as early as pregnancy, suggest promising strategies to protect the developing brains of their children. It is of extreme importance to raise awareness of the impact of alcohol/drug use and to encourage the use of effective screening tools to reduce the incidence of problems related to prenatal substance exposure, which can profoundly impact not only the individual and his family but the health care, education, and legal systems as well as society. Only through the cooperative investment of providers of all specialties can truly universal screening and intervention take place for these high-cost, high-risk families.

Integrating Translational Science with Adolescent Addiction Treatment: Treatment Implementability and Relapse Prevention

139

Will M. Aklin and Jessica C. Chambers

Contents

Abstract

The integration of translational science into adolescent addiction has the potential to greatly improve treatment outcomes and relapse prevention. This chapter highlights several promising substance abuse interventions for adolescents and ways to improve treatment outcome, implementability, and relapse prevention through integrating translational research findings into treatment. Areas of research that focus on potential behavioral and neurobehavioral targets have direct implications for treatment efficacy and build on the current treatments that have been successful. With a better understanding of these processes and their influence on treatment of youth, such findings may provide information on increasing treatment acceptability. This is of great public health importance, given the clear relationship between initiating, remaining in treatment,

long-term abstinence, and relapse. Developmentally appropriate, targeted treatments are likely to be more efficient and potent, require less staff time, lead to less relapse, and, ultimately, reduce the burden on providers.

139.1 Introduction

The integration of translational science into adolescent addiction treatment is intuitively appealing. Comprehending this integrative relationship is important in terms of understanding adolescent substance abuse behaviors, treatment processes (e.g., outcomes, dropout, treatment implementability), and relapse. Further developing the integrative relationship by moving beyond descriptive studies to theoretically driven models of behavior change and treatment in adolescents has the potential to greatly improve treatment implementability and relapse prevention. However, to truly understand this relationship of integrating translational science with adolescent addiction treatment, it is important to first highlight current adolescent addiction treatments and explore potential theoretical frameworks that may guide this work. The purpose of this chapter is to highlight empirically supported addiction treatments for drug-abusing youth. In lieu of providing a theoretical explanation after every highlighted treatment, an executive summary of potential behavioral targets that show considerable promise in their integration will be provided at the end of the chapter. Finally, implications for treatment efficacy, implementability, and relapse prevention will be discussed.

The majority of treatments shown to work for adolescent drug abusers have been family-based therapies, although a few combined (e.g., MET/CBT) treatment packages have shown promise. A number of these therapies are highlighted below. For a comprehensive review of adolescent drug abuse treatments, please see Macgowan and Engle (2010), Rowe (2013), Waldron and Turner (2008), and Winters et al. (2011).

139.2 Treatment for Adolescent Drug Abusers

139.2.1 Family-Based Therapies

Family-based therapies primarily treat drug abuse indirectly, through improving family functioning, but also directly, through impacting each system in which the adolescent functions (e.g., family, school, extracurricular activities).

139.2.1.1 Multisystemic Therapy (MST)

MST is an individualized, intensive home-based treatment program that focuses on family, school, neighborhood, and the social network factors that contribute to antisocial behavior. The ultimate goal of MST is to improve family functioning and leverage these improvements to facilitate healthy and sustainable changes

in the youth's environment (Henggeler 2011). MST has a strong evidence base demonstrating treatment efficacy for substance-abusing and substance-dependent youth (Henggeler et al. 1999, 2002, 2006). Not only does MST decrease drug use, it also decreases days in out-of-home placement (Henggeler et al. 1999), violent crimes, and criminal arrests (Henggeler et al. 1999). In addition, research has shown that MST, in conjunction with drug court, may enhance substance use outcomes for alcohol and marijuana and that treatment fidelity may be linked with decreases in drug use and other outcomes (Henggeler et al. 2006). For reviews of this research, please see Sheidow and Henggeler (2008) and Henggeler (2011).

139.2.1.2 Multidimensional Family Therapy (MDFT)

MDFT is a comprehensive and multisystemic family-based, outpatient program. MDFT targets four domains: (1) youth as an individual and with family and peer group, (2) parent as an individual and within the family context, (3) family functioning, and (4) interactions between family members and key social systems (Liddle 2002). Studies have shown the efficacy of MDFT in reducing substance abuse (Liddle et al. 2001, 2008, 2009; Liddle 2002, 2010; Liddle and Dakof 2008), improving school performance (Liddle et al. 2001, 2009), and improving family functioning (Liddle et al. 2001, 2009) in polydrug users, as well as marijuana- and alcohol-only users. The reductions in substance use have been maintained up to 1 year following treatment (Liddle and Dakof 2002; Liddle et al. 2008) for high-risk early initiators (Liddle et al. 2009) and for youth involved in the juvenile justice system (Liddle et al. 2001). Furthermore, findings suggest that MDFT may be particularly useful in treating cases of high severity and frequency of use and comorbidity (Liddle et al. 2008). For an overview and review of findings from research on MDFT, please see Liddle (2010).

139.2.1.3 Brief Strategic Family Therapy (BSFT)

BSFT targets self-sustaining changes in the family environment. The main therapeutic techniques fall into three categories: (1) the therapist initially "joins" the family by encouraging family members to behave as they normally would while the therapist is present, (2) then he/she diagnoses repetitive patterns of family interactions, (3) and finally he/she restructures family dynamics to promote new, more adaptive patterns of interaction. The primary goals of BSFT are to eliminate or reduce the adolescent's use of drugs and associated problem behaviors ("**symptom** focus") and to change the family interactions that are associated with the adolescent's drug abuse ("**system** focus"; Szapocznik and Hervis 2003). In addition to efficacy for drug abuse treatment for youth (Robbins et al. 2011; Santisteban et al. 2003), BSFT is associated with high levels of engagement of family members (Robbins et al. 2011) and in improving conduct problems and delinquency (Santisteban et al. 2003) and family functioning (Robbins et al. 2011; Santisteban et al. 2003). BSFT has primarily been studied with Hispanic youth samples.

139.2.2 Motivational Enhancement Therapy (MET) and Cognitive Behavioral Therapy (CBT)

MET/CBT is a combined treatment package (Dennis et al. 2002; Sample and Kadden 2001). The initial sessions include MET, which aims to elicit intrinsic motivation to change substance abuse by resolving client ambivalence. CBT follows, with a focus on helping individuals become abstinent. The underlying assumption of CBT is that learning processes play an important role in the development and continuation of abuse and dependence and that these same learning processes can be used to help individuals reduce their drug use. Much of the evidence for the efficacy of MET/CBT for adolescence comes from the Cannabis Youth Treatment studies (CYT; Dennis et al. 2004). CYT consist of two large-scale studies of adolescent treatments. Two combinations of MET/CBT (MET/CBT5 – two individual MET sessions, three group CBT sessions; MET/CBT12 – two individual MET sessions, ten group CBT sessions) were found to be efficacious in treating adolescent marijuana abuse. Results favored MET/CBT5.

139.2.2.1 Improving Adolescent Treatments Through Translational Science

One approach to improve empirically supported treatments that exist currently is through the integration of translational science. Specifically, translational research is one way to guide the integration of neuroscience into the development, refinement, adaptation, and implementation of adolescent drug treatment. In other words, translation frameworks aimed at applying basic science to the development of treatments for disorders in clinical populations have considerable promise to enhance drug treatment efficacy, potency, implementability, and relapse prevention. For example, neurobiological research on brain plasticity has demonstrated that the brain circuitry changes as a result of *actual* behavior change that occurs during treatment (e.g., Kolb and Gibb 2003). Recent technological advances in structural and functional neuroimaging have made it possible to observe these brain circuitry changes and measure the associated behavioral changes that occur during the course of treatment, all of which have the potential to inform the treatment process.

Recent compelling data suggest that behavioral, neurobehavioral, and/or neuroendocrine targets (e.g., impulsivity, risk-taking propensity, delay discounting, sensation, and novelty seeking) play an important role in substance abuse/dependence, treatment dropout, relapse, and treatment outcome. There is great potential in research to understand the malleability of these neurobehavioral processes and in developing and testing novel treatments and/or modules that specifically target them. We will provide a brief summary of these potential processes below.

Impulsivity

One possible target that has been well studied and linked to addiction in youth is impulsivity. The focus on this behavioral index is not surprising, given that substance abuse and other comorbid conditions include impulsivity within the

diagnostic criteria. Further, substance use itself has been conceptualized as impulsive behavior (e.g., Lane et al. 2003; Reynolds et al. 2006). However, beyond the general documentation of impulsivity in drug-using youth (i.e., greater levels of impulsivity are related to greater levels of addiction; Kirby et al. 1999; Krueger et al. 2002; Moeller et al. 2001), there is reason to believe that levels of impulsivity may be differentially associated with variations in risk (e.g., injection drug users may have highest levels of pathology and impulsivity) and should be considered during treatment and in relapse prevention.

Understanding how addiction and impulsivity converge, as well as the contextual profiles in which they occur, would permit interventions to be targeted toward specific needs and goals for given individuals or subpopulations. Not only would this provide a strong theoretical framework, but it also would help to better individualize assessment approaches and evaluation throughout the course of treatment. It is essential for these assessment and evaluation tools in the treatment context to capture variables related to decision making (i.e., personality and behavioral) that have been linked to drug use in youth.

Risk-Taking Propensity

With regard to the intersection of impulsivity and treatment outcome, risk-taking propensity may be one potential predictor underlying treatment dropout or adherence. Traditionally, risk-taking propensity is conceptualized as one's decision to engage in a particular behavior that balances the probability of unpredictable rewards and punishments (Byrnes et al. 1999; Leigh 1999). For example, while drug use produces reinforcing effects, there remain potential but generally unpredictable punishers that may include compulsive drug seeking, withdrawal, adverse health effects, and criminal penalties. With respect to risk-taking propensity as a behavioral target in treatment, available studies indicate that engagement in risk-taking behaviors often is established during adolescence and remains as major contributors to the health problems of adults (Aklin et al. 2005; Lejuez et al. 2002, 2005, 2007; Mitchell et al. 2008). There is a clear need to develop assessment tools that can effectively identify adolescents most vulnerable for engaging in risk-taking behaviors and developing dependence. Indeed, the ability to prospectively predict future engagement in risk-taking behaviors would have profound effects on the ability to develop tailored treatment approaches. These elements need to be studied empirically and translated into developmentally appropriate interventions for adolescents.

Delay Discounting

Delay discounting (DD) is described as a choice preference between a "smaller sooner" reward and a "larger later" reward, with increased DD referring to a more rapid loss of value over time. Specifically, the relative inability to wait for a larger reward (delayed gratification) is often considered to reflect personality traits of impulsivity and a failure of inhibitory control. Extant data suggest that DD decreases with age (Steinberg et al. 2009) and that the greatest changes occur during mid-adolescence.

Increased "delay discounting" (DD), i.e., choosing the "smaller sooner" reward, is particularly severe in populations characterized by drug use, dependence, and other disorders characterized by poor self-control (Bickel et al. 2012). Repeated testing of DD behavior suggests that individual differences remain relatively stable between different potential rewards (Odum 2011). With respect to drug abuse findings, a recent comprehensive meta-analysis (MacKillop et al. 2011) of dozens of case-control comparisons indicated that 75 % of studies found (on average) more severe DD in the substance-using group compared to matched controls.

Several longitudinal findings also have indicated that DD behavior at baseline is moderately prognostic of initial drug use in youth (Audrain-McGovern et al. 2009) as well as predictive of relapse following substance abuse treatment (MacKillop and Kahler 2009). Researchers have begun to study the extent to which DD behavior is malleable with intervention, where specific training that targets working memory has spillover benefits to reduce DD behavior (Bickel et al. 2011). Because brain systems implicated in DD develop at different rates, adolescents may be particularly vulnerable to making poor decisions around substance use. The plasticity of DD during adolescence may provide a unique window to intervene and reduce DD. Germane to adolescent addiction treatment, the dual systems theory predicts that problematic DD behavior might be remedied by bolstering the executive system in some subjects, but tamping down the approach/impulsivity in other subjects (to the extent that these are separable).

139.2.2.2 Theoretical Perspectives

Given the promise of behavioral and biological targets as components of adolescent addiction treatment, it is important to highlight some theoretical perspectives that may be useful to guide this work. Although there are a number of theoretical approaches in the literature, a comprehensive review of each perspective is beyond the scope of this chapter. Instead, we will provide a sampling of perspectives that have been studied extensively and have the potential to be integrated into adolescent addiction treatment and relapse prevention.

From a developmental perspective, adolescence is a unique period of peak vulnerability for engaging in substance abuse (Ernst et al. 2006; Spear 2000). Adolescents are more at risk for initiating substance use and progressing toward dependence than adults (Chambers et al. 2003). This vulnerability for drug addiction may rely on similar features of reward function as those characterizing externalizing disorders. Therefore, examining normative neurodevelopmental changes in reward function may prove helpful in understanding mechanisms that underlie addiction. Following this idea, neuroimaging studies are beginning to shed light on the neurobiological development of reward function during adolescence (Bjork et al. 2004; Ernst et al. 2005; van Leijenhorst et al. 2006). These studies may greatly inform current knowledge on the development of reward-related disorders such as substance abuse and assist in tailoring developmentally appropriate treatments to enhance treatment outcomes and prevent relapse.

Another widely cited framework is the social-cognitive model (Bandura 2001). The social-cognitive model explains how people acquire and maintain certain behavioral patterns, while also providing the basis for intervention strategies. Although this model was not developed with specific reference to any one drug, it has relevance to and compatibility with translational science. In addition to providing adolescence with the behavioral means and other treatment resources, there is a sizable gap between simply possessing self-regulative skills and being able to use them effectively under difficult circumstances, which requires one to exercise impulse and/or self-control.

In line with a neurobehavioral perspective, increased risk for drug addiction may reflect a vulnerable reward system in adolescents, particularly among youth with comorbidity (Chambers et al. 2003). The pattern of the developmental trajectory of addiction may provide valuable information about the contribution of reward function of addiction and developmentally appropriate treatment strategies for youth. Two basic types of reward-related mechanisms have been proposed to underlie drug addiction, and these models are based on opposite assumptions. One mechanism describes a hyperactive reward system that results in the search for more rewarding stimuli. The other posits a hypoactive system that requires more reward exposure to maintain homeostasis. The latter model, also called the allostatic model, has been proposed by Koob (2002). Such a framework would predict enhanced reward consumption without leading to faster progression across addictive stages (Koob 2002; Spear 2000). Irrespective of which reward patterns are operative, having a better understanding of the characteristics of reward-related behaviors and susceptibility to addiction for youth has the potential to inform targeted treatments that integrate neurobehavioral findings.

139.3 Conclusion

This chapter highlighted several promising substance abuse interventions for adolescents and ways to improve treatment outcome, implementability, and relapse prevention through integrating translational science findings into treatment. Areas of research that focus on potential targets have direct implications for treatment efficacy and build on the current treatments that have been successful. Considering the context of the larger literature on impulsivity, risk-taking propensity, delay discounting, and drug abuse treatment, novel targets as core features of treatment have the potential to improve retention, compliance, long-term treatment outcomes, and implementability and relapse prevention. For example, youth with increased levels of risk-taking propensity may be prime candidates for specialized treatment and other supportive measures, whereas standard protocols of treatment may well be adequate for youth with lower levels of risk-taking behavior. With a better understanding of these processes and their influence on treatment among youth, such findings may provide information on increasing treatment acceptability. Additionally, the integration of these processes is of great public health importance,

given the clear relationship between initiating, remaining in treatment, long-term abstinence, and relapse. Developmentally appropriate treatments targeting individual differences in these processes have the potential for enhanced treatment implementability. These targeted treatments are likely to be more efficient and potent, require less staff time, lead to less relapse, and, ultimately, reduce the burden on providers. The series of studies and the corresponding theoretical perspectives of each, as covered in the chapter, suggest potential value of targeting youth with high levels of impulsiveness to receive modified and/or specialized treatment modules. Perhaps an emphasis on effective decision-making skills, risk modulation, behavioral control, and treatment adherence may be especially important in addiction treatment for youth. However, these are empirical questions that should be subject to scientific inquiry.

Section XII

Education and Training

Nady el-Guebaly and Cornelis A. J. de Jong

Education and Training: An Introduction

140

Nady el-Guebaly and Cornelis A. J. de Jong

This section on Education and Training appropriately concludes the textbook. Following the exposé of the breadth and depth of the knowledge base in Addiction Medicine, the first part of the section presents several select examples of the valiant efforts conducted in several countries to educate and train the next generation of practitioners in the field. Some countries focus on primary care, others have a focus on specialties. The process is universally incremental.

The first chapter by Drs. De Jong and Luycks describes the 2-year Dutch Master in Addiction Medicine (MIAM) leading to, in 2012, Addiction Medicine being recognized as a medical specialty by the Royal Dutch Society of Medicine (▶ Chap. 141, "Addiction Medicine Training in the Netherlands"). The curriculum involves a theoretical course of 1 day a week and training in clinical practice 4 days a week in accredited facilities by approved clinical supervisors. The competencies required are outlined and are concretized in 29 Characteristic Professional Situations (CPSs) in Addiction Medicine. For all these CPSs, tools are developed for assessment and examination.

The second chapter by Drs. Crockford and el-Guebaly reviews the core training requirements developed over the last 10 years under the purview of Canada's two colleges, the College of Family Physicians and the Royal College of Physicians and Surgeons (▶ Chap. 142, "Medical Education in Addiction and Related Disorders: The Canadian Experience"). There is no formal subspecialty recognition at this point with

N. el-Guebaly (✉)

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment: International Perspectives*, DOI 10.1007/978-88-470-5322-9_159,

the colleges struggling with some 45 similar requests for subspecialty status from other fields. The training requirements and objectives in family medicine and psychiatry are detailed.

The third chapter by Dr. Welle-Strand describes the steep course towards recognition of Addiction Medicine as a specialty in Norway based on a governmental Drug Reform Action Plan initiated in 2007 (▶ Chap. 143, "Development of a Full Medical Specialty in Addiction Medicine: The Norwegian Experience"). The plan was pursued with the eventual support of the National Medical Association, the Council for Specialists and Specialist Education, and the Ministry of Health. The training requirements and competencies are being both developed and implemented.

The fourth chapter in this first part is by Drs. Parawita Ayu, Schellekens, Iskandar, Pinxten, and De Jong (▶ Chap. 144, "The Development of a National Training Program on Addiction Medicine in Indonesia"). It outlines the laudable efforts in Indonesia to replace the traditional criminalization of addiction by a public health approach with a training course based on the Dutch model. The Bandung Addiction Working Group has undertaken to start a national training program, including distant learning. However, a proposed short course is still seeking governmental support. Furthermore, the occasional 1-h lecture at the undergraduate level at the Atma Jaya University has been replaced by a 5-week elective. The course will be scientific, evaluated on its effectiveness on changing attitudes of future medical doctors towards addicted patients in a positive direction.

The struggle for recognition has been supported by the development of educational resources available to an international audience, and the section's second part describes examples of such resources.

For the last decade, the International Society of Addiction Medicine (ISAM) has undertaken to develop a test of knowledge based on a pool of 225 multiple choice questions with a committee chaired by Dr. el-Guebaly. Repeated administration of the examination to 110 applicants from 13 countries so far has demonstrated the validity of this process, along with challenges to be overcome.

The second resource by Dr. Bryant describes a project aiming at identifying an optimal pathway to navigate the extensive available literature as a part of Evidence-Based Addiction Medicine. Designed from the experience of Hubert H. Humphrey Fellows training in the United States and taking advantage of Open Access literature repositories, optimal resources available to translate research into practice are recommended.

The development under the auspices of NIDA of a network of International Fellowships for research training has added a much needed new resource for the development of an international workforce of investigators. The range of opportunities is described by Dr. S. Gust, the Program Director.

Another new resource has been the development of the Treatnet program under the auspices of both UNODC and WHO. Dr. Saenz et al. describe the experience gleaned from the project's results along with emerging themes and lessons from its implementation, including combating the social stigma attached to the field.

Last, but not least, the practice of Addiction Medicine as a resource in pain management has been identified as one of the new frontiers of the field. Dr. Murnion describes the curriculum developed by the International Association for the Study of Pain (IASP).

From this section on Education and Training, a number of conclusions emerge. The initiatives described are uniformly recent ones and are at various stages of development. Until recently, there was little international awareness of each other's national efforts, and it is hoped that the section will promote more international collaboration and support and may even be a catalyst for long-distance learning.

We still lack a clear picture of undergraduate education at various medical schools as in many countries each designs its own. This is important because almost every medical doctor will be confronted with addicted patients. A well-designed curriculum will presumably help to destigmatize addicted patients but will also bring to the fore that Addiction Medicine can be an interesting field for future doctors.

Consensual strategies are emerging. More and more countries seem to be adopting a framework of competencies similar to the CanMEDS model as well as education being perceived as a lifelong process.

Concerning the training in different countries, we must conclude that there is no "one size model fitting all." The journey towards specialty recognition must adapt to local educational and licensing requirements that govern the national practice of medicine. Opportunities must be seized, often as the result of societal peaks in awareness or workforce crises. Different career paths or remuneration issues may affect the optimal recommendations needed.

Some countries have adopted a focus on primary care; others have a focus on specialties including psychiatry, internal medicine, and community health; and most are adopting a two-prong approach. Addiction affects every medical practice.

The process is universally incremental and currently in transition creating unique challenges in implementation but also opportunities for international group support.

Addiction Medicine Training in the Netherlands

Contents

Abstract

Since 2007 there is a full-time, 2-year professional training in addiction medicine in the Netherlands. In 2012 addiction medicine is approved as a medical profile specialty by the Royal Dutch Society of Medicine. The aim of this chapter is to describe the present status of the Dutch Master in Addiction Medicine (MiAM). In this competency-based professional training, theoretical courses are integrated with learning in clinical practice under guidance of an experienced clinical teacher. The theoretical courses consist of evidence-based medicine, communication and basic psychotherapeutic skills, neurobiology of addiction, addiction medicine, addiction and psychiatry, clinical leadership, and public health. The seven main competencies are concretized in so-called

Characteristic Professional Situations (CPS) which are integrated in the personal education plan (PEP) and are evaluated by different ways of examining. The ways in which the residents are assessed and examined are described as well as the way in which the quality of the MiAM is managed.

141.1 Introduction

Addiction medicine should be made interesting for young physicians (DeJong and van de Wetering 2009; Soyka and Gorelick 2009). Therefore, training and research facilities for physicians are to be improved to stimulate their interest in this challenging area of medicine. In this chapter we will describe the way of training physicians in addiction medicine in the Netherlands. The professional training to get a Master in Addiction Medicine (MiAM) started in 2007 and is competency based from the start (Carraccio et al. 2002). This means that the residents are trained to combine knowledge and skills in the context of their daily work in addiction treatment services or other mental health facilities. The theoretical courses are given 1 day per week; skills are trained in every practice by a clinical teacher with due experience in addiction medicine. The historical background is described in detail elsewhere (DeJong et al. 2011).

In 2005 the medical directors of the leading addiction treatment facilities took the initiative to develop a nationwide professional Addiction Medicine Training (AMT) course for promising physicians.

This initiative fitted well in the growing attention in medical associations and employers in mental health and addiction treatment field to improve the quality of care given by professionals.

Between 2006 and 2007 we developed a state-of-the-art curriculum for a 2-year full-time professional training in addiction medicine. SPON Post Academic Education in Health Care organizes the MiAM. SPON is a cooperation between the Radboud University and the Foundation of Organizations of Post Academic Education in Health Care in Eastern Holland (www.spon-opleidingen.nl).

During 2007–2012, a lot of accomplishments were made (DeJong et al. 2013a). The first group started in 2007, and since then, five groups of approximately 20 medical doctors each started with the MiAM. In 2012 we had a pool of 23 training facilities. Several graduates are now involved in the MiAM as lecturers or clinical teachers; some of them are Ph.D. candidates. Parallel to the course for the residents, an intensive training program for clinical teachers was developed and implemented. The MiAM is now embedded in the Faculty of Medical Sciences within the postgraduate curricula of the unit Primary Health Care together with the curricula for general practitioners, occupational medicine specialists, and geriatric medicine. To become approved by the Royal Dutch Society of Medicine (RDSM), an extensive educational program had to be written (Luijkx 2012). Based on this program, addiction medicine is recognized as a medical profile specialty in 2012, and the register is opened for qualified doctors in June 2013. This means that residents in the Dutch MiAM can be registered as soon as they are graduated and

that they have the same status as other profile specialists. The Dutch medical system is comparable with the ones in other EU members.

In this chapter we will describe the present state of affairs of the Dutch MiAM and the status of addiction medicine specialists in medicine.

141.2 Master in Addiction Medicine (MiAM)

141.2.1 Addiction Medicine Training: State of Affairs

141.2.1.1 Competencies of Addiction Medicine Specialists

The aim of the professional training is to teach the residents to become competent addiction medicine specialists in the addiction treatment and mental health facilities. To find out at the start in 2006 what should be integrated in our theoretical program, we made use of several sources in major textbooks (Levin et al. 2004; Chappel 2005).

In our opinion a competent medical doctor is able to perform a professional activity adequately in a specific context. He can do that because knowledge, insights, skills, personal attitude, and characteristics are present in an integrated way (Carraccio et al. 2002).

The competencies for the addiction medicine specialist are derived from the model of the Royal College of Physicians and Surgeons of Canada (Frank et al. 1996), the CanMEDS 2005 Physician Competency Framework "Better standards. Better physicians. Better care" (Frank 2005), the Profile of the Dutch addiction medicine specialist (VVGN 2008), the Dutch Profile Psychiatrist (NVVP 2005) and international programs for addiction psychiatry (http://www.acgme.org/acWebsite/home/home.asp), criteria for international certification in addiction medicine (http://www.isamweb.org), and the SAMHSA (Center for Substance Abuse Treatment 2006).

The goals of qualification in seven domains of competency are summarized in Table 141.1.

141.2.1.2 Educational Concepts

In the MiAM, we use a "student-centered approach" (Mickelson et al. 2009); this means that the resident takes an active and central role in the learning process. For example, the individual goals of every MiAM resident are (self)assessed at the start of the training and are written down in the personal education plan (PEP) together with the planned activities to reach these goals. They are based on the seven aforementioned competencies. The PEP is an instrument for the resident to design their learning process and for the clinical teacher to monitor this process.

Critical reflection plays an important part in the curriculum. The ideal process of reflection is described by Korthagen (1992). The model is based on Kolb's experiential learning cycle (Kolb 1984) (see Fig. 141.1) that involves concrete experience followed by observation and experience followed by forming abstract concepts followed by testing in new situations.

Table 141.1 Goals of qualification of addiction medicine specialists in seven domains of competency

Domain of competency	Goal of qualification
Medical practice	The addiction doctor shows professional conduct and has knowledge and skills to the position of the field. It allows him/her to collect data and to interpret them, so that diagnostic and therapeutic and evidence-based decisions can take place within the boundaries of the discipline and expertise. He/she gives up-to-date effective care, in an ethically responsible way. He/she combines his own clinical expertise with the most recent scientific findings and the preferences of the patient
Communication	To ensure that the levels of high quality of patient care and patient satisfaction are maintained, the addiction doctor communicates in an effective and respectful way with patients and their environment. The addiction physician practices a clear, transparent, effective, and efficient way of communication. It involves both verbal and nonverbal communication. He/she takes care of responsible shared decision-making procedures
Collaboration	The addiction doctor knows the structure of health care, social services, and the organization. He/she participates in a network of functional relationships and makes optimal use of available expertise of other professionals
Knowledge and science	The addiction doctor is characterized by his/her commitment to increase his/her knowledge and skill in addiction medicine. He/she may raise questions emerging from his/her clinical practice and is able to answer them following the principles of evidence-based medicine including critical appraisal of the scientific literature. The addiction doctor promotes both his/her own expertise in the field of addiction medicine and also that of all professional fellow actors. He/she will preferably engage in scientific research projects
Operating in the social domain	The addiction doctor is able to weigh the interests of the patient in relation to the interests of other people asking for help and other social interests. Central is practicing in such a way that it meets the requirements of the medical profession and the society in general. Included in the social and cultural context are knowledge of medical ethics, law, and legal aspects
Organization of care	To be able to function efficiently and effectively as addiction doctor, he/she endeavors to optimize the healthcare organization he/she is working for. The addiction doctor is able to manage his/her own work, as well as those of others. The addiction doctor takes decisions relating to the use or deployment of resources and staff, setting goals and priorities, and making policy, and he/she organizes the work to a balance between professional practice and the need for further development of themselves and the organization
Professionalism	The addiction physician provides patient care in an honest, sincere, and committed way. The aforementioned competencies are integrated in an adequate way. He/she takes responsibility for his/her actions and keeps the right balance between personal and professional roles. He/she knows the limits of his/her competence and acts within it or calls in other experts. He/she puts himself on testable. He/she records in a responsible manner patient data. He/she participates in the scientific society of addiction medicine. He/she recognizes ethical dilemmas, has insight into the ethical standards, and adheres to the law. He/she is aware of his role model within health care

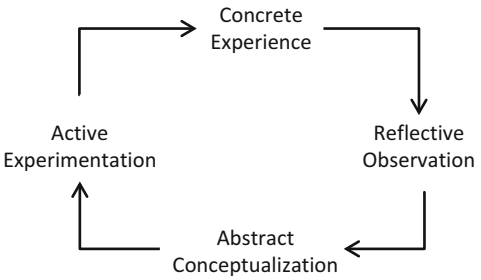

Fig. 141.1 Kolb's circle of learning

Kolb describes the force of experience and reflection on that experience: "Immediate concrete experience is the basis for observation and reflection. These observations are assimilated into a theory from which new implications for action can be reduced. These implications of hypotheses then serve as guides in acting to create new experiences." This experiential learning cycle shows close resemblance with Popper's evolutionary approach of objective knowledge (Popper 1973) and fits well with the basic of Evidence-based medicine (Sestini 2010).

The residents use three important sources of input in their learning process. They are stimulated to reflect on their own experiences in clinical practice; they can make use of the extensive experience of their clinical teachers and of the scientific knowledge of the teachers in the theoretical course. In the curriculum these three aspects are integrated. The whole training is a process of bringing practical experiences into the theoretical course and vice versa. It's a permanent, iterative process of education. The clinical teachers, employees of addiction treatment centers, and the theoretical teachers strengthen this iterative process with their knowledge about practice and theory. The level of knowledge and practical work is examined constantly, for instance, by means of evaluations of assignments, presentations, and video recordings.

141.2.1.3 General Aspects Program of the MiAM Program

The curriculum of the 2-year MiAM is divided into a theoretical course at the Radboud University in Nijmegen 1 day a week and training in clinical practice 4 days a week in addiction treatment facilities or in general mental hospitals with a specialized department for psychiatric patients with co-occurring substance-related disorders. Both aspects are highly integrated as is described in the Training Plan for Addiction Medicine, developed by the Dutch Society of Addiction Medicine (Luijkx 2012).

The MiAM training is designed along six central themes: diagnosis and intake, treatment, psychiatric comorbidity, somatic comorbidity, public health and prevention, management, and safety. These themes are integrated in the six modules of the theoretical course. For all themes the competencies are described in more or less general terms. For instance, in the theme diagnosis and intake, the competency communication is divided in ten phrases such as "He uses

motivational interviewing in the diagnostic phase and is able to handle the five core skills of motivational interviewing." It is quite hard to formulate more exactly what a resident has to learn. Therefore, 29 Characteristic Professional Situations (CPS) in addiction medicine are defined, ranging from "an alcoholic patient with impairment in executive functions" to "an addicted pregnant woman with ongoing harmful substance use for the fetus." For each CPS the knowledge aspects to be addressed in the theoretical courses are described as well as the competencies that are to be observed in clinical practice. For both aspects the ways of assessment and examination are described in detail in a test-book.

141.2.1.4 Starting a Learning Group

In the 2-year course in addiction medicine, the residents start the first and second year with a retreat of 3 days at a monastery. The first retreat focuses on getting to know the other trainees and the trainers. Therefore, the more serious parts, such as short academic lectures and role-playing, are alternated with group activities like singing, dancing, and performing. This is in part based on the philosophy that learning is fun. However, the goal of the exercises is also to raise the awareness of the verbal and nonverbal communication of the resident on a patient as partner in a conversation.

141.2.1.5 Theoretical Courses in AMT

The theoretical part of curriculum is organized in six modules (Table 141.2) with the following main topics:

1. Evidence-based medicine, communication, and interaction
2. Neurobiology of addiction
3. Addiction medicine
4. Addiction and psychiatry
5. Public health
6. Clinical leadership and management of care

The first five modules are introduced in the first year and are explored in depth in the second year. The sixth module is given in the second year. For all modules detailed course books are written by the teachers and are available in Moodle, our digital learning management system (LMS). Moodle is a free web application of such an LMS. It offers not only the possibility for placing course books in it but also for sending assignments to residents, for sending them back to the teachers, and for reviewing them by the teachers. All residents can make use of an iPad in the classrooms.

141.2.1.6 Training in Clinical Practice

All potential clinical training facilities are visited and inspected before they are certified as such. The inspection is carried out according to a checklist approved of by the professional group and that follows the guidelines of the Dutch Medical Society.

Table 141.2 Examples of the themes in the six modules of the MiAM

Module	First year	Second year
Evidence-based medicine (EBM)	How to practice EBM	Writing a single-case study based on EBM principles
Communication and interaction	Motivational interviewing	Individual coaching
		Family and system encounters
		Dealing with moral dilemmas
Neurobiology of addiction	Neuroembryology, neuroanatomy, neurophysiology, neurotransmission, neurogenetics of addiction Neuropharmacology of main psychoactive substances	Neurobiology of related psychopathology (i.e., aggression) and psychiatric syndromes (i.e., ADHD, PTSD, bipolar disorder, OCD)
Addiction medicine	Epidemiology, assessment and diagnosis, and approaches to management of the main psychoactive substances (detoxification, relapse management, maintenance treatment) according to guidelines	Assessment, diagnosis, and management of substance-related disorders and related somatic syndromes (internal medicine, neurology, gynecology) according to EBM principles
Addiction and psychiatry	Psychiatric assessment and diagnosis, integrated treatment for dual diagnosis, involuntary treatment, pharmacotherapy	Assessment, diagnosis, and management of substance-related disorders and related psychiatric syndromes (autism, schizophrenia, personality disorders, anxiety and mood disorders, ADHD, and PTSD)
Clinical leadership and management of care	Knowledge and skills for leadership, development of professional attitude, facilitation of collaboration, and strengthening the organization and for improving professional communication, development, and maintenance of a continuum of care shared with professionals, patient, family/environment, and organizations/institutions involved in prevention care and treatment of addiction	
Public health	Principles of general public health; international perspective; funding of healthcare system; juridical framework; general mental health care; epidemiology, prevention, organization, and finance of mental health care; Dutch policy of addiction and addiction care; disease management	

Evaluation of the professional, scientific, and educational qualities of the clinical trainer is an important part of the inspection. At the start of the MiAM training, there were no formally trained clinical teachers so a teaching program for the trainers accompanies the residents' professional training. Therefore, all clinical teachers are involved in a parallel training program to improve their qualities on these three domains.

Working with addicted patients is challenging for the young professional and stirs a lot of reactions in healthcare providers including medical doctors (Forrest 2002; Imhof 1995). Therefore, all residents have an individual psychotherapeutic

supervisor. During 60 h, spread over the 2 years, they can reflect on their own functioning in relation to patients, colleagues, managers, and so on. The supervisors are highly skilled psychiatrists with a psychotherapeutic background and not in a hierarchical position towards the resident.

The training in clinical practice is given by a medical doctor with extensive experience in addiction medicine or addiction psychiatry. The clinical teacher helps the resident to bridge the gap between theoretical knowledge and practical experiences. To do this in an optimal way, the clinical teacher has full access to the LMS of his or her resident. At the start of the professional training, the clinical teacher helps the resident to make up the PEP. This personal plan is evaluated and adapted at the end of the first year and is used as an instrument for testing the competencies at the end of the second year. In weekly meetings with the resident, the clinical teacher makes use of direct clinical exposure, video recording of encounters, examination of taped sessions, and a standardized instrument on nonverbal communication, interpersonal behavior, and motivational interviewing skills (Norcini 2003) to give corrective and normative feedback.

141.2.1.7 Integration of Theory and Practice: Evidence-Based Medicine and Conversational Skills

Besides the six central themes, the curriculum has two cornerstones: evidence-based addiction medicine and communication and psychotherapeutic skills.

The principles of evidence-based addiction medicine are cornerstones for the six modules of the theoretical course and for the practical training. Firstly, the theoretical course is given by experienced researchers who are preferably active in patient care. On the other hand, the clinical teachers are stimulated to become active as researchers and in scientific writing. Secondly, we use national and international evidence-based guidelines if available for well-defined diagnostic and therapeutic interventions. Thirdly, the residents are trained in evidence-based medicine as initially defined by Sackett et al. (1997; Scott Richardson et al. 2007). They learn how to develop searching strategies for finding answers on questions from their own consulting room and appraising in a critical way scientific publications found (CAT) and then applying these results into daily practice. Thus, evidence-based addiction medicine is a goal in the sense that they practice addiction medicine according to accepted guidelines, but even more important it is a method for reducing their insecurity in everyday practice by means of searching professional literature, critically appraising the findings, and applying it in their own practice. In all parts of the theoretical curriculum, the residents practice these EBM competencies in an assignment in which they have to perform a literature search and a CAT for one of their own clinical problems. Finally, the students have to write an EBM scientific paper in the format of a single-case study that will be peer reviewed and has to be accepted for publication. The papers of the first groups are published in a book (DeJong et al. 2009). The residents get support in scientific research and writing by experienced scientists.

Just like evidence-based medicine, conversational skills are of the utmost importance for effective and high-quality care for patients with substance-related disorders. Communicational and psychotherapeutic skills are basic skills for an addiction medicine specialist. Communication and motivational enhancement are essential parts of the daily work for they are integrated in the training of all residents in medicine (Leung et al. 2009). Details of this important part of the MiAM are described elsewhere (DeJong et al. 2013b).

Most residents in addiction medicine don't have an educational background in such skills. Therefore, we start the 2-year curriculum with an intensive 3-day retreat focusing on conversational skills. In a competency-based training, the first question should be how experienced the residents are at the start of the training? The assumption is that different residents, with different backgrounds, have different entrance levels. This becomes clear during the first training retreat. Three trainers give short introductory lectures on general aspects of medical consultations; motivational interviewing, interpersonal communication, unconscious feelings, and body language are followed by role-playing. During role-plays every resident plays the role of one of his or her own patients. Another resident plays the role of the doctor or therapist. At the end of the retreat, all residents receive oral and written comments on their skills and indications for improvement. The resident integrates these goals in their personal education plan (PEP).

After the introductory retreat, the residents make videotapes of their consultations in everyday clinical practice and discuss them with their clinical supervisor and their personal psychotherapeutic supervisor. After 1 year their skills are examined by their clinical supervisor in a formative way. The results of the examination play an important role in the decision if they are to be accepted for entering the second year of the MiAM.

In a second intensive 3-day retreat for the residents that have passed their examination at the start of the second year, their skills are explored intensively in role-playing sessions. Each of the three trainers focuses on one aspect of conversational skills: motivational interviewing, interpersonal interaction and unconscious feeling, and body language. Again the residents receive oral and written comments on their skills and indications for improvement, and they have to write an evaluation themselves. They are invited to discuss these comments and self-reflection with their clinical and psychotherapeutic supervisors. At the end of the 2-year course in addiction medicine, their skills are examined resulting in a "yes" or "no" for passing their final exam. The final assessment of the conversational skills is done by judging two video fragments of 10 min of conversation between the resident and a patient by four examiners. The assessment is done with a standardized instrument, the Quality Aspects of Professional Communication (QAPC) (DeJong et al. 2013b), consisting of five subscales: general aspects of conversation (GAC), nonverbal communication (NVC), motivational interviewing skills (MIS), clinical skills (CS), and interpersonal behavior skills (IBS). The inter-rater reliability of the QAPC is good for the total score (ICC = 0.79) and good to fairly good for the subsequent subscales (ICC_{GAC} = 0.81; ICC_{NVC} = 0.68; ICC_{CS} = 0.68; ICC_{CS} = 0.67 and ICC_{IBS} = 0.64).

141.2.2 Assessment, Examination, and Quality Management

Assessment is a powerful tool for the student to support its development. It gives information about their achievements or where gaps may occur. In competency-based learning, ongoing assessment is the base of the learning concept. Especially the clinical teacher has to find out together with the resident what the level of mastering competencies is. They can use the following levels of mastering to find out in what way the resident can start practicing in a safe way the CPS:

1. The resident has adequate knowledge of the subject of a CPS.
2. The resident can perform the professional activities associated with this theme under strict supervision.
3. The resident can perform professional activities under limited supervision.
4. The resident can perform professional activities without supervision.
5. The resident supervises and teaches others effectively in the professional activities associated with this theme.

In the MiAM both summative and formative assessments are used, each with a different purpose. Formative tests are aimed at development. It provides feedback regarding the learning process. The key question is what can the student perform/answer already and what not yet? The focus in summative tests is on determining what the student has learned at a given moment. It has a selective purpose. The key question is can the student perform/answer what is asked for yes or no?

Table 141.3 shows the formative and summative tests that are represented in the theoretical course and in clinical practice. Assessment, especially formative assessment, is part of the daily routine and of the observation of CPS. At the end of the first and the second year, a summative overall assessment is held in which all the study results of theoretical course and clinical practice are weighted. The portfolio based on the personal education plan is an important tool to do this. After the first year, the overall assessment provides information whether the student is allowed to start the second year and if so what his or her goals for the second year could be. After the second year, it has to give the input for the examination board whether the student can graduate or not.

The quality of the MiAM course is monitored and evaluated by means of several instruments.

For the six modules of the theoretical courses, standard evaluation forms are used. These forms are developed especially for all post-academic training programs of the educational training center SPON. The general questionnaire covers 22 questions (five-point Likert scale) on the teachers' quality, the content of the course, and the relevance for the clinical practice. Besides the fore written questions, the residents can give written comments. The results of each evaluation are discussed with the teachers and may lead to changes within the course.

An important factor of success of the training is the quality of the relationship between the resident and the clinical teacher. The clinical teacher is evaluated yearly by the resident in a structured way (Lombarts et al. 2007). The questionnaire

Table 141.3 Overview of the training program, assessment, and examination

Assessment and examination	First year					Second year				
Theoretical course In-between assignments	Module 1	Module 2	Module 3	Module 4	Module 5	Module 1	Module 2	Module 3	Module 4	Module 5
Theoretical course Final assignments	Module 1	Module 2	Module 3	Module 4	Module 5	Module 1	Module 2	Module 3	Module 4	Module 5
Progress interview with Clinical teacher (PEP*)	1 hour a week					1 hour a week				
- portfolio assessment - reflection - competencies - professional functioning - CPS** (10-12/year)										
Psychotherapeutic supervision sessions	30 hours a year					30 hours a year				
Psychotherapeutic supervision Amount of sessions, quality of learning process and development										
Formal scoring conversational skills QAPC*** ()	At least 6 a year				6	At least 6 a year				6
Master proof: video assessment conversational skills						1				2
Master proof: peer-reviewed scientific article										

Red: summative
Green: formative

*PEP=Personal Education Plan, **CPS=Characteristic Professional Situation, ***QAPS=Quality Aspects of Professional Communication

consists of 26 questions (five-point Likert scale) covering educational climate, personal treatment, communication about learning goals, assessment, feedback, role model and organization, and context. The data are used individually for the communication between the resident, clinical teacher, and principle lecturer. The first results of the first two groups (2007 and 2009) show that the residents are quite satisfied with the general quality of the clinical teachers as is expressed with a 4.2 on a scale ranging from 1 to 5.

The quality of the personal psychotherapeutic supervisor was explored by one of the residents, as a part of the scientific EBM paper he has to write for the MiAM (Reifenschweiler et al. 2012). It comes out that that in general the residents ($N = 19$) are quite satisfied with a mean score of 7.6 (0 = very poor – 10 = excellent). Despite the good quality 7 out of 19 residents indicate that they lack supervision issues. Some residents called their supervisor "short-sighted" and "self-gratifying". These bottlenecks are congruent with the literature (Van Staveren and VanOs 2009).

141.2.3 Relation with Other Professional Groups

The Dutch Society of Addiction Medicine (VVGN) and the Dutch Society for Psychiatry (NVVP) cordially support the MiAM. Specialists in addiction medicine could best be described as specialized generalists, meaning that they know a little (but enough) about many things. This is in contrast with specialized specialists who know almost anything about a very few things. Addiction medicine specialists

should be competent to recognize somatic and psychiatric co-occurring disorders besides the substance dependence syndromes as such.

The background of the residents is described elsewhere (DeJong et al. 2013a). In the first groups, medical doctors with already a career in addiction medicine entered the MiAM as well as medical doctors with a refugee status, and they are not allowed to continue working in their original specialty. In the last training groups, more young doctors entered the MiAM who recently graduated from medical school. In our opinion the last group is favorable for the further development of a new specialty.

After graduation and registration, the overlap in working field between addiction medicine specialists and psychiatrists is the most obvious. Since the start of the MiAM, a discussion is going on about who will be in charge in what domain. Happily we notice that in most facilities a constructive and respectful collaboration develops between the specialist in addiction medicine and the psychiatrist. There is less discussion about domains with general practitioners or medical specialists such as neurologists, internists, and gynecologists. In the addiction treatment facilities, medical doctors work together with clinical or general healthcare psychologists. The content of the work of each of these professional groups differ enough to recognize them as separate professionals. If there are problems between them, it has more to do with who will be in charge than with the level of competencies.

141.2.4 Funding

There is no governmental funding for the professional training yet, so the costs are brought up by the treatment centers. The direct costs to be paid at the educational center SPON amount to 8.500 euro per year per resident. The indirect costs consist of time the clinical teacher and the supervisor spend at the training of the resident and the time the resident follows the theoretical course (1 day a week) and is working on practical assignments. Usually this time is spent at the treatment of patients. Furthermore, the treatment centers must update their library and gain access to electronic libraries to fulfill the requirements of EBM. Finally, most of the treatment centers offer addiction medicine specialists a higher salary after graduation.

141.3 Conclusion

We developed in quite a short time a competence-based professional training program for addiction medicine in the Netherlands. In almost 6 years, four groups graduated; the fifth group will finish in December 2015. We can conclude that the MiAM is answering the needs of the mental health and addiction treatment field. The next step is to formulate the criteria for reregistration of all addiction medicine specialists in the profile register of the Dutch Society of Medicine. Furthermore, for the future of professional medical specialists in addiction medicine, it seems to us

important to get to know more about the international development of training programs in addiction medicine. The reason for sharing this information is that we want to be involved in a shared European or even a global initiative to train certified medical specialists in addiction medicine. The exchange of knowledge and experience in joined forces is absolutely necessary to accomplish such an endeavor.

Acknowledgment The professional training in addiction medicine would not be possible without the contribution of many organizations. We would like to thank especially all senior lecturers – H.A. de Haan, J.J.H.M Luijkx, W.J.L. Pinxten, A.F.A. Schellekens, G.M. Schoof, S. Medema, G.H. de Weert-van Oene, M.T. Arends, and B. van de Wetering – and all clinical supervisors: M. Bongaerts, M. Boonstra, A.F.M. van Hoek, M.E. Janssen van Raaij, O.J.A. Lovera Rivas, K. Markus, J.J.H.M. Luijkx, H. Post, C.M.M. Rijk, P.C.T.J. Vossenberg, P. van Waveren, P. C. van den Berg, I. van der Schaaf, P. de Visser, R.H. Jamin, F. Himmelmann, T. Linka, V.J. van Petegem, T.H. Loef, G.C.J.M. van Riel, A.G.M. Wijdeveld, and J.F. Werkman.

Medical Education in Addiction and Related Disorders: The Canadian Experience

142

David Crockford and Nady el-Guebaly

Contents

Abstract

Historically, the medical education in substance-related and addictive disorders in Canada has been disproportionately limited in residency training programs compared to other major illnesses and disorders. While currently in Canada, there is no formal subspecialty recognition or designation of addiction medicine or addiction psychiatry, over the last 10 years there has been increasing interest by the College of Family Physicians of Canada (CFPC) and formal establishment by the Royal College of Physicians and Surgeons of Canada (RCPSC) of core training requirements for addictions to be met during residency training in order to qualify for certification in family medicine and psychiatry, respectively. Proposed components for the curriculum for substance-related and addictive disorders applicable to family physicians and their challenges in their

implementation are described. Established curriculum and training requirements for psychiatrists are then described with specific content areas, and means for Canadian residency training programs to meet these requirements are reviewed. Ultimately, it is hoped that as both family physicians and specialists build on the training requirements, their impact will broaden and lessen the gaps in care present for patients with addictions.

142.1 Introduction

Canada is the second largest country in the world by size but has a relatively small population of 34.5 million people. The country is divided into provinces and territories each having jurisdiction over how health care is delivered within the confines of the Canada Health Act. Provinces and territories are allowed to focus health care resources to identified priority areas based on regional need, but the Canada Health Act helps maintain a remarkable amount of general congruence in the delivery of health care. Core health services are publically funded with most patients receiving care by this means. More for the mind is the core report credited for the inclusion of mental health and addiction within the national health care scheme (Tyhurst et al. 1963). In Canada, parity of coverage exists for the treatment of addiction and psychiatric disorders equivalent to other medical diseases, but many addiction treatment services also exist outside of the publically funded health care system, where patients or families pay via private insurance, contracts, or directly out of pocket.

In Canada, substance related and addictive disorders are estimated to affect one out of every seven persons in their lifetime (Veldhuizen et al. 2007), where the annual societal cost is estimated to be 40 billion dollars annually (approximately $1,000 per person in Canada) (Rehm et al. 2007). Not unique to Canada, most persons with addiction do not receive any treatment at all or, if they do, often report unmet needs (Harris and Edlund 2005; Urbanoski et al. 2007; CASA 2012. Most of the approximately 75,000 physicians in Canada (physician to population ratio: 1 per 467) encounter patients at risk for or have active addiction (Canadian Institute for Health Information 2009). While up to 20 % of all visits to a family physician's office are either directly or indirectly related to addiction (Bradley 1994), the skill set of this large physician group to appropriately screen, identify, motivate, treat, and/or refer is limited (Midmer et al. 2002). A next level of addiction medicine practitioners involves some 1,150 mostly part-time family physicians who focus on the management of opioid dependence at methadone clinics (national mean = 47 patients per physician, SD +/−41.5) (Luce et al. 2011). Knowledge and skills in addiction beyond methadone prescribing are variable given that the completion of a 1-day course is only required to acquire a methadone exemption from the provincial/territorial college level for patients with opioid dependence. A much smaller group of family physicians focus full-time in the field and address a broader range of addiction issues. Among the specialties, psychiatry provides the majority of the specialist services in addiction, with more limited services provided by internal medicine, reproductive medicine, and pediatrics. The group of full-time

family physicians and specialists focusing on addiction medicine may account, in all, for only some 200 physicians where estimates are based on membership in national associations. Thus, despite parity in coverage for persons suffering from addiction, access to physician-led medical care may be limited by the relatively small number of physicians practicing in addiction medicine, potentially further contributing to the limited numbers of patients entering evidence-based treatments.

Reflecting and potentially directly contributing to unmet treatment needs, training in the management of addictions for family physicians and in the medical specialties has been disproportionately limited in residency training programs compared to other major illnesses and disorders (Gunderson et al. 2008). Until recently, few residents received training in addictions unless elective experiences were pursued. Moreover, a lack of experienced faculty, negative attitudes towards addicted patients, lack of adequate curriculum, and poorly defined educational goals and requirements have been identified as factors leading to the lack of training in addictions (Gunderson et al. 2008).

Two separate national colleges set and oversee the standards for the training of physicians in Canada. Family physicians (otherwise known as general practitioners or primary care providers) require 2 years of postgraduate training followed by a certification exam before practice eligibility and are overseen by the College of Family Physicians of Canada (CFPC). All medical and surgical specialties require at least 5 years of postgraduate training, then must pass a certification examination before practice eligibility. Medical and surgical specialists are overseen by the Royal College of Physicians and Surgeons of Canada (RCPSC). Due to the country's vast geography, remote areas, and concern that too much specialization may potentially lead to a loss of continuity in care and increased "fragmentation," both colleges have promoted the training of "generalists" and "sophisticated generalists," respectively, rather than promote further subspecialization. Despite this, both colleges have, over the last 10 years, been challenged by the request for recognition by an increasing number of specialty practices, including addiction medicine. As there is no formal subspecialty recognition or designation of addiction medicine or addiction psychiatry in Canada at present or requirement for these to focus practice in addictions, physicians pursue recognition then via sitting certification examinations with the American or International Societies of Addiction Medicine, where the Canadian Society of Addiction Medicine recognizes those who have successfully completed either exam as being certified in Canada.

A potential future direction may include family physicians working more in a collaborative care model. Collaborative care is defined as care provided by providers from different specialties, disciplines, or sectors working together to offer complementary services and mutual support. Over the last 10 years, a successful collaborative partnership between primary care and mental health care providers has resulted in improved access to mental health care as well as an enhanced capacity of primary care to manage mental health problems (Kates et al. 2011). While there is no single collaborative model or style of practice, ingredients of a successful initiative include personal contacts; mutual respect,

trust, and recognition of each partner's contribution; evidence- and experienced-based practices; and responsiveness to changing needs and relevance to local resources availability, interests, and culture. In order to be successful, roles in the collaborative system need to be delineated. In its application to the management of patients with the continuum of substance use and behaviors, from at risk use to addiction, a collaborative model may best allow for flexibility in care options able to be provided to patients depending on their severity, complexity, and other needs.

142.2 Generalist and Specialist Training

142.2.1 Family Physician Training

Canada has one of the strongest primary care systems in the developed world. Family physicians represent the primary gatekeepers to the delivery of medical services in all Canadian settings. Previously, some jurisdictions allowed physicians to practice as primary care physicians with only 1 year of postgraduate training, but now, the only route to practice eligibility is through a 2-year postgraduate residency in family medicine, followed by a certification exam, before practice eligibility. Residents in any 1 of the 14 programs accredited by the CFPC are trained to provide comprehensive and continuing care across the life span where the family physician is expected to be a skilled clinician with expertise in managing common problems in the community, ranging from acute, simple conditions to more complex biopsychosocial problems. Although the management of addiction (including screening, identification, motivation, treatment, and referral along with medical care and long-term follow-up) likely should represent a core aspect of all family physician practices, many do not address addiction and related disorders in their patients. There appear to be a number of practice-based factors contributing to this. First off, most provinces do not fully compensate family physicians for addiction or other types of counseling via the publically funded fee-for-service system. Visits to the family physician office then tend to focus on medical consequences of addiction rather than treatment of the addiction. If counseling is desired, typically patients are then referred to nonphysician services either within their practices, but more commonly outside, often resulting in a lack of continuity in service provision or loss to follow-up. Screening is also not entrenched in typical practice patterns to help identify patients without overt consequences of addiction. Adding to this, provincial and territorial drug plans typically do not cover many medications used to treat addiction (e.g., buprenorphine, naltrexone, acamprosate), further limiting visits to medical consequences of addiction, rather than addressing their causes.

Beyond practice-related issues, to date the CFPC has also not instituted a set curriculum in addictions, and few academic family physicians have expertise in addiction, making them reluctant to address addiction issues in seminars or clinical supervision. For example, in a qualitative study, a sample of Ontario's medical faculty admitted that they did not know how to intervene with addicted patients and were unsure if addiction interventions would make a difference (Midmer et al. 2002).

In another qualitative study, Ontario medical students reported that supervising staff rarely addressed the patient's addiction during encounters with addicted patients (Midmer et al. 2008).

Recognizing the deficits, the CFPC has attempted to target residency training in addiction a priority topic based on a 1998 needs assessment survey of Canadian family medicine faculty (Working Group on the Certification Process 2009). In the survey, faculty members were asked to identify which clinical topics residents must be competent in upon graduation. Sixty percent listed substance abuse as a priority, placing it third highest on a list of 100, ahead of ischemic heart disease, diabetes, and hypertension. For each priority topic, the CFPC has developed a list of evaluation objectives, which can be included on the CFPC national certification exam. For addiction and related disorders, the evaluation objectives focus on screening and are listed in Table 142.1.

Further components that likely will need to be added to would also include skills in performing brief interventions (especially for tobacco and alcohol as these represent over two thirds of the substance-related costs to Canadian society annually (Rehm et al. 2007)), recognition of at risk individuals for developing prescription opioid and benzodiazepine dependence, patient placement decision making for detoxification or treatment, and how to refer for treatment when beyond the scope of a family physician. Specific competencies will need to be defined to accompany the evaluation objectives and targeted recommendations, and accreditation by the CFPC of the 14 individual family medicine residency programs will need to become contingent upon their implementation to promote a common curriculum or national curricular mapping. Potentially, the grid included to describe psychiatry training could be applied to family physician training as found in Table 142.3.

As a common curriculum is not yet present, family physicians that have developed more focused addiction medicine practices typically have done so by pursuing education in addiction medicine through self-learning or continuing medical

Table 142.1 CFPC Evaluation Objective and Target Recommendations

Evaluation objective:
For all patients, especially high-risk groups (e.g.: mental illness, chronic disability), screen for the presence of a substance use disorder (tobacco, alcohol, illicit drugs)
Target recommendations:
Screen for blood-borne illnesses (e.g., human immunodeficiency virus, hepatitis) and offer relevant vaccinations or initiate treatments/referrals in patients with intravenous drug use
Diagnose and manage substance-induced intoxication and withdrawal syndromes
Discuss substance use with adolescents and their caregivers when warning signs are present (e.g., school failure, behavior change)
Consider and look for substance use disorders as a possible contributing factor when presenting problems fail to respond to appropriate initial interventions
Offer support to patients and family members affected by substance use disorders
Determine if a patient identifies with a diagnosis of a substance use disorder, elicit willingness to abstain or reduce use, and screen for comorbidities (e.g., sexually transmitted infections, mental illness) or long-term complications (e.g., cirrhosis)

education (CME) primarily, with the minority seeking formal postgraduate training in addiction medicine. Only two centers in Canada currently provide fellowship training in addiction medicine for family physicians. They are flexible programs that provide an opportunity to train in settings with a wide range of clinical services devoted to addiction care.

It is hoped that addiction medicine will in time become a formal part of the curriculum in family physician training over time. As a step towards this, the CFPC has introduced a section of family physicians with special interests or focused practices where addiction medicine has received approval to form a working group to develop a program within this section. The process that follows opens opportunities to develop and ensure guidelines for family physician post graduate education, training, and practice in addiction medicine. Hopefully then, one of the strongest primary care systems in the developed world will be further improved to provide more consistent and comprehensive care for patients with addictions and related disorders.

142.2.2 Psychiatry Training

Specialist training in psychiatry in Canada involves 5 years of training where components depend on the postgraduate year (PGY) training level of the resident. In PGY-1, residents complete basic clinical training that is meant to encompass a broad medical experience relevant to their future practice in that subspecialty. For psychiatry, this includes exposure to family practice, psychiatry, emergency medicine, internal medicine/neurology, and pediatrics primarily but can also include exposure to general surgery, intensive care, and obstetrics and gynecology. In PGY 2 and 3, residents complete foundational training in core components of the specialty. For psychiatry, this includes rotations in child and adolescent, adult, and geriatric psychiatry in both inpatient and outpatient settings. In PGY 4 and 5, consultation skills in complex care patients are further emphasized with elective and selective rotations to further develop areas of subspecialty skill while maintaining generalist competencies. Across the 5 years, psychotherapy training in at least three modalities is expected (typically psychodynamic, cognitive behavioral, and group/family as the core) as well as care of patients with chronic and persistent mental illness. Formal subspecialty designation extends training one more year (PGY-6), for a total of 6 years, if residents are seeking designations in one of the three RCPSC recognized subspecialties: child and adolescent, geriatric, or forensic psychiatry.

In 1997, the initial Curriculum Guidelines for Residency Training of Psychiatrists in Substance-Related Disorders was published by the Canadian Psychiatric Association (CPA) as a position paper (el-Guebaly and Garneau 1997). The stated goals of those guidelines were to:

- improve the knowledge, skills, and attitudes of psychiatrists about substance-related disorders to a level comparable to other mental disorders;
- ensure better evaluation and treatment of alcohol and other substance abusers;

- foster recognition of the impact of co-morbid substance abuse on the treatment and evolution of other physical and psychiatric conditions;
- prevent marginalization and excessive demedicalization of clinical services to substance abusers;
- ensure that psychiatrists develop an understanding of the spectrum of health care systems providing services to substance abusers; and
- foster advanced training and subspecialization of a greater number of psychiatrists to develop clinical services, teaching, and research in substance abuse.

However, without the 1997 proposed Curriculum Guidelines being directly incorporated into the RCPSC Specialty Training Requirements (STR) in psychiatry, curriculum changes were left up to individual programs to voluntarily implement, and relatively little change occurred.

In 2000, the RCPSC adopted minimum expected competencies in each of seven roles to be achieved by the end of training of a specialist revolving around the central role of the medical expert, including professional, scholar, communicator, manager, collaborator, and health advocate (Frank et al. 1996). The framework called the "CanMEDS roles" is derived from the "Canadian Medical Education Directions for Specialists" and forms the basis for educational standards for the Royal College. It has been incorporated into residency training accreditation and evaluation, examinations, individual specialty Objectives of Training (OTR), and standards for continuing professional development.

To attempt to begin to address the training deficiency in addictions, in 2007 the RCPSC released the new STR in psychiatry outlining more specifically expectations in training for psychiatry residents in addiction. Psychiatry is the first specialty in Canada to include specific training expectations in addiction. While the Objectives of Training (OTR) in psychiatry mentions alcohol and other substance use disorders, it does not currently include pathological gambling or potentially other research criteria behavioral addictions (e.g., Internet use gaming disorder), which would be recommended to reflect the changes in DSM-5 terminology and trends in addiction treatments. Proficiencies in addictions and related disorders are now part of the training requirements for all Canadian psychiatry residents who began their training as of July 1, 2009, to be realized over the 5 years of residency training with there being no less than the equivalent of a 1-month clinical experience evaluated separately from other rotations occurring sometime during PGY 2–5. Although it is unlikely that a 1-month experience would fully allow the resident to fully realize the proficiencies expected in the OTR/STR, the 1-month experience coupled with seminars should provide an adequate foundation for residents in addiction and related disorders that can be further built upon via additional training experiences and ongoing continuing medical education.

The OTR/STR as they apply to training in addiction include the following:

1. Supervised experience in the treatment of patients with addictions in a variety of settings. A learning portfolio or log should be maintained and reviewed by the program director. This experience must be undertaken as a discrete rotation of no less than 1 month or incorporated as a longitudinal experience (at any time during PGY 2–5) of no less than the equivalent of 1 month. This must be documented and evaluated separately from other rotations.

2. Availability of a selective rotation in addictions of no less than 3 months but preferably 6 months during senior psychiatric residency training (PGY 4–5) to develop advanced knowledge (see definition in Table 142.2) in addiction psychiatry.
3. Proficient (see definition in Table 142.2) clinical knowledge, skills, and attitudes appropriate to their practice in addiction.
4. Function effectively as consultants, integrating all of the CanMEDS roles to provide optimal, ethical, and patient-centered medical care by identifying and appropriately responding to those patients with addiction comorbidity.
5. Demonstrate introductory (see definition in Table 142.2) knowledge in assessing suitability for prescribing and delivery of motivational interviewing.

Table 142.2 Definitions

Introductory knowledge: able to recognize, identify, or describe principles
Working knowledge: able to demonstrate core aspects of psychiatry, such as basic interviewing, problem formulation, and treatment. The resident can understand the scientific literature
Proficient: able to demonstrate working knowledge enhanced by a developmental, cultural, and life span perspective, allowing detailed interviewing and biopsychosocial problem formulation with capacity to teach, consult, assess, and manage referrals. The resident can critically review and apply the scientific literature relevant to this competency
Advanced: detailed and sophisticated understanding which is multimodal and interdisciplinary, leading to advanced teaching and consultation on complex referrals. The resident has a detailed knowledge of and is able to apply the scientific literature, adapting and extrapolating as required

Table 142.3 Proposed stage-specific competencies in addictions and related disorders

[a]Psychiatry 3–6-month selective training

Based on program and resident-derived factors, each training program will need to determine the optimal positioning of the clinical rotation in addictions. The flexibility in the timing and duration of the addiction rotation, however, could lead to significant variability in the foundational knowledge and skills that each resident would possess at that time in their training, a factor that would need to be considered by program directors when establishing rotations. Junior residents may be more proficient in the medical management of intoxication and withdrawal states but less proficient in assessment, diagnostic, and psychotherapeutic practices for these chronic disorders, potentially limiting the impact of early addiction training experiences on future psychiatric practice. Positive experiences in earlier training though may set the stage for psychiatry residents to seek out selective rotations in addiction psychiatry in their senior training years, helping to establish future leaders in addiction psychiatry. Senior residents may benefit more from addiction training experiences given their greater exposure to psychotherapy training, enhanced assessment skills, and likely better established future practice plans, allowing them to better focus learning to those areas most applicable to their future practices (e.g., screening and brief intervention skills for consultation-liaison psychiatrists, motivational interviewing and other engagement skills for inpatient psychiatrists, or use of evidence-based harm reduction approaches for assertive community treatment team psychiatrists working with chronic psychotic disorders), but residency training programs may have greater difficulty integrating these experiences in the senior years due to limited availability of concurrent psychiatric and addictive disorder training centers and limited access to primary addiction services. Longitudinal experiences may bridge this divide but may also be difficult to ensure a consistent training experience involving addiction psychiatry role models and evidence-based practices. To ensure appropriate evaluation and oversight, all training programs will need to appoint a training coordinator for this endeavor who ideally would already be certified in addiction medicine or addiction psychiatry or have completed a fellowship in addiction psychiatry.

The goal of the new OTR/STR was not only to provide a template for training the "sophisticated generalist" in contemporary psychiatric practice but also to provide a potential template for psychiatric subspecialization and its recognition (Leverette 2009). In 2011, the RCPSC drafted a series of white papers, including one on specialization (Royal College of Physicians and Surgeons of Canada. Generalism: achieving a balance with specialization. Draft: January 31 2011). The white paper recognizes that "the areas of focus and competence (diplomas) are one method to encourage physicians to learn new skills to adapt to community needs." In 2002, the RCPSC adopted the following definition (Committee on Specialties (COS) 2002): "A subspecialty is defined as having a body of knowledge and identifiable competencies that build upon the broad-based body of knowledge defined as a specialty. There must be evidence of societal need for the subspecialty to justify development and support for an RCPSC-accredited training program. Successful completion of a subspecialty requires certification by examination in one of the primary specialties and successful completion of a subspecialty-training program. Subspecialty training must be at least one year in duration, can only be entered in the final year of

primary specialty training, and may be evaluated with or without a RCPSC examination." Increasing demands to recognize more and more subspecialities has led the RCPSC to develop an innovative diploma category where the more formal and rigorous standards attached to subspecialty recognition do not have to be met. Diploma recognition will be based on 1 year of training establishing and educational portfolio instead of an examination. This initial step may help gauge interest in addiction psychiatry in Canada, better establish manpower needs, and better standardize the content for fellowship training in addiction psychiatry. The downside of this is that the focus on psychiatry in those examinations is more limited in nature, there is no commensurate change in remuneration for completing certification, and physicians can still choose to practice in the field without certification. With the number of experienced faculty in addiction psychiatry in Canada at present being relatively limited, a tenuous balance needs to be maintained between moving towards subspecialty recognition for addiction psychiatry without dissuading potential interested psychiatrists from pursuing additional training. Ideally, the year of subspecialty training could occur within the current 5-year residency training or, likely, with a fellowship year.

In Canada, there currently is no defined subspecialty of addiction psychiatry, like there is recognized by the American Boards in the United States. While fellowships in addiction psychiatry are available in Canada, their content and expectations varies from institution to institution with only a minority of training programs being able to provide fellowship training. The OTR/STR for addictions describes that a selective (or elective) in addiction psychiatry or addiction medicine of 3 months to a year in duration be available to senior psychiatry residents (PGY-4/5) to developed advanced knowledge in addiction psychiatry. Currently, few programs have this capability in Canada, but this may allow the better identification of Canadian training sites with the capacity and facilitate fellowship/diploma development at those identified sites.

The OTR/STR for addictions has a number of deficits or weaknesses. Residents will only be required to have an introductory knowledge (ability to recognize, identify, or describe principles) of motivational interviewing (MI), even though the ability to provide MI and integrate it into day-to-day practice is typically viewed as a core component of addiction psychiatry (Crockford and el-Guebaly 2009; Renner et al. 2005). The OTR/STR also fails to identify the other core psychotherapeutic approaches utilized in standard addiction psychiatry practice including cognitive behavioral therapy (CBT)/relapse prevention and 12-step facilitation.

It is recommended that clinical knowledge, skills, and attitudes in addiction involve the following domains:

1. ***Substance Effects*:**
   (A) Knowledge of the mechanism of action for the primary drugs of abuse and dependence including alcohol, nicotine/tobacco, caffeine, cannabis, sedative-hypnotics (benzodiazepines, barbiturates, GHB), stimulants (cocaine, amphetamines, and "designer" stimulants), opiates, NMDA antagonists (PCP and ketamine), inhalants, steroids, and hallucinogens

(classical and "designer" hallucinogens). This would represent a foundation to understanding how substance dependence develops and the basis for different intoxication/withdrawal syndromes.

(B) Knowledge of substance intoxication/withdrawal syndromes enabling their identification and acute management.

(C) Knowledge of the effects of chronic substance use on the development and perpetuation of medical complications (e.g., hepatitis, HIV) and psychiatric comorbidity.

(D) Awareness of the similarities and differences between behavioral and substance-related addictions.

2. ***Developing a biopsychosocial understanding of addiction and their overlap with major psychiatric disorders*:**

(A) Knowledge of the critical role of the brain's extended dopamine reward pathway as the key mediator of the neurobiological basis for how addiction develop incentive salience for future behavior choice over natural rewards, balanced with the understanding of other biopsychosocial factors contributing to risk and resilience including drug type, delivery method, dosing, age of exposure, genetics, underlying psychiatric disorders and personality traits, expectancies from use, environment, peer use, availability, cultural/religious factors, and economics.

(B) Awareness of how initial psychosocial factors contribute to the initial exposure to addictive substances and behaviors, then progress to having a more biologic and chronic basis once addiction develops. The same would help frame the basis for choosing different strategies to address the continuum of addiction behavior from at risk use to the most severe forms of addiction.

(C) Understanding of how common comorbid psychiatric disorders have overlapping neurobiological and psychosocial contributors contributing to the development and perpetuation of addiction.

3. ***Addiction Epidemiology*:**

(A) Knowledge of the prevalence of each of the addiction and the differences between populations based on age, location, and ethnicity.

(B) Knowledge of the comorbidity with the spectrum of major psychiatric (including mood, anxiety, psychotic, cognitive, sleep, attention deficit hyperactivity, personality, and somatic/pain disorders) and medical disorders.

(C) Knowledge of developing trends in addiction related to availability, perception of harm, and other factors that promote and protect their development.

(D) Awareness of the different trajectories and predictors for the course of addiction. Understanding how access to evidence-based treatments can change outcomes and awareness of the phenomenon of natural recovery, to help build appropriate optimism for change.

4. ***Assessment and Diagnosis*:**

(A) Knowledge and skills in the identification of addiction and their diagnostic definitions. This would include knowing how to elicit history

indicative of addiction and related disorders, awareness of typical signs and symptoms that would prompt more in depth screening, and the importance of screening for tobacco use, prescription drugs, over-the-counter medications, and behavioral addictions in addition to alcohol and illicit drugs.

(B) Familiarity with the use of screening instruments for substance use disorders (e.g., CAGE, Alcohol Use Disorders Identification Test (AUDIT) for alcohol, Drug Abuse Screening Test (DAST) for drugs) and their minimum cutoff values. Awareness of more comprehensive instruments to more thoroughly evaluate the impact of addictive behaviors (e.g., Addiction Severity Index). Familiarity with use of the Clinical Institute Withdrawal Assessment for Alcohol, Revised (CIWA-Ar).

(C) Awareness of the role of urine drug screening, other forms of drug screening, and their potential limitations.

(D) Knowledge and skills to attempt to reasonably differentiate substance-induced psychiatric symptoms from independent psychiatric disorders. Awareness of common comorbid conditions when one disorder is identified (e.g., problematic sexual behavior with stimulant addictions; anxiety, depressive, and sleep disorders with sedative-hypnotic dependence).

5. ***Stage of Change and Treatment Planning*:**

(A) Knowledge of the different stages of change reflective of the transtheoretical model and how it is assessed. Awareness that stage of change may change over time and may be different for each psychiatric and/or addictive disorder.

(B) Know how and when to use a brief intervention, motivational interviewing, cognitive behavioral therapy (CBT)/relapse prevention, or 12-step facilitation with awareness of contingency management as a method to create short-term incentives towards drug use reduction and abstinence.

(C) Understand what constitutes appropriate addiction treatment as it relates to setting (e.g., outpatient, residential, inpatient), minimum durations, and types of providers. Skills to select best treatments and modify these based on response (e.g., use of the American Society of Addiction Medicine Patient Placement Criteria (ASAM PPC-2R)).

(D) Knowledge and skill in the use of pharmacotherapy for addiction including those for alcohol withdrawal, opioid substitution, treatment of alcohol dependence (e.g., naltrexone, disulfiram, acamprosate) and nicotine dependence (e.g., nicotine replacement therapy, bupropion, varenicline), and tapering off of opioids and sedative-hypnotics.

(E) Knowledge and skills in the use of pharmacotherapy and psychotherapy for comorbid psychiatric and addictive disorders.

6. ***Community Resources*:**

(A) Knowledge of mutual help (e.g., Alcoholics Anonymous, Rational Recovery) and how to facilitate involvement in these resources (e.g., 12-step facilitation).

(B) Knowledge of the spectrum of other community resources available to help manage addictions and related disorders unique to their community including evidence-based harm reduction approaches, detoxification facilities, outpatient treatment options, and residential treatment centers.

7. ***Role of Family*:**
   (A) Knowledge of the impact of addiction on the addicted person's family and contacts.
   (B) Knowledge and skills to support and involve the person's family in the recovery process from psychoeducation to couples/family therapy.
8. ***Attitudes*:**
   (A) Awareness of potential biases held towards patients with addiction and development of empathy for their condition.
   (B) Development of appropriate optimism for change and improvement over time in persons with addiction while recognizing that addiction requires an approach reflective of a chronic disorder.

The recommended areas for clinical knowledge in addiction psychiatry in Canada are outlined in Table 142.3. Beyond clinical knowledge competencies, the curriculum in addiction psychiatry will need to emphasize one that is skills based and interactive/experiential in nature (both in seminar teaching and active patient care) to have meaningful impact on future practice patterns as well as recognize the lifelong process of learning building from medical school and reinforced through continuing medical education (CME).

142.3 Conclusion

Medical education in addiction is a work in progress in Canada, but promising developments may help shape standard setting for training in primary care and psychiatry. The challenge going forwards, for both family physicians and specialists, will be to build on the training requirements to broaden their impact. Opportunities for learners to experience collaborative care learning together and from each other further establish administrative structures and support experienced faculty in addiction medicine/psychiatry to train the next generation, establish/expand upon core knowledge and skill-based competencies ensconced in accreditation standards, and eventually develop capacity for subspecialty recognition through defined selective/fellowship training guidelines.

Development of a Full Medical Specialty in Addiction Medicine: The Norwegian Experience

143

Gabrielle K. Welle-Strand

Contents

Abstract

In June 2012, the Norwegian Minister of Health and Care Services put forward a Governmental White Paper on "Drug and Alcohol Policy" which included the decision to establish a full medical speciality in addiction medicine. The Norwegian substance use problems are of typical European pattern. During the

last 20 years, addiction treatment in Norway has developed from a nonmedical, social service-based approach to a comprehensive interdisciplinary service based on health laws for treatment and social service laws for rehabilitation. Increasing overdose mortality and the spread of HIV caused trial projects with methadone, and in 1997 a national program for substitution treatment was established. The specialized treatment service for drug- and alcohol-using patients is called interdisciplinary specialized treatment (IST). There has been increasing awareness of the physical and mental health condition of substance use patients and the rising morbidity and mortality. Both nationally and internationally, there has been an expansion of the knowledge base for addiction medicine.

The organization and responsibility for the education and approval of all medical specialties are also undergoing a major change to match future needs of the patients and a changing and modern society. The specialty in addiction medicine is in many ways an acid test for these changes.

Addiction medicine is a new specialty. It is 15 years since the last time a new medical specialty was launched in Norway. A broad process has been and is taking place in order to develop all necessary parts of the new specialty.

The suggested specialty regulations include 5 years of internship in accredited institutions:

1. 42 months of internship in interdisciplinary specialized treatment (IST), including 12 months in a detoxification department, 6 months in inpatient addiction treatment, and 12 months of outpatient addiction treatment. The last 12 months can be chosen from a range of services.
2. 18 months in other specialist areas: 6 months in a psychiatric ward. For the last 12 months, the candidate must choose two of the following: 6 months more of psychiatry, 6 months in a somatic ward, or 6 months in general practice.

The candidate must have 270 hours of coursework and regular clinical supervision and also 30 hours of specialized supervision in therapy related to addictions.

We also have developed a suggestion for interim regulations, to be able to approve the first specialists in addiction medicine in the autumn of 2014; they will be the mentors/supervisors for the new specialist candidates of addiction medicine. Hopefully the first candidates of this full specialty in addiction medicine will be in training from 2015 at the first accredited teaching institutions, to improve the quality and competence of the medical doctors in the substance use field for the benefit of our patients.

143.1 Introduction

Nothing less must be provided for the treatment of substance dependence than a qualified, systematic, science-based approach such as that developed to treat other chronic diseases considered untreatable some decades ago (World Health Organization 2004).

Norway is in some ways different from the rest of Europe, not being a part of the European Union, but nevertheless in most ways integrated in the European collaborations. The substance use problems are of typical European pattern, but there are some special traits of interest in relation to addiction treatment. Norway has five million inhabitants with some urban centers such as the capital Oslo with 550,000 inhabitants and cities such as Bergen (250,000), Trondheim (150,000), and Stavanger (100,000), but the degree of urbanizations is relatively low. Nevertheless, the addiction problems are on average European levels.

During the last two decades, drug and alcohol treatment in Norway has developed from a nonmedical, social service-based approach to a comprehensive, interdisciplinary service based on health laws for substance treatment and social service laws for the rehabilitation process. There has been increasing demand for evidence-based approach and research. In June 2012, the Norwegian Minister of Health and Care Services, Anne-Grete Strøm-Erichsen, put forward a Governmental White Paper on "Drug and Alcohol Policy" for the Norwegian parliament. One of the decisions in this paper was to establish a full medical speciality in addiction medicine. In this chapter we describe the core elements in the development and the plans for the medical specialty in addiction medicine.

143.2 The Medical Specialty Project

143.2.1 Drug and Alcohol Treatment in Norway: Past and Present

Until the turn of the century, addiction was largely seen as a social problem. Medical treatment and the disease model for addiction were to a large extent rejected. The treatment was organized within the social welfare system and based on social care laws. Health care was mainly considered when indicated by psychiatric or somatic comorbidity. Opioid maintenance treatment (OMT) for opioid-dependent patients was rejected. Increasing overdose mortality and the spread of HIV caused trial projects with methadone from 1991, and in 1997 the parliament decided on a national program for OMT.

During the same period, the health-care system underwent basic structural reforms. The system had been a centralized system basically planned and led by the ministries and directorates. Now Norway developed a system based on municipal social care and primary health services and local hospitals run by the four regional health enterprises. Further, new law reforms established a health-care system based on new health laws. This meant that municipal health and social care and specialized health-care services were structured with appointed municipal GPs and specialist services from health enterprises headed by the regional health authorities.

This development also necessitated changes in addiction treatment. So far, the addiction treatment had been organized on municipal level as a responsibility of the social welfare system and on regional level as a responsibility for the counties, also based on social care law systems.

The Drug and Alcohol Treatment Reform that was passed as a Law Amendment in the Norwegian Parliament in 2003 established addiction treatment as an interdisciplinary specialized treatment which became the responsibility of the regional health authorities. This "Drug Reform" laid the organizational foundation for expansion and improvement for the specialized services for patients with substance use problems. The introduction of patient's rights in the "Drug Reforms" was an important step for improving the treatment for substance-using patients. The focus has since then increasingly been put on patient involvement in the treatment process both on an individual and a general level. The "Drug Reform" has been evaluated to be successful as far as organization is concerned, but as lacking both in the quantity and quality of the treatment offered.

The specialized treatment services for drug- and alcohol-using patients is called interdisciplinary specialized treatment (IST), indicating the necessity for the involvement of different health and social welfare system professionals in the treatment, even though the treatment is organized under the health-care system. The government has been giving priority to drug and alcohol treatment and psychiatric treatment in the budgets for hospital funding for some years. There has been a general expansion in the treatment capacity for interdisciplinary specialized treatment since 2004, but there are still too few treatment slots for both in- and outpatient treatment. As in other countries, the expansion has primarily been for outpatient services.

In the municipalities the social welfare system still has the main responsibility for the follow-up and rehabilitation for substance use patients, but general practitioners have been given a more important role in substance treatment than previously. The continuity of the services and the smooth cooperation between the social welfare system, the general practitioners, and the specialized treatment system has "always" been and still is one of the greatest challenges in substance treatment systems.

In October 2007, as part of its budget proposal, the government presented an action plan for the drug and alcohol field for 2007–2012. The plan ranged from prevention to treatment and rehabilitation. The aim of the plan was a policy with a clear public health perspective. The aim was also to raise professional standards through research and strengthening competence and quality. The five main goals of the action plan were:

1. A clear public health perspective
2. Better quality and increased competence
3. More accessible services and increased social inclusion
4. Binding cooperation
5. Increased user influence and greater attention to the interest of children and family members

In 2010 "the Coordination Reform" was amended by the Norwegian parliament. The goal of this reform is for the patient to receive the proper treatment – at the right place and right time. It is stated that the patients' needs for coordinated services are

not being sufficiently met. The reform presumes that the municipalities will play the largest part in meeting growth in demand for health services.

143.2.2 Patient Population

The total alcohol consumption in 2012 was estimated to be approximately 6.2 litres of alcohol per inhabitant over 15 years of age (1995: 5.4 litres). The estimate for high alcohol consumption from the National Institute for Drug and Alcohol Research (SIRUS, the Norwegian abbreviation) in 2006 was between 66,000 and 122,000 persons in Norway (Bretteville-Jensen and Amundsen 2006).

Two surveys on drug use among young people in 2006, one among the 15–20 age group and one among young adults aged 21–30, showed major differences (Skretting 2007; Lund et al. 2007). The percentage of 15–20-year-olds ever having used cannabis was 13 %, whereas 34 % of the 21–30-year-olds reported cannabis use. For people under 20 years, lifetime prevalence of amphetamine, cocaine, and ecstasy has declined from 1998 to 2006. For the young adults, 21–30 years of age, the lifetime prevalence for all three drugs has increased considerably. Cocaine was reported to have ever been used by 2.2 % of the 15–20-year-olds in 2006, while 9 % of the 21–30-year-olds reported the same. Concerning amphetamines, 3.1 % of the 15–20-year-olds reported use, whereas 9 % of the 21–30-year-olds. SIRUS estimated in 2005 that there were between 8,200 and 12,500 injecting drug users in Norway (Bretteville-Jensen and Amundsen 2006).

The number of HIV cases among injecting drug users remains low in Norway, and the yearly incidence has been low for the last 15 years. The prevalence rate even in the most affected groups in Oslo is less than 5 %. The HIV-testing rate is high, and there are very few undetected HIV cases when AIDS is diagnosed. There has been a hepatitis B outbreak among injecting drug users during recent years. During the period 1995–2006, the total number of reported cases of acute hepatitis B among drug users was 1,812. The infection rate of hepatitis C among injecting drug users is high, ranging from 60 % to 90 % prevalence in different tested populations throughout the country. The degree of comorbidity concerning both somatic and psychiatric illness is high among both drug- and alcohol-dependent patients.

Drug overdose deaths rose from the mid-1990s until 2001 (338 people that year), and thereafter there has been a decline. In the years 2006–2010, between 200 and 250 persons died each year as a result of opiate overdose. This puts Norway among the three countries with highest incidence of opioid overdose deaths in Europe (Mortality related to drug use in Europe 2011) even though figures are not directly comparable from country to country due to differences in registration and autopsy practices.

In 2011 there were 1,753 inpatient treatment slots in interdisciplinary specialized treatment (IST) and approximately 300,000 outpatient consultations in IST. There

were 7,000 patients in opioid maintenance treatment (OMT) at the end of 2012, estimated to be more than 50 % of the target population. Half of the patients were treated with methadone and the other half with buprenorphine.

143.2.3 Development of the Addiction Field in Recent Years

There has been increasing awareness of the health condition of substance use patients and their rising morbidity and mortality. Both nationally and internationally, there has been an expansion of the knowledge base for addiction medicine, including better treatment possibilities. Research on substance use patients has increased in Norway. In addition to the existing institutions performing research in the drug and alcohol field, the Norwegian Centre for Addiction Research (SERAF, Norwegian abbreviation) at the University of Oslo was established after an initiative from the Norwegian government in 2007 (Bramness et al. 2011).

The development of national treatment guidelines, headed by the Norwegian Directorate of Health, has been given high priority. A national treatment guideline for opioid maintenance treatment (OMT) was published in 2010 (Norwegian Directorate of Health 2010), a national treatment guideline for pregnant women in OMT and the follow-up of the children and their families until school age was published in 2011 (Welle-Strand and Bakstad 2011), and also in 2011, a national treatment guideline for the diagnosis, treatment, and the follow-up of persons with both substance use disorders and psychiatric disorders was published (Norwegian Directorate of Health 2011). A national guideline for detoxification and another for treatment of substance use patients will be finalized in 2014 and 2015, respectively.

143.2.4 A Full Medical Specialty in Addiction Medicine

As described above, the development in Norway has brought an increasing emphasis on health-care treatment systems for addiction. Interdisciplinary specialized treatment has been placed at the core of the services. This means that substance treatment is organized based on specialized hospital units. In contrast to other areas, however, specialized medical competencies have been lacking in the addiction treatment. There are 44 recognized medical specialties in Norway, of which eight are subspecialties in internal medicine and five are subspecialties in general surgery. The majority of these are linked to specialist health care, but there are also specialties in primary health care, family medicine, community medicine, and occupational medicine. There is one physician for every 278 people in Norway. More than half of Norway's 18,000 active physicians are qualified as specialists, and most of the other physicians are in specialist training to become specialists. To be appointed to a senior medical post, specialist approval is a minimum requirement.

The situation is somewhat different for the specialist services for addiction – the IST. The Norwegian Directorate of Health performed a survey of medical doctors

working in IST both in 2009 and in 2011. Putting together the results, a total of 132 positions for medical doctors were identified within IST, and 12 % of the positions were vacant. Of specialists working in the IST services, at least 32 psychiatrists, 14 general practitioners, and 13 doctors with other specialties were identified. The numbers are not complete, while some hospitals did not send in their records. The Norwegian Association of Addiction Medicine (NFRAM, Norwegian abbreviation) analyzed the situation and suggested that the need was a total of 400–450 medical doctors in IST, with half of them being specialists and the other half being doctors in training for a specialty.

For each medical specialty, there exists a specialty committee which has up to recently been responsible for the content of the training and for the accreditation of hospitals for graduate medical education. The 44 medical societies (associations of physicians with shared professional interests) work in close contact with relevant specialty committees and have up till now provided the hospital courses required for each specialty.

To become a medical specialist, a minimum of 3–4 years of residency in the main subject is required. For most specialties, 1 year in a subsidiary subject has also been required. A certain amount of coursework is required, on average 200 h. There are also specific requirements in relation to skills and procedures which have to be documented by attestation, checklists, and so on. The national courses have up to now been organized by the NMA (Norwegian Medical Association) in cooperation with the four Norwegian medical schools; there are approximately 350 courses each year in the 44 specialties.

Hospitals eligible for training specialists have to be approved. The criteria evaluated are staffing, patients, equipment, diagnostics and therapeutic procedures, and training plans, including plans for the tutorials. A tutor or a supervisor must be assigned to each resident. Approved training institutions are evaluated annually by reports on their teaching activities.

143.2.5 The Planning and Development of a New Specialty

A specialty in addiction medicine was initially proposed in 1999. It was turned down by the Norwegian Medical Association (NMA) arguing that GPs or other specialists, as, for instance, psychiatrists or internists, should deal with a patient's addiction problems. The second proposal from the Norwegian Association of Addiction Medicine (NFRAM) was considered positive by the NMA but was turned down in 2003 by the Norwegian Council for Specialities and Specialist Education. The reason for the rejection was once again that other specialities could deal with addiction problems and also that it would be difficult to establish enough teaching institutions and proper guidance for the specialist candidates.

The proposal was actualized again when the "Drug Reform" was launched by the government giving the specialized health-care system the responsibility for the treatment of drug and alcohol patients. The interdisciplinary specialized treatment (IST) was established for the treatment of patients with problems with alcohol,

prescribed drugs, illegal drugs and other addictions. The situation was thus that we had a new medical speciality without specialist medical doctors. In 2008, the Norwegian Medical Association (NMA) made a general report describing the education of medical specialists in Norway compared to other European countries. In this process the question concerning a new specialty in addiction medicine was raised again.

NMA therefore asked NFRAM, which is one of the 60 specialty branches in the NMA (associations of physicians with shared scientific interests), to make an evaluation of a possible new speciality in addiction medicine. NFRAM concluded in its report that it was both feasible and appropriate to establish a new specialty in addiction medicine and recommended this be done (Strøm et al. 2008). This report was approved by the general assembly in NMA in June 2009. NMA subsequently sent a recommendation to the Ministry of Health and Care Services and to the Norwegian Directorate of Health to establish a full specialty in addiction medicine. The report was further developed and then approved by the Norwegian Council for Specialties and Specialist training and the Norwegian Directorate of Health in 2010. Finally, on 22 June 2012, the decision was announced by the Ministry of Health and Care Services. A full medical speciality in addiction medicine was now a reality.

A medical speciality is characterized by a defined set of medical problems and diseases not covered by other medical specialities: a specified theoretical base and knowledge base, specified techniques, and competence in examination and diagnosis related to this specialty.

143.2.6 The NMA Suggestion: Goals for Competence and Suggested Specialty Rules

Addiction medicine is related to problems due to the use of psychoactive substances and also includes the behavioral addictions such as gambling and Internet addiction. The patients' problems are usually due to biological, psychological, and social factors. The clinical scope of addiction medicine comprises prevention, examination, diagnostics, treatment, and rehabilitation. To cover these areas, special medical knowledge and skills are needed. The patient's treatment should be multidisciplinary and based upon close cooperation between doctors, psychologists, social workers, and other professions.

Addiction medicine has four main perspectives: clinical activity, prevention and information to the public about drugs and addiction, guidance to other specialists and to general practitioners, and research and further development of addiction medicine.

The responsibility for developing new specialties and the postgraduate education of medical specialists in Norway have been moved from the Norwegian Medical Association to the Norwegian Directorate of Health in recent years. The specialty in addiction medicine is the first specialty to be developed by the Directorate. The suggestion for the education in addiction medicine which was put forward prior to the decision of a full specialty in addiction medicine in 2012 was in line with the general rules which existed then.

143.2.7 New Changes in the Development of All Medical Specialties in Norway

The Norwegian Directorate of Health was in 2011 commissioned by the Ministry of Health to evaluate the present specialty structure and content for all medical specialties and to suggest changes which will improve the current system. Which medical specialties do we need based on the demography and medical and technological development and the recent law amendments? How should the structure of the specialty education be? Should there be a common trunk for all the specialties? And further, should there be a common competence platform for groups of specialties? What ought to be the content of the education? The Directorate was also asked to suggest how the future roles and responsibilities for the specialist education ideally should be.

The purpose of this evaluation and change is a specialty education which matches the patients' needs and specialty education which is in line with the future need for the patients and the health service system. The specialty education should be national, but at the same time in line with the EU requirements.

The draft with the suggested changes was sent to the Ministry of Health in June 2013 (Fremtidens legespesialister 2013). The suggested structure divides the specialty education into three parts:

1. Eighteen months comprised of 1 year of internship at a hospital and half a year in general practice in the municipalities should be common for all the specialty candidates.
2. One to three years of specialty education for groups of specialists naturally belonging together. The suggestion also implies that subspecialties no longer will exist.
3. Two to four years of internship for each main specialty separately.

The common competence for all specialties could include teaching in communication, leadership and development of organizations, cooperation and coordination, team work, and quality improvement.

The framework for the future education of all medical specialties in Norway is presently being further developed by the Norwegian Directorate of Health and other bodies. Probably it will take another 3–5 years before the new system will be put into action.

The process of developing a new specialty in addiction medicine must be faster than the above process, and our first goal is therefore to make a kind of hybrid specialty: We will base the new specialty in addiction medicine on the present regulations for medical specialties, but at the same time we will be looking into the future and incorporate some of the probable future changes described in the document for future medical education in Norway (Fremtidens legespesialister 2013).

143.2.8 The Process of Establishing the Specialty in Addiction Medicine

Our aim has been to have a broad process with the involvement of all necessary parties in the process leading to a full medical specialty in addiction medicine.

At the same time we want to establish the new specialty rather fast, knowing that many of the present "specialists" in addiction medicine are aging and we need their competence to teach the future specialists.

In January 2013 we established an external committee with representation from all the involved parties: medical doctors working in addiction medicine in the four regional health enterprises, the municipalities, the Norwegian Medical Association, the other professions working in the field of addiction (psychologists, social workers), and service user's representatives. We also invited the members of the newly established specialty committee in addiction medicine in NMA into the work. At the same time we established an internal committee in the Norwegian Directorate of Health with representation from the relevant departments involved in medical education. Both committees have been working on further development of the specialty regulations for addiction medicine and other requirements for the new specialty. The regulations are based on the existing regulations for medical specialist education, but are at the same time taking into account the suggested changes for the future. We have also visited all the possible training hospitals, a total of 14 different hospitals around Norway. At the hospitals we have met a broad representation of professionals involved in addiction medicine and professional training in general, as well as the administration of the hospitals. As many of the interdisciplinary specialized treatment clinics are run by NGOs, they were also invited to the local meetings.

We have developed suggestions for both the specialist education regulations and for the interim regulations, to be able to approve the first specialists in addiction medicine. One large summit meeting has been arranged to ensure that the suggested rules and structure for the specialty in addiction medicine are well known in the relevant areas of medicine and that professionals have had a saying in the shaping of this new specialty. We have also performed a short written summit after the summit meeting. The suggested specialist and interim educational regulations will be sent to the Ministry of Health after an external review, which is responsible for the formal approval of the set of regulations.

143.2.9 The Framework for the New Specialty

The specialists in addiction medicine must have knowledge and skills in alcohol and legal and illegal drugs of abuse, other addictions, pharmacology, somatic and mental comorbidity, psychosocial conditions, prevention, treatment and rehabilitation, collaboration and cooperation, legislation, research, evaluation, and quality standards. Other areas in which the addiction medicine specialists need competence are substance use and pregnancy, addiction among young and elderly people, and other cultural subpopulations with addiction problems.

The structure for the internship after the 18 months of internship required for all doctors after medical school is as follows:

1. Five years of internship in accredited institutions.
   (a) Forty-two months of the internship should be in IST, including 1 year in a hospital department for detoxification/acute ward for drug and alcohol

patients, 6 months in an inpatient ward for substance use treatment, and 12 months in a department for outpatient addiction treatment, including practice with opioid maintenance treatment (OMT). The last 12 months of IST internship can be chosen from the following: more internship in any of the abovementioned departments, up to 6 months in municipality treatment for drug and alcohol (low-threshold health services, OMT at municipality level, prison health service, etc.) or addiction medicine Research.

(b) Eighteen months should be in other specialty areas: 6 months in psychiatry (acute ward, general psychiatry ward), and for the last 12 months, the candidate has to choose two of the following: 6 months of psychiatry (any part, including child and youth psychiatry), 6 months in a somatic ward (internal medicine, emergency ward, infectious disease ward, pharmacology, neurology, pediatrics, gynecology/obstetrics), or 6 months as a general practitioner.

All the internship has to be in accredited institution supervised by a specialist. There is a possibility of combining clinical work with addiction medicine research.

The candidate must have a total of 270 hours of compulsory coursework in defined areas of addiction medicine and other subjects.

The candidate must receive regular clinical supervision from a senior addiction medicine specialist, 1 hour per week, and have 30 hours of systematically specialized supervision in therapy related to addictions. Further, the candidates should have individualized learning plans which are evaluated every 6 months and which describe the candidate's skills and development in addiction medicine.

143.2.10 Why Did We Succeed to Get a Full Specialty in Addiction Medicine?

This has been a long struggle for Norwegian doctors involved in the treatment of addictions. We reached our goal and the decision to establish an addiction medicine specialty because of the steady and systematic work of many engaged doctors working with these patients who never gave up. The "Drug Reform" in 2004 was an important milestone and so was the strong support from the Norwegian Medical Association. The NFRAM report was solid, and the arguments for establishing a specialty in addiction medicine were based on evidence and understood by the other specialist associations in NMA. General practitioners, the psychiatrists, and the internists all supported the proposal. The Coordination Reform which was launched in 2012 relies on the support the specialized health-care system can give to the primary health care. This means that the doctors in the specialized health care (IST) must have expert's skills and knowledge about addiction medicine.

143.2.11 The Way Forward

Addiction medicine is a new specialty. Our goal is to have the first new specialist candidates in training in at least four hospitals from 2015.

As soon as the specialty and interim regulations are approved by the Ministry of Health, the Norwegian Directorate can receive applications from the medical doctors applying to be addiction medicine specialists after the interim regulations. These medical doctors have the necessary competence in addiction medicine to ensure clinical supervision for the new specialist candidates. They will be given a compulsory "crash course" focusing and central issues in addiction medicine and on how the training for the new addiction medicine specialists should be run.

When the first addiction medicine specialists are approved, their hospitals can apply to the Directorate to be appointed and accredited teaching institutions. We also have to develop assessment standards for the specialist candidates.

We are also in the process of establishing necessary structures to develop the necessary coursework for the new specialty.

143.2.12 Is the Norwegian Experience Applicable in Other Countries?

The development in addiction treatment has been quite different in countries around the world. This means that each country has to take steps forward at a pace and in a direction which is in line with both the health service in general and the treatment services for substance users in each particular country.

In Norway we are looking very much forward to establishing the new specialty in addiction medicine, and we are sure that this will represent a major step forward in improving the medical quality of the treatment services for substance use patients.

Norway is happy to share the experiences on developing a full specialty in addiction medicine, both the steps we have made up till now and those of the future, for the benefit of patients and professionals in other countries. This can surely be done through international organizations in addiction medicine as ISAM where we are about to build up a database focusing on what kind of systems for postgraduate training in addiction medicine exist in different countries around the world. In January 2014, ISAM has a network of approximately 30 national contacts from different countries on all five continents. ISAM also have the information about postgraduate training in addiction medicine in 25 of these countries. The database will also have contact information to both national and international Addiction Medicine Associations.

143.3 Conclusion

Addiction medicine is decided to be a full medical specialty in Norway. We have come a long way in the development of the new specialty, but there is still a lot of work ahead. We are happy to go on with this work for the benefit of our patients. It is axiomatic that more competent doctors mean better treatment for our patients.

Abstract

In Indonesia, substance use and misuse are a major public health concern with several problems, such as a huge prevalence of drug users, a small number of addiction treatment facilities, low utilization rate of treatment facilities, limited capacity of health professionals in addiction treatment field, and ongoing stigmatization. Addiction has been criminalized for a long time and has not

been regarded yet as a medical problem. Addiction medicine is not recognized as a medical (sub)specialty. Most of the professionals working in addiction care have never received training on addiction. Medical education only provides addiction medicine training as a one-hour lecture as one of the psychiatric topics for medical students at the preclinical level. There is no formal training in addiction medicine for graduated medical doctors.

The Bandung Addiction Working Group developed as a part of the IMPACT program (Integrated Management of Prevention and Control and Treatment of HIV/AIDS) and in collaboration with several national and international institutions a national addiction medicine training program. They organize an expert consensus meeting of selected Indonesian experts in the field of addiction medicine. The meeting was followed by a training needs assessment and the curriculum development workshop. Those processes continued with the development of a national Indonesian Short Course in Addiction Medicine (I-SCAN). The kickoff I-SCAN training, planned for January 2012, was postponed. Lessons learned conclude this chapter.

144.1 Introduction

In Indonesia, substance use and misuse are a major public health concern. The National Narcotics Board estimated in 2008 that there were 3.3 million (1.99 %) drug users in Indonesia, including 1,580,384 (47 %) drug-addicted patients and 237,057 (15 %) injecting drug users (IDUs) (Suriakusumah 2011). It is estimated that these will increase even further, up to 2.8 % drug users (about five million people) in 2015 (Suriakusumah 2011). Besides the direct substance use-related health concerns, drug use is a major factor in the ongoing HIV epidemic in Indonesia. Injecting drug use increased dramatically in the late 90's in Indonesia, acting as the main force driving the HIV-epidemic. Among the general population, the prevalence of HIV-infection is still low (0.3 %), but up to 50 % or more of IDUs are already HIV-infected (Source: National Aids Commission: Country Report on The Follow Up to The Declaration of Commitment on HIV/AIDS: UNGASS Reporting Period 2006–2007. Committee NA 2007). In 2012, from 21,511 patients with HIV infections, 2,461 (>10 %) cases were IDUs (Laporan situasi perkembangan HIV&AIDS di Indonesia tahun 2013). The Integrated Biological Behavioural Surveillance (IBBS 2011) found syphilis infections among IDUs in Indonesia in about 3 % of cases (Integrated Biological and Behavioural Survey 2011). Moreover, substance use is also involved in other forms of transmission risk behavior, including sexual risk behavior (Iskandar et al. 2009).

Since over a decade Indonesia has implemented evidence-based and effective interventions for the prevention and treatment of both substance dependence and HIV/acquired immunodeficiency syndrome (AIDS). Examples are the development of needle and syringe exchange programs (NSPs) and opioid substitution therapy (OST). Besides residential treatment for substance dependence, Indonesia currently has 242 nonresidential facilities that give services for drug users. However, the utilization rate is very poor (only 0.5 %) (Suriakusumah 2011). In addition,

coverage of HIV prevention and treatment strategies for IDUs in Indonesia is similarly low: about 30 % of the Indonesian IDUs make use of an NSP and 1 % of the IDUs are covered by OST programs; importantly only 6 % of the HIV + IDUs received antiretroviral treatment (ART) (Mathers et al. 2010; Mboi 2010).

Several factors contribute to these poor coverage rates, including limited capacity of well-trained professionals; limited consultation time with medical doctors and poor competencies of healthcare professionals in the addiction treatment field, concerning addiction medicine; and limited availability of integrated services for the patient's medical and psychosocial health and stigma to addicted patients both in the society and in treatment centers (Irwanto et al. 2010; Utami 2001; Pinxten et al. 2011). In Indonesia addiction has been criminalized for a long time and has not been regarded as a medical problem. Moreover, addiction medicine is not recognized as a medical (sub)specialty. Indonesia has about 200 professionals working in addiction care, of which about 17 % never ever received training on addiction (Sarasvita 2010). Most of these addiction care professionals only received a short training in OST and/or NSP management (Sarasvita 2010).

Fortunately, in 2009, the law on narcotics was changed. The old law viewed drug users as criminals that had to be punished. The new narcotics act ("Undang-Undang Republik Indonesia Nomor 35 Tahun 2009 tentang Narkotika 2009") states that people with addiction problems should get medical treatment and rehabilitation (Undang-undang Republik Indonesia Nomor 35 tahun 2009 tentang Narkotika 2009). This paradigm change requires specific addiction training of healthcare professionals, for providing evidence-based and effective treatment for these patients.

To date, medical education in Indonesia sometimes only provides addiction medicine training as a one-hour lecture as one of the psychiatric topics for medical students at the preclinical level. There is no formal training in addiction medicine for graduated medical doctors (Utami 2001; Pinxten et al. 2011; Joewana 2012). Only one medical school in Indonesia (Atma Jaya Catholic University of Indonesia, Jakarta) has a curriculum on addiction medicine as an elective, 5-week block that has been established in 2009 (Joewana 2009, 2012).

144.2 Training Features in Addiction Medicine

144.2.1 Current Training on Addiction Medicine in Indonesia

The Ministry of Education in Indonesia developed the Core Curriculum in Medical Education as a guideline for national faculties of medicine in Indonesia (Joewana 2012). In the Core Curriculum 1980, addiction medicine is embedded in 5-hour psychiatric lectures (Joewana 2012). In 1990, the same concept was applied. The new medical curriculum in 2006 ordered medical education to be more competency based and student centered with an excellence competency to be developed by each university (Joewana 2012). One medical faculty chose addiction medicine as one of its excellences and developed addiction medicine training as an elective training block. In addition, the Ministry of Health, National Narcotics

Board, and National AIDS Commission conduct informal short addiction medicine trainings (2–3 days workshop) for medical doctors who work in their healthcare services. There are also specific short training courses such as harm reduction training and training on methadone or buprenorphine maintenance treatment.

144.2.2 The Addiction Medicine Training Need Assessment

As a part of 5-year European Commission-funded, IMPACT program (Integrated Management of Prevention and Control and Treatment of HIV/AIDS), the Bandung Addiction Working Group was developed. Padjadjaran State University (UNPAD) in Bandung, West Java, Indonesia, and the Dutch Maastricht University, Radboud University Nijmegen, the Nijmegen Institute for Scientific Practitioners in Addiction (NISPA), and Antwerp University of Belgium collaborated in order to take the first steps in the development of a national addiction medicine training program (Pinxten et al. 2011; Alisjahbana et al. 2009). This program offered the opportunity to address also the problem of lacking well-trained professionals in addiction medicine.

Early 2010, in the last program year of the IMPACT program, the Bandung Addiction Working Group, consisting of professionals working with IDUs and HIV patient in IMPACT, University of Padjadjaran, and the psychiatric department of Dr. Hasan Sadikin Hospital, supported by the secretary of the National AIDS Commission (Dr. Nafsiah Mboi) and by the senior IMPACT advisor Prof Dr. C. de Jong, director of the Nijmegen Institute for Scientist Practitioners in Addiction (NISPA), joined forces and took the lead in the development of an Indonesian evidence- and competency-based addiction medicine course (Pinxten et al. 2011). On April 1, 2010, the Bandung Addiction Working Group took the initiative to organize an expert meeting of selected Indonesian experts in the field of addiction medicine. During this meeting, these experts searched for professional consensus on the development of a national curriculum for addiction medicine. This first consensus meeting was joined by 13 high-ranking representatives from national addiction treatment centers, professional organizations, and academic training professionals. During this consensus meeting, all participants decided to continue as the Indonesian Addiction Medicine Study Group and to support the development of a national short course on evidence- and competency-based addiction medicine (Pinxten et al. 2011).

During this meeting training needs were assessed using the training needs assessment (TNA) questionnaire. A detailed report is published elsewhere. This questionnaire was based on the medical competencies as defined by the Indonesian Medical Association as well as on international competencies for the Addiction Medicine Specialist derived from the models of the Royal College of Physicians and Surgeons of Canada (Frank et al. 1996), the CanMEDS 2005 Physician Competency Framework "Better standards. Better physicians. Better care" (Frank 2005), the Profile of the Dutch Addiction Medicine Specialist (VVGN 2008), the Dutch Profile Psychiatrist (NVVP 2005) and international programs for Addiction Psychiatry (http://www.acgme.org/acWebsite/home/home.asp), criteria for international certification in addiction medicine (http://www.isamweb.org), and the

SAMHSA (Center for Substance Abuse Treatment 2006). Implications for the medical education in psychiatry were also taken into account (Scheiber et al. 2003).

During the meeting the experts selected the core competencies that should be covered in such a national addiction medicine training curriculum from this extensive list of competencies. This resulted in 30 selected competencies covering three domains:

1. Assessment of substance use disorders
2. Treatment initiation
3. Continued treatment of patients with chronic substance use disorders (Pinxten et al. 2011)

This consensus meeting was followed by a 2-day addiction curriculum workshop for about 35 Indonesian addiction medicine professionals from all over Indonesia. During this workshop the 30 selected addiction medicine competencies were prioritized using a 5-point Likert scale covering all topics previously identified (Pinxten et al. 2011). The participants were also asked to select the ten most important competencies from the list. Based on these ratings, the following ten core competencies for the national addiction medicine curriculum were identified (Pinxten et al. 2011):

- Selecting appropriate screening/assessment tools for substance use disorders
- Screening risk of substance use problems
- Assessing substance use problems by taking a patient's history
- Interpreting substance use by screening, assessment, and lab results
- Formulating a substance use disorder (SUD) diagnosis according to DSM-IV
- Explaining diagnosis, prevention, and treatment plan to the patient
- Developing a written treatment plan
- Selecting indicated initial treatment medications
- Using motivational techniques to support adherence to treatment
- Managing withdrawal

During the second day of the 2-day conference, it was decided that the comprehensive professional training course would include the following seven theoretical modules (Pinxten et al. 2011):

- General introduction including history of addiction and addiction care, co-occurring disorders, and legal aspects
- Basic concepts of addiction including different aspects of the biopsychosocial model
- Psychopharmacological characteristics and neurobiology of psychoactive substances
- Clinical features, assessment, and diagnosis
- Management of treatment
- Addiction care skills, including behavioral and technical competencies
- Monitoring, evaluation, and research

144.2.3 Indonesia Short Course in Addiction Medicine (I-SCAN)

The next step in the development of a national addiction medicine curriculum was to develop the content of this course, based on the professional consensus as

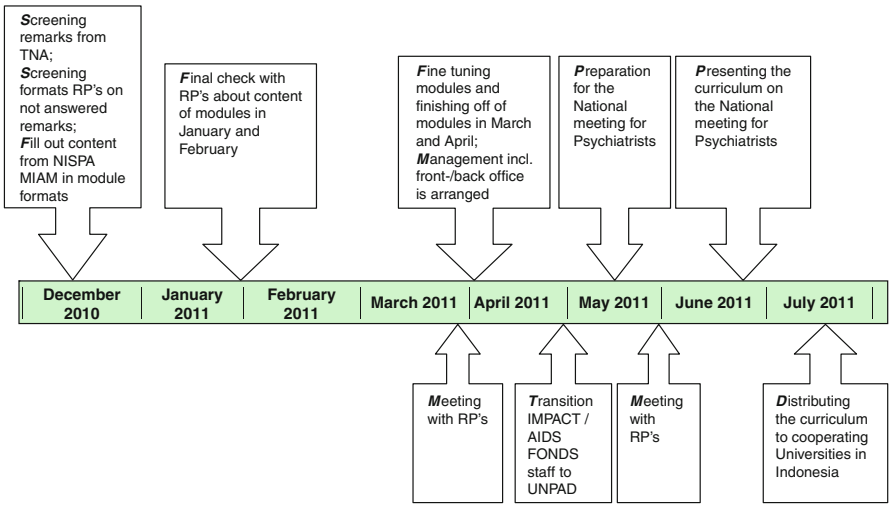

Fig. 144.1 Time line curriculum development Indonesian short course in addiction medicine

described above. Bandung Addiction Group hosted two 2-day workshops for the Indonesian Addiction Study Group. In November and December 2010, a broad alliance of national stakeholders in addiction and HIV care joined forces to further develop a national Indonesian Short Course in Addiction Medicine (I-SCAN). Stakeholders included healthcare professionals, representatives from the Indonesian Psychiatric Association, national and international NGOs, the national AIDS Commission, Ministry of Health, and some universities (University of Indonesia Jakarta, Atma Jaya Catholic University of Indonesia Jakarta, Udayana University Bali, Gadjah Mada University Yogyakarta, and Airlangga University Surabaya).

During this meeting the general objectives were defined, as well as specific objectives per training module. The overall study load of the course was agreed upon (including total contact hours/self-study, practical/field training, research and thesis writing) as well as the mixture of knowledge, attitude, and skills training per training module. Contact persons were identified for each participating organization, resulting in one teaching team per module. In addition a national I-SCAN directorate and secretariat were appointed, as well as a quality control mechanism and certification. Finally, a budget was estimated and a strategy was defined to find additional funding for a first tryout of the I-SCAN.

Following these workshops, the Bandung Addiction Working Group finalized the national curriculum by fine-tuning organizational, logistic, and professional aspects of I-SCAN, including the detailed content, organizing a national Ministry of Health accreditation, and establishing an electronic library of international and national reference publications (Fig. 144.1).

In order to facilitate long-distance learning, the NISPA supported the Bandung Addiction Working Group in the development and installation of an electronic

learning environment (Moodle). By mid-2011 a complete and detailed Indonesian evidence-based addiction curriculum was ready and marketed.

Unfortunately, the kickoff I-SCAN training planned for January 2012 had to be postponed because of several reasons. Targeted participants questioned the practical use of the I-SCAN certification for their carrier: they rather preferred a master type of course that fits in the normal medical career path instead of this 3-month course. Until now, there is no supportive policy from Ministry of Health stating the need for addiction services and addiction medicine training: national policy support is difficult to get at the end of the process; one should start with it. It is difficult to find donor support for a national training: a buy-in process should be started in an early phase of the curriculum development process. Targeted participants were those who already work in addiction services. Without explicit permission from their institution, it is difficult for them to leave their work for joining this 3-month course. Trainers come from several cities in Indonesia; therefore, the fee for joining this course is quite expensive without financial input from national level or from donor side.

144.2.4 Lessons Learned

A successful bottom-up and multi-stakeholder development process by addiction professionals does not guarantee the continuous leadership and momentum needed to mobilize national and international support. We suggest that a major operation like the development of a national curriculum should never start at the end of a donor-funded program. Finally we have to conclude that it is politics that matters at least as much as educational process and professional content.

Contents

Abstract

This chapter reviews a decade's effort by the International Society of Addiction Medicine to develop a multiple choice test of knowledge in the field. The process of establishing a pool of questions as well as criteria for eligibility to challenge such an examination is described.

Lessons derived from the repeated administration of the exam are reviewed. An international examination is possible involving questions with good psychometric properties. The challenges of striving for an "a-cultural examination" are reported as well as the necessities of cost accessibility, security, and sensitivity.

145.1 Introduction

In 1999, the International Society of Addiction Medicine (ISAM) came into being. Its mission was to promote an international agenda, including advancing the knowledge about addiction seen as a treatable disease, advocating for the major role physicians play in its management as well as enhancing the credibility of their role, and, last, developing educational kits accessible to an international audience.

The need for improved medical education in the field is well recognized in both developed and developing countries and is detailed in other chapters of this textbook's section (Crockford and el-Guebaly in press; Ayu and De Jong in press). The call for educating all physicians in playing their respective roles in the care of patients affected with the disorders of addiction has been made repeatedly (Crockford and el-Guebaly in press; Ayu and De Jong in press; Soyka and Gorelick 2009). An increasing number of generalists and specialists physicians are dedicating a major portion, if not all of their practice, to this significant public health issue. Enhancing their credibility and validating their practice through a formal process of certification became a goal of ISAM.

There is a growing international consensus about the core competencies required of every physician in treating abusing or addicted patients. They are *s*creening, *b*rief *i*ntervention including motivational interviewing, and awareness of *r*eferral for *t*reatment options including mutual help. In the USA, these competencies are known by their acronym SBIRT (Madras et al. 2009). By comparison, the boundaries of individual specialty competencies are understandably less defined. Based on core concepts from the basic sciences, evidence-based practices include, but are not limited to, prevention strategies; diagnosis, assessment, and early interventions; detoxification and craving; relapse prevention; psychotherapy, CBT, 12-step, motivational enhancement, contingency management, and cue exposure; psychopharmacology, general and specific including maintenance and medication interaction; physical and psychiatric concurrent disorders, primary or secondary disorders; ethical and legal issues around the workplace, including a physician's own impairment; chronic pain; forensic issues; cultural factors; age and gender issues; and behavioral addictions.

In the USA, the first medical association's certification examination in the field was held in 1983 by the California Society of Addiction Medicine, followed by the first national examination in 1986 under the auspices of the American Society of Addiction Medicine (ASAM). The American Academy of Addiction Psychiatry established the first subspecialty examination under the auspices of the American Boards in 1993, and more recently the American Society of Addiction Medicine has created an independent American Board of Addiction Medicine (ABAM). Currently, those board certifications or diplomas are valid for 10 years. A commitment to maintenance of certification through documented lifelong learning and assessment of practice-based performance is also required. The criteria of eligibility for challenging these examinations limit the access to candidates mostly from within North America.

145.2 The Certification Process

145.2.1 Chronological Development of an International Certification

Based on the US experience, in Sept 2003, in Amsterdam, the Board of the International Society of Addiction Medicine (ISAM) accepted to set up a valid but affordable international certification. An Editorial Board was formed composed of ten senior clinician members of ISAM from seven countries. An expert in medical education research, including examination psychometrics (C.V.), joined that Board.

ISAM recognized three English language multiauthored textbooks, as a repository of current knowledge in the field through their successive editions (Galanter and Kleber 2008; Ries et al. 2009; Ruiz and Strain 2011). These texts are backed by some 150 peer-reviewed journals in the field, ranging from basic science to clinical practice. An increasing number of research institutes are disseminating information across the world, including leading institutions such as, in the USA, the National Institute of Drug Abuse and the National Institute on Alcohol Abuse and Addiction.

To meet the criterion of affordability as well as reducing the differential access to the literature in different parts of the world, the knowledge basis of the examination is from the three identified textbooks with a primary reliance on the *Principles of Addiction Medicine* (Ries et al. 2009). In addition, the nomenclatures of *Diagnostic and Statistical Manual of Mental Disorders*, (4th ed., text rev.; *DSM-IV-TR*; American Psychiatric Association, 2000) and *International Statistical Classification of Diseases and Related Health Problems*, *Tenth Revision* (ICD 10) (http://www.who.int/classsifications/icd/en/; Nedelsky 1954) were also recommended. Soon these nosologies will be updated with a DSM-V and ICD 11 versions.

Next came the draft of multiple choice questions. From the onset, a concerted effort was made to select as many "culture-neutral" questions as possible. Half of the Editorial Board were ASAM certificants and aware of the preponderance of research data based on US populations in the textbooks that would be of lesser significance in other continents. This meant that the epidemiological database had to shift to the data collected by international bodies such as the World Health Organization (WHO) and the United Nations Office of Drug Control. Another implication was the exclusion of questions about national legislation replaced by questions about the International Conventions. At the end, from an initial pool of 450 questions, 200 multiple choice questions (MCQs) were selected at a 2-day meeting in September 2004 in Calgary. It was recommended that four options for each MCQ were sufficient (25 % chance per option instead of five with 20 % chance). From the very onset, it was clearly stated that the certification would be a test of *knowledge* with some clinical *judgment*. The number of questions allocated to each content area was debated at length. It was eventually agreed that the proportion of content questions would reflect the extent of coverage of the topic in the selected textbooks (See Table 145.1).

Table 145.1 List of topics and questions

Content areas	No. of questions[a] (2011)
I. Definitions and core concepts, basic sciences, including neurobiology, epidemiology, and pharmacology	40
II. Diagnosis, assessment, and early intervention, including prevention and family	10
III. Intoxication and withdrawal	12
IV. Treatment, including linkages, pharmacological interventions (opioid), behavior interventions, family, 12-step/spirituality	65
V. Workplace issues/physician health	10
VI. Physical disorders and complications	27
VII. Psychiatric comorbidities and complications	24
VIII. Pain and addiction	12
IX. Children and adolescents	15
X. Behavior addictions	10

[a]Including 25 experimental questions

145.2.2 The Minimum Performance Levels (MPL) Method

To fulfill their mandate of protecting the public, licensure and certification boards in the health professions need to determine which candidates are qualified to attain certification (pass the examinations) or not (fail). Many of these organizations use criterion-referenced testing with predetermined cutoff scores for pass/fail on licensing or certification examinations. There are many ways to set such cutoff scores, but most rely on expert judgment employing empirical approaches such as the Nedelsky (1954) procedure based on the principle of minimum performance levels (MPL). Accordingly, we employed a modified Nedelsky procedure for setting cutoff scores using MPLs.

In this criterion-referenced testing procedure, the total test score MPL is the sum of each item MPL (Violato et al. 2003). The item writer, therefore, sets an MPL for each item. The MPL is the value ranging between 0.25 and 1.0 which reflects the probability that even a *minimally competent* candidate can answer this item correctly. An MPL of 0.25 indicates a very difficult item with an MPL of 1.0 reflecting an easy one.

145.2.2.1 Example Item from an ISAM Examination

An added formulation of buprenorphine designed to discourage intravenous use contains? (**stem**)

(a) Gabapentin (**distracter**)
(b) Nalmefene (**distracter**)
(c) Acetylcysteine (**distracter**)
(*d) Naloxone (**keyed response**)

a = 1.0 b = 0.75 c = 0.75 d = *

$$\text{MPL} = 1/(4 - \text{sum of p}) = 1/(4 - 2.50) = 0.67$$

Each question having undergone a thorough and rigorous editing process receives an MPL. The construction and psychometric analysis of the exam is under the auspices of faculty from the Faculty of Medicine at the University of Calgary.

To renew the pool from September 2006 on, 25 "dummy" or experimental questions were added for psychometric testing and formed the basis of new yearly questions. This is a common practice in the testing industry to identify questions performing well enough to be retained for future test takers.

The current exam is in two parts with an allowed duration of 2:15 h each.

145.2.3 Psychometric Analysis

145.2.3.1 Item Analysis

A complete analysis of the test requires an item analysis. There are three essential features that constitute an item analysis: (1) difficulty of the item, (2) item discrimination, and (3) distracter effectiveness (el-Guebaly and Violato 2011).

The difficulty of the item is the percentage or proportion of people who got the item correct. Item discrimination has to do with the extent to which an item distinguishes or "discriminates" between high test scorers and low test scores. Distracter effectiveness refers to the ability of distracters in attracting responses. A distracter that attracts no response is not effective; it begins to become effective when it attracts some responses.

145.2.3.2 Reliability and Validity

The reliability of scores is assessed using the coefficient α. Coefficient α estimates the amount of variability in applicants' scores that is due to the difference in ability rather than random influences such as guessing. In the initial series of applicants, the reliabilities of all subtests ranged from adequate to good. Validity of a test has to do with extent to which it measures whatever it is supposed to measure. As very careful attention is given to the development of the appropriate sampling of the subject matter and content (i.e., addiction medicine) of the ISAM test, it has adequate content validity. Empirical evidence of validity is sought by evaluating the correlations between the subscales of the test.

145.2.4 Criteria of Eligibility and Applicants' Countries of Practice

To enhance access to the examination by an international audience, the following eligibility criteria were recommended:

- Graduation from a medical school recognized by the WHO
- Valid license to practice medicine from a licensing jurisdiction (national, regional)

- Good standing in medical community, evidenced by at least three letters of recommendation, from *physicians* knowing the applicant for at least 2 years including, if possible, one current ISAM member
- Documented substantial portion of medical practice over a 3-year continuous period in the addiction field
- Peer-supported evidence of continuing education (conferences, workshops, courses, etc.) over the past 3 years

The above criteria seem to be within the reach of all applicants, and no noticeable impediment to access of the required information has been recorded.

FEES: An international money order payable to the *International Society of Addiction Medicine* for $700 US (non-ISAM members), $600 US (ISAM members), and $625 US (Affiliate Societies members) is forwarded, along with the application.

Since 2005, the examination has been held thirteen times. Practitioners from Canada (21 candidates), Egypt (37 candidates), and Saudi Arabia (17 candidates) have formed the bulk of the applicants so far. Candidates from Hong Kong, Iceland, Kuwait, Sudan, Turkey, and Vietnam have also challenged the examination. The overall pass rate has been 75 % so far.

145.2.5 Lessons Learned

In North America, the Canadian Society of Addiction Medicine recognizes both ASAM and ISAM certificates as equivalent. These qualifications are readily recognized to designate experts in courts and with independent medical examinations (IMEs) for a host of insurance and other agencies.

In Egypt, the ISAM certification is recognized by the Ministry of Health as a professional qualifier. The universities have agreed to use the examination as an end of training knowledge qualifier followed by a clinical skills examination.

A dialogue is ongoing, in several countries in Europe, to use the certification as adjunct to local diplomas. Setting a valid and reliable examination is a time- and resource-intensive exercise, and from our experience, the process of testing core knowledge does not need to be duplicated in every country. Potential addition of questions of national interest to the core questions is a possibility.

As the ISAM certification enters its tenth year, a review of the experience leads to the following conclusions:

1. An international certification examination is possible! While the experience so far focuses on Canada and the Middle East, the process is slowly gaining credibility judging from the inquiries from other regions. As of this year, the examination is available to international fellows training in North America's leading institutions. Local leadership support to disseminate information and promote the value of a clinical knowledge qualifier is critical.
2. The questions show good discriminatory performance. Following the first exam set of 200, 9 questions were dropped and new ones added from the pool, and 36 others had their MLP readjusted, "raising the bar." To renew the pool,

25 "dummy" questions are added to be tested in each examination. A major editorial update was conducted in 2010 and 2011, resulting in the replacement of one third of the questions by new ones and another third being modified. Only the references of the remaining third were updated. The third cycle of editorial update will begin next year.

3. The careful development of the ISAM test has resulted in evidence for both validity (content, empirical) and reliability (internal consistency) and items that are carefully reviewed and evaluated for difficulty, discrimination, and distracter effectiveness.
4. The recommended curriculum should inform examination and vice versa. Topics where the candidates are the weakest included pain and addiction; behavioral addictions; and diagnosis, assessment, and early intervention. In several countries, the field of addiction is limited to the management of substance misuse. Addition of "local" questions to the core examination has been proposed to accommodate the local legislative and possible cultural needs.
5. An "a-cultural" examination may be only a goal to strive for. Biological or laboratory tests may be largely culture-free, although epigenetic findings are showing a number of ethnic differences. Epidemiological data, psychological treatments, mutual help resources, and workplace guidelines are more influenced by the local culture. Many countries forbid the use of methadone maintenance, for example. Can a core examination be fair globally when the medical practices are subject to different cultural and economic constraints? Candidates appreciate the need to be aware of evidence-based treatment options available in other parts of the world and may promote their culturally sensitive adaptation in their own country.
6. The cost, integrity, and sensitivity of the examination are critical in all areas of the world but particularly in developing countries.
7. We continue to rely on standard textbooks, which are updated regularly. Increasingly, these texts are available in electronic versions and may be published with a companion set of questions. So far, few of these questions adhere to exam setting standards but may serve as good training exercises. The ISAM textbook where this chapter will appear aims at further collating international practices.
8. Each successful candidate receives a numbered certificate to avoid forgery. Displays of association membership certificates in practitioners' offices as evidence of competence have been reported. This increases the need for a recognized certificate, testing clinical knowledge through MCQs, and clinical vignettes.
9. The repeated experience of the examination in developing countries is that the pool of often university-based candidates readily achieves pass and higher scores. This pool is however finite. This observation calls for enhanced national efforts to increase the pool of justified candidates practicing evidence-based medicine across the nation.

10. Presenting standardized review courses and complementing the test of clinical knowledge with a standardized objective structural clinical exam (OSCE), administered locally, is the next frontier.

There is no doubt that language proficiency can be a barrier. Discussions have been underway to translate the examination into Spanish and Italian. Settings where a computerized version of the examination can be administered are being contemplated. The security of this process may be improving. The cost remains significant. The search for funding support is ongoing. Several examination sets are being administered by different academic institutions worldwide; must we reinvent the wheel time and time again?

Navigating Access to Addictions Literature: The Hubert H. Humphrey Fellowship Experience

146

Nita Bryant

Contents

Abstract

Treatment providers lacking access to university libraries and/or costly journals have greater access than ever before to the scientific literature in the field and to the companion gray literature that distills the science into practical information. Educational sources essential for understanding and engaging in evidence-based practice (EBP) are also increasingly available online free of charge. While this is clearly cause for celebration, awareness of these resources is low, and navigating this highly complex and disjointed literature terrain can be daunting without professional guidance. The intent of this chapter is to raise awareness of these complementary sources, demonstrate their scope and utility, and encourage their use.

146.1 Introduction

Evidence-based practice requires a wide range of competencies. Among the most important is the ability to translate clinical problems from every day practice into focused questions that facilitate efficient evidence searches. Equally important is the ability to read and critically appraise the primary evidence for rigor, relevance, and utility (Carr et al. 2011; Mokhtar et al. 2012). Busy clinicians may prefer to utilize time-saving pre-appraised information like systematic reviews, evidence-based synopses, and clinical practice guidelines (Ilic 2009). Unfortunately, while evidence for answering many clinical questions exists, it may not be easily accessible (Leffler et al. 2013). For treatment providers lacking access to university libraries and/or costly journals, retrieving this essential literature can be problematic. One means of bridging this gap lies in the growing body of "gray literature" that is available from organizations directly involved in science-based addiction technology transfer efforts (Clark 2002; Condon et al. 2008). Disseminated via governmental websites rather than peer-reviewed journals or commercial publishing routes, gray literature includes bulletins, research reports and summaries, best-practice guidelines, training materials, and technical manuals (Alberani et al. 1990). Although not considered "scholarly" per se, this vital information effectively distills the best available scientific evidence into a language that makes findings accessible to a wide audience of stakeholders (Brown 1995). As such, gray literature is an essential complement to primary research in the field (Marinelli-Casey et al. 2002; Coomber et al. 2003; McGrath et al. 2006; Lin and Vaska 2009; Ali et al. 2010).

Until recently, much of this primary research has been too costly and out of reach (Brower 2010). Through the collective efforts of organizations like the International Network for the Availability of Scientific Publications (INASP), journal publishers, research institutions, scientific societies, librarians, and research funding agencies, these economic barriers are being dismantled in favor of open access (OA) publishing models and public access policies that make research available online free of charge to anyone with an Internet connection. The rapid and efficient global dissemination of research findings also increases the visibility of research from emerging countries (Arunachalam 2003), allowing everyone to build on the science, experiences, and culturally specific approaches of other nations. Taking full advantage of this openness, however, requires a solid foundation in evidence-based skills.

While EBP is being integrated into graduate and training programs worldwide, many professionals have not been sufficiently trained in EBP techniques (Leffler et al. 2013; Mokhtar et al. 2012). Fortunately, introductions to and continuing education EBP modules are widely available on the web. These sources complement the gray literature and open access publications which have made essential information more widely available to the field than ever before. While this is clearly cause for celebration, awareness of these resources is low, and navigating this highly complex and disjointed literature terrain can be daunting without professional guidance (Lin and Vaska 2009; Brower 2010). The intent of this chapter is to raise awareness of these valuable information sources and guide readers to sources that might otherwise go untapped.

146.2 Open Access Features

146.2.1 Setting and Methods

The chapter draws insight from the experiences of Hubert H. Humphrey Fellows affiliated with the Institute for Drug and Alcohol Studies at Virginia Commonwealth University in the USA (www.vcu.edu/idas/humphrey.html). The Humphrey program, which is funded jointly by the US State Department and the National Institute on Drug Abuse, brings mid-career professionals from developing nations to the USA to learn about evidence-based government policy, prevention, and treatment programs. Representing a wide spectrum of stakeholders, fellows include attorneys, clinical psychologists, correction officers, educators, forensic toxicologists, government and NGO consultants, physicians, and social workers from Brazil, Kazakhstan, Myanmar, Nigeria, Sri Lanka, Togo, Trinidad and Tobago, Uganda, and Uruguay. Despite their professional and geographic diversity, Fellows share common needs and concerns: locating evidence-based sources they can adapt to specific regional contexts, maintaining access to resources after leaving the university and losing library privileges, and feeling lost in the maze and sheer volume of available information.

These needs and concerns generated a lengthy search for solutions and led to the development of a Drugs and Alcohol Research Guide (http://guides.library.vcu.edu/drugs-alcohol). The portal facilitates access to OA publications and gray literature, reduces the volume of resources to a select few, and can be accessed by anyone with an Internet connection. It also includes educational sources for continuing education in EBP. The development of the portal required an extensive review of websites and electronic databases that might include open access resources. These were then narrowed down by assessing their scholarly merit, utility, relevance, and stability. It also required an extensive search for gray literature produced by credible noncommercial organizations directly serving the practical needs of stakeholders in the field. This vetting process required a substantial investment of time and effort, but the selected resources free users from sorting through the larger volume and variable quality of online information regarding addiction. This chapter draws selected examples from the portal to demonstrate the nature, scope, and utility of these sources; provides information about how to locate addictions research, gray literature, and evidence-based practice sources; and includes an annotated list of useful websites and search tools.

146.2.2 Open Access to Scholarly Research

The prevention and treatment of addictions depend on access to and sharing of primary research worldwide. Today, this is becoming increasingly possible through the growth of OA articles that appear in traditional journals; through peer-reviewed fully OA journals in medical, social, and behavioral sciences that include research in addictions; and through a small subset of subject-specific journals. The latter

include *Addiction and Health* (published by the Kerman University of Medical Sciences and Health Services, Iran), *Addiction Science & Clinical Practice* (previously published by NIDA), *Harm Reduction Journal* (affiliated with Harm Reduction International and the Eurasian Harm Reduction Association), *Heroin Addiction and Related Clinical Problems* (official journal of EUROPAD), *Substance Abuse*: *Research and Treatment* (published in partnership with HINARI, the World Health Organization's Access to Research in Health Programme), and *Tobacco Induced Diseases* (the official journal of the International Society for the Prevention of Tobacco Induced Diseases).

146.2.3 OA Journal Repositories

Most OA journal publishers deposit articles in searchable, internationally recognized OA repositories like PubMed Central (PMC) in the USA (www.ncbi.nlm.nih.gov/pmc/), PMC Canada (http://pubmedcentralcanada.ca/pmcc/), and Europe PMC (http://europepmc.org/). These are repositories for author manuscripts submitted in compliance with public access policies mandated by funding agencies. Among these bodies are the US National Institutes of Health (NIH), the Canadian Institutes of Health Research (CIHR), the National Research Council's Canada Institute for Scientific and Technical Information (NRC-CISTI), the European Research Council, and the Wellcome Trust.

146.2.4 Institutional Repositories

The momentum of the OA movement is evident in the growth of institutional repositories that collect, preserve, and freely disseminate the intellectual output of colleges, universities, research organizations, and institutions. The Directory of Open Access Repositories/OpenDOAR (http://www.opendoar.org/search.php) enables users to search across all available repositories from Africa, Asia, Australasia, the Caribbean, Central America, Europe, North America, Oceania, and South America simultaneously using a familiar Google Custom Search Engine (CSE). Because PubMed Central is among these depositories, OpenDOAR can be a valuable starting point and discovery tool for locating journal articles, relevant theses, dissertations, research reports, and working papers from international organizations that would otherwise be hard to locate.

While OA is not yet the default method for distributing new peer-reviewed research in the biomedical sciences, it is gaining momentum globally and represents an essential chain of communication from researcher to practitioner (Chan et al. 2009). As such, awareness of these resources and how to access them is important for researchers and practitioners alike (Brower 2010). Equally important is the ability to critically appraise the quality and rigor of research articles, an essential component of EBP. Many for-profit OA publishers claiming to be legitimate are not. Jeffrey Beall, a librarian at the University of Colorado, in Denver

(USA), maintains a continuously updated list of suspect ("predatory") publishers available at http://scholarlyoa.com/publishers/. In this environment, the need for critical appraisal skills is clear.

146.2.5 The Role of Gray Literature in Addiction Treatment: *Translating* Research to Practice

The term "translate" aptly describes the problem at hand. Research scientists and practicing professionals have very different missions, roles, means of communication, and information needs (Leckie et al. 1996; Marinelli-Casey et al. 2002; Ali et al. 2010; Rosa et al. 2012). A professional's time is devoted to task-oriented activities that arise from serving multiple roles simultaneously. For instance, Humphrey Fellows may need to develop a prevention or treatment program that is compatible with conditions in their home countries, demonstrate the need for doing so to policy makers and funders, and then educate and recruit community leaders and counselors to help carry it out. Although these interrelated activities must be informed by the best available scientific evidence, much of the practical information will not be found in peer-reviewed journal articles. Fellows often require information delivered in specific formats like implementation manuals or in PowerPoint slides explaining the components of an intervention program. They require information delivered in nontechnical language that makes it accessible to a wide audience of constituents and influencers (Brown 1996).

Over the last several decades, local, national, and international agencies have emerged to meet these practice needs, and today, this type of information is widely available. Agencies like the National Institute on Drug Abuse (NIDA) in the USA, the European Monitoring Centre for Drugs and Drug Addiction (EMCDAA), and the World Health Organization's Department for the Management of Substance Abuse disseminate tools for planning, screening, training, assessment, continuing education, and other needs that arise in the course of day-to-day practice. Considering the importance of gray literature to the addictions field, knowing how to access it is essential (Lin and Vaska 2009). Given the sheer volume of this literature, however, navigating it can be a daunting task. There are simply far too many relevant websites to search them all regularly, and many of these sites can be overwhelming in and of themselves. One solution to this problem is a single portal enabling users to search across multiple potentially relevant sites simultaneously (LaPelle et al. 2006). The Google Custom Search Engine described below does just that.

146.2.6 Intergovernmental Organization (IGO) Search Engine

Global in scope, the Intergovernmental Organization (IGO) Search Engine (http://www.google.com/cse/home?cx=006748068166572874491%3A55ez0c3j3ey) was

launched by David Oldenkamp, International Documents Librarian at Indiana University. It has proven a valuable tool for locating a wide range of technical manuals, reports, and other materials relevant to the needs of international addiction practitioners. An example of a search carried out at the time of this writing demonstrates the reach, relevance, and utility of this Google Custom Search Engine. Searching "*evidence-based*" *implementation* "*needle exchange program*" generated results that included a World Bank policies and procedures manual for starting and managing needle and syringe programs, a literature review of international prison-based syringe exchange programs carried out by NDARC (the National Drug and Alcohol Research Centre at the University of New South Wales), a legal framework for needle exchange programs from the European Monitoring Centre for Drugs and Drug Addiction, and a guide to evaluating needle exchange programs from Harm Reduction International.

146.2.7 Selected Resources

This section provides an annotated list of evidence-based resources chosen for their relevance to the needs of Humphrey Fellows. The sample sites provide tools that focus on workforce and organizational development for effective program implementation; tools for planning, monitoring, and evaluating program activities; instruments for assessing the extent of drug use in their home countries; and opportunities for continuing professional education. As such, the selected sources should be of value to an international audience of addiction professionals.

146.2.7.1 Addiction Technology Transfer Centers (ATTCs)

In the USA, the National Institute on Drug Abuse (NIDA) and the Substance Abuse and Mental Health Services Administration (SAMHSA) are charged with the task of moving of important scientific findings into mainstream addiction treatment practice. SAMHSA's Addiction Technology Transfer Center (ATTC) Network is one of the primary vehicles for accomplishing this task (http://www.attcnetwork.org/explore/priorityareas/). Focused on workforce development, the ATTC Network is committed to improving the competency of current and future practitioners primarily by creating and expanding continuing education courses and modules. Of particular note is *The Change Book*: *A Blueprint for Technology Transfer*. It includes evidence-based principles, steps, strategies, and activities for implementing change initiatives that improve prevention and treatment outcomes across multiple interacting systems. At the time of this writing, *The Change Book* had been downloaded more than 21,000 times from the ATTC Network website above. Through the ATTC Online Learning Portal (http://www.attcelearn.org/), frontline counselors, clinical supervisors, administrators, and students can enroll in free online self-paced courses that range from essential substance abuse skills, foundations for working with addictions, to clinical supervision foundations to foundations of SBIRT.

146.2.7.2 SAMHSA's Knowledge Application Program (KAP) (http://kap.samhsa.gov/index.htm)

SAMHSA's KAP resources include the TIPS (Treatment Improvement Protocols) Series. Each TIP contains best-practice guidelines for topics that range from *Improving Treatment for Drug-Exposed Infants* (TIP 5) to *Comprehensive Case Management for Substance Abuse Treatment* (TIP 27). The TAPS (Technical Assistance Publications) Series provides practical guidance and information related to the delivery of treatment services. Among these are *Addiction Counseling Competencies*: *The Knowledge*, *Skills*, *and Attitudes of Professional Practice* (TAP 21) and Competencies *for Substance Abuse Treatment Clinical Supervisors* (TAP 21A). KAP Curriculum packages include trainers' manuals, participants' manuals or handouts, and PowerPoint/overhead slides. For instance, the *Therapeutic Community Curriculum Trainers Manual* provides teaching materials for an 11-module training course designed to help new employees in a therapeutic community (TC) understand fundamental TC concepts. Included are step-by-step presentations, reproducible resource sheets, and PowerPoint slides. Many KAP materials are adapted for consumers or clients whose first language is not English.

146.2.7.3 Methadone Research Web Guide and Tutorial (http://international.drugabuse.gov/educational-opportunities/certificate-programs/methadone-research-web-guide)

Part of the NIDA International E-Learning Certificate Program Series, this Web Guide gives a basic overview of research supporting approval of methadone maintenance as a viable opioid treatment therapy in the USA. It answers the most frequently posed questions by the international community regarding the path of research inquiry used by the USA to support approval of methadone as a treatment therapy. The tutorial addresses questions in four subject areas, and each question links to the Methadone Research Web Guide for more information. Readers may answer the questions before or after reviewing the full Web Guide or concentrate on the section of the Web Guide that is most relevant to them.

146.2.7.4 Motivational Incentives Suite: A NIDA-SAMHSA Blending Initiative (http://www.bettertxoutcomes.org/motivationalincentives/index.html)

This collection of tools assists organizations along a continuum from raising awareness about motivational incentives (also referred to as contingency management) through dissemination and implementation activities. PAMI (Promoting Awareness of Motivational Incentives), an introductory training tool, exposes organizations to the principles of MI and demonstrates evidence of clinical effectiveness. Behavioral health-care practitioners can then deepen their knowledge through participating in the free, self-guided, interactive online course, Motivational Incentives: Positive Reinforcers to Enhance Successful Treatment Outcomes (MI: PRESTO). Of particular note, treatment organizations can also access additional implementation support through the Motivational Incentives Implementation Software (MIIS), developed by the National Institute on Drug Abuse and available

at no cost. This desktop software provides mechanisms for maintaining patient information and Motivational Incentive activities.

146.2.7.5 Global Assessment Programme on Drug Abuse/GAP (http://www.unodc.org/unodc/en/GAP/index.html)

The United Nations Office on Drugs and Crime (UNODC) distributes the GAP methodological toolkit to strengthen the global information base on drug abuse through the use of harmonized indicators among Member States. The toolkit includes eight modules covering topics that include indirect methods for estimating prevalence, measurement of drug treatment demand, conducting school surveys on drug abuse, and data management. Most of the modules are available in English, French, Russian, Spanish, and Arabic.

146.2.7.6 Treatnet Training Package (http://www.unodc.org/treatment/en/training-package.html)

This is the largest international training initiative in the addictions. Treatnet, a 20-country UNODC international consortium, is currently active in drug dependence treatment service improvement projects in Africa, Central Asia, the Middle East, South America, and Southeast Asia. . . The curriculum emphasizes evidence-based addiction treatment practices with a strong empirical foundation. The four-volume training package created for this initiative covers Screening, Assessment and Treatment Planning; Elements of Psychosocial Treatment; Addiction Medications and Special Populations; and an Administrative Toolkit. It also includes a question-by-question manual for using the Addiction Severity Index (ASI), an addiction assessment tool widely used throughout the USA and in other countries.

146.2.7.7 Best-Practice Portal (http://www.emcdda.europa.eu/best-practice)

Developed by the European Monitoring Centre for Drugs and Drug Addiction (EMCDDA), this portal is focused on illicit drugs and polydrug use in Europe. The portal is structured by thematic modules that include the available evidence for prevention (families, schools, communities), treatment (amphetamines, cannabis, cocaine, opioids), harm reduction (opioid injectors, stimulant injectors, non-injecting drug users), and social reintegration (drug treatment, criminal justice, housing, education/vocational training, employment). Of particular note is the Evaluation Instruments Bank (http://www.emcdda.europa.eu/eib), an extensive online archive of freely available instruments for treatment, prevention, or harm reduction interventions.

146.2.7.8 SAMHSA's National Registry of Evidence-Based Programs and Practices (NREPP) (http://www.nrepp.samhsa.gov/)

NREPP is a searchable online registry of more than 260 interventions supporting mental health promotion, substance abuse prevention, and mental health and substance abuse treatment. Each intervention is independently reviewed to rate

the strength of available implementation materials, training and support resources, and quality assurance procedures. Each intervention includes cost information and provides contact information. The latter enables potential adopters to talk to intervention developers directly and learn how to implement these approaches in their own communities.

146.2.7.9 Tools and Education for Clinical Decision Making

Locating evidence to inform decision making requires an understanding of evidence levels; the ability to formulate a clinical question based on the PICO model (identifying patient/ intervention/ comparison/outcome); knowing how and where to search for primary sources; and understanding where, how, and why to look for secondary sources. The latter includes systematic reviews, evidence-based synopses, and clinical practice guidelines which save busy clinicians valuable time (Ilic 2009). They represent the accumulated evidence on common clinical interventions that are essential for clinical decision making, and yet use of these resources is relatively low (Andrews et al. 2005; Lasserre et al. 2011; Thomson 2013). One problem is that they are spread out among so many websites that choosing which one to use and/or navigating dissimilar interfaces can be a daunting task (LaPelle et al. 2006). Equally problematic, many clinicians lack the requisite knowledge and search skills to take advantage of them (Schardt et al. 2007; Cullen et al. 2011; Judd and Kennedy 2011). The final resources on this list help mitigate these problems.

146.2.7.10 The Centre for Evidence-Based Medicine (CEBM)

The CEBM at the University of Oxford provides a suite of online tools enabling health-care professionals to maintain the highest practice standards. The suite includes tutorials on asking well-built clinical questions, the systematic retrieval of the best evidence available, critical appraisal of evidence for validity, clinical relevance and applicability, the application of results in practice, audit and feedback of clinical practice to improve performance, and designing trials or assessing research design. It also provides a computer-assisted critical appraisal software tool (CATmaker) that can be downloaded free of charge. This enables users to create critically appraised topics (CATs) for the key articles they encounter about therapy, diagnosis, prognosis, etiology/harm, and systematic reviews of therapy. All can be accessed via http://www.cebm.net.

146.2.7.11 Evidence Based Behavioral Practice (EBBP)

Funded by the US Office of Behavioral and Social Sciences Research, National Institutes of Health, this site provides online training enabling users to conduct the steps of the EBBP process with a simulated client and/or community, learn about the shared decision-making process as a practitioner working through cases and client preferences in a clinical setting, and use two real-world case examples to understand and practice implementing evidence-based practices. These and more modules are accessible via http://www.ebbp.org/training.html with free registration.

146.2.7.12 TRIP Database (Turning Research into Practice) (http://www.tripdatabase.com/)

TRIP is a free meta-search engine enabling users to search 150 health resources simultaneously, including MEDLINE, Bandolier, BestBets, POEMs, Clinical Evidence, and the Cochrane Library, which is internationally recognized as the highest standard in evidence-based health care. Using a simple interface, users can access best evidence categories that include evidence-based synopses, clinical questions, systematic reviews, and guidelines (North America, Europe, others) and more. To facilitate effective searching, the database provides a "PICO" search feature prompting users to create a structured clinical question targeting a specific population, intervention, comparator (if relevant), and outcomes (Meats et al. 2007). This increases the likelihood of efficiently locating high-quality, current evidence directly relevant to practice needs (DiCenso et al. 2009). For instance, a recent search for "injecting drug users," "needle or syringe exchange," and "cost-effectiveness" generated 11 sources including systematic reviews and clinical guidelines from Australia/NZ, Canada, the UK, and the USA. For users who need additional help understanding this approach, the TRIP database conveniently links to tutorials from the Centre for Evidence-Based Medicine mentioned above (http://www.cebm.net/?o=1036). Considering that well-built clinical questions are the key to evidence-based decision making and that access to systematic reviews, evidence-based synopses, and clinical practice guidelines save clinicians time, TRIP is a valuable tool on multiple counts.

146.3 Conclusion

As a result of the open access movement in scholarly communications, addiction professionals have greater access than ever before to the scientific literature in the field. Access to the companion gray literature that distills and translates this science into practical information is also widely available. The growth of these complementary resources has coincided with the fortuitous rise of free EBP tutorials for clinicians and other health-care providers in the field. The intent of this chapter was to raise awareness of these sources, demonstrate their scope and utility, and encourage their use. Readers are also encouraged to visit the Drugs and Alcohol Research Guide available via http://guides.library.vcu.edu/drugs-alcohol. Hopefully, users will benefit from the sources reviewed here as have the Humphrey Fellows whose concerns shaped this endeavor.

NIDA International Fellowships: Research Training for Addiction Specialists

147

Steven W. Gust

Contents

Abstract

The demand for drug treatment remains largely unmet. According to the World Health Organization, only 1 in 5 people who need drug treatment receives it, and there are only 1.7 treatment beds per 100,000 people. The American Academy of Psychiatrists in Alcoholism and Addictions and the Association for Medical Education and Research in Substance Abuse *Consensus Standards for Postgraduate Medical Fellowships in Alcoholism and Drug Abuse* call for training opportunities that help physicians learn to design, conduct, and interpret drug abuse research studies and introduce addiction specialists to the principal drug abuse research organizations. The National Institute on Drug Abuse (NIDA) International Program fellowships are reviewed, including details about the research training and professional development opportunities provided and the career levels and citizenship requirements for applicants. The professional advantages of NIDA International Program fellowships include a global network of drug abuse scientists working collaboratively to develop, validate, and implement evidence-based treatment and prevention programs around the world.

147.1 Introduction

Building a global cadre of addiction specialists is a crucial task: Illicit drug use is one of the top 20 risk factors to health (United Nations Office on Drugs and Crime [UNODC] 2009). The *World Drug Report 2012* reports that drug abuse costs lives, contributes to disease, and reduces productivity. Globally, 1 in 100 adult deaths is due to illicit drug use. Injecting drug use – a primary vector for transmission of HIV and other infections – is reported by 148 countries, and 120 of those countries report HIV among the injecting drug-user population. In 2010, 20 % of injection drug users (IDUs) had HIV, 46.7 % had hepatitis C, and 14.6 % had hepatitis B. Drug abuse costs society in terms of lost productivity, which UNODC estimates to be nearly 1 % of the US gross domestic product (GDP), and in drug-related crime, which in England and Wales amounted to 1.6 % of GDP (UNODC 2012). The Joint UNODC/WHO Programme on Drug Dependence Treatment and Care found that the economic cost of drug abuse approaches 2 % of GDP in some countries (UNODC 2009).

The demand for drug treatment remains largely unmet: Only 1 in 5 people who need drug treatment receives it, and there are only 1.7 treatment beds per 100,000 people (World Health Organization [WHO] 2012). In 2008, only 30 % of countries offered pharmacotherapy with treatment medications that have been proven effective (WHO 2012).

In the United States, 23 experts in academic medical training for the addiction field developed *Consensus Standards for Postgraduate Medical Fellowships in Alcoholism and Drug Abuse* for the American Academy of Psychiatrists in Alcoholism and Addictions and the Association for Medical Education and Research in Substance Abuse. These national consensus standards called for "a meaningful, supervised research experience" to help physicians learn to design, conduct, and interpret research studies in drug abuse epidemiology, genetics, pharmacology, social theories, psychology, toxicology, and treatment outcomes (Galanter et al. 1991, p. 6). The standards also recommended that addiction specialists be introduced to the principal drug abuse research organizations. The need for addiction specialists is especially acute in developing countries (WHO 2010). Medical students who participate in mentored research programs develop positive opinions about both clinical care and academic research in substance abuse (Solomon et al. 2003; Truncali et al. 2012).

147.2 Fellowships To Advance Careers in Addiction Research

147.2.1 Fellowships Supported by the NIDA International Program

For more than two decades, National Institute on Drug Abuse (NIDA) International Program fellowships have trained drug abuse research experts from other countries

in US research methods, helped fellows enhance their understanding of the scientific basis of drug abuse and addiction, and introduced NIDA grantees to talented drug abuse researchers from other countries. Fellows join a network of drug abuse scientists working to develop, validate, and implement evidence-based treatment and prevention programs around the world.

NIDA International Program fellows have studied every aspect of addiction, beginning with the underlying biomedical and behavioral causes and progressing through drug use patterns and trends; prevention and treatment interventions; individual, familial, and societal consequences; and policy studies that compare and contrast the effect of government actions across borders. Current scientific questions in global addiction research include treatment of stimulant abuse; demonstrating accessible, acceptable, and affordable models of drug treatment; testing new formulations of effective medications; hepatitis C virus treatment strategies for drug users; effective models to integrate risk reduction interventions with addiction treatment protocols; and diversion and abuse of prescribed medications.

In addition to research training in their specific area of expertise, NIDA International fellows participate in professional development programs throughout the year. While they are in the United States, fellows attend scientific meetings, meet with officials from NIDA and the John E. Fogarty International Center at the National Institutes of Health (NIH), learn about online resources supported by the International Program and the National Library of Medicine, and network with one another. Scientific conferences and social media help fellows stay connected after they return home.

NIDA International Program fellowships provide research training and professional development opportunities for scientists at every stage of their careers, from postdoctoral students to senior researchers. Junior researchers may receive 12 or 18 months of postdoctoral training through the INVEST, INVEST/Clinical Trials Network (CTN), US–Mexico Drug Abuse Prevention, and International AIDS Society (IAS)–NIDA Drug Use and HIV/AIDS Research Fellowships. The NIDA Hubert H. Humphrey Drug Abuse Research Fellowships for midcareer drug abuse professionals enhance the 10 months of mentored academic study offered by US Department of State Hubert H. Humphrey Fellowships by providing additional mentoring and professional development activities. Senior scientists may receive support for short-term research exchanges through the Distinguished International Scientist Collaboration Awards (DISCA) and the Distinguished International Scientist Collaboration Awards for US Citizens (USDISCA). Individuals interested in the NIDA Hubert H. Humphrey Fellowships use the US Department of State application process. All other applicants identify a potential mentor and develop a fellowship proposal in conjunction with that mentor. Table 147.1 provides details about the career level, audience, features, and application deadlines for each fellowship. Additional details are available on the NIDA International Program

Table 147.1 NIDA International Program fellowships

Career level	Program name	Eligible audience	What fellowship includes	Application deadline
Postdoctoral training	INVEST Drug Abuse Research Fellowship	Non-US citizens with a doctoral degree in medicine, public health, or biomedical, behavioral, or social sciences with a minimum of 2 years of postdoctoral research experience	Provides 12 months of postdoctoral training with an established NIDA-supported drug abuse and addiction scientist at a US institution. Each fellow receives training in drug abuse research methods while developing and conducting research under the guidance of a mentor	April 1
	INVEST/Clinical Trials Network (CTN) Drug Abuse Research Fellowship	Non-US citizens with a doctoral degree in medicine, public health, or biomedical, behavioral, or social sciences with a minimum of 2 years of postdoctoral research experience	Provides 12 months of postdoctoral training in the United States with a NIDA-supported drug abuse and addiction scientist affiliated with 1 of the 13 NIDA CTN Regional Research and Training Centers. Each fellow receives training in drug abuse research methods while developing and conducting research under the guidance of a mentor	April 1

	US–Mexico Drug Abuse Prevention Research Fellowship	Mexican citizens or permanent residents with a doctoral degree in medicine, public health, or biomedical, behavioral, or social sciences with a minimum of 2 years of postdoctoral research experience	Provides 12 months of postdoctoral drug abuse prevention research training with an established NIDA-supported scientist at a US institution. Each fellow receives training in drug abuse prevention research methods while developing and conducting research under the guidance of a mentor	April 1
	International AIDS Society (IAS)–NIDA Research Fellowship in Drug Use and HIV/AIDS	Junior scientist with doctoral degree (e.g., Ph.D., M.D.)	Provides an 18-month postdoctoral training fellowship, focusing on HIV and drug use, at a leading research institute with a mentor who is an expert in HIV-related drug use research	Check NIDA website for details: www.drugabuse.gov/international/fellowships-landing
Midcareer training	NIDA Hubert H. Humphrey Drug Abuse Research	Drug abuse professionals from eligible low- and middle-income countries	Provides a 10-month, midcareer, nondegree fellowship to study and work with professionals in the United States. Fellows learn about NIDA-supported drug abuse research and the application of research to the development of science-based government policy and prevention and treatment programs	Deadlines vary. Check with the US embassy or Fulbright Commission in your country

(*continued*)

Table 147.1 (continued)

Career level	Program name	Eligible audience	What fellowship includes	Application deadline
Senior researcher opportunities	Distinguished International Scientist Collaboration Award (DISCA)	Non-US citizen senior researcher with a minimum of 7 years of experience in drug abuse research beyond the postdoctoral level	Supports a professional exchange visit between a drug abuse researcher from another country and a NIDA-funded US scientist. The international drug abuse researcher applies to visit his/her US partner, for up to 3 months, to complete a project best conducted in the United States	January 1
	Distinguished International Scientist Collaboration Award for US Citizens and Permanent Residents (USDISCA)	NIDA-funded US researcher with a minimum of 7 years of experience in drug abuse research beyond the postdoctoral level	Supports a professional exchange visit between a NIDA-funded US scientist and a drug abuse researcher from another country. The US scientist applies to visit his/her international partner, for up to 3 months, to complete a project best conducted outside the United States	January 1
	International AIDS Society (IAS)–NIDA Research Fellowship in Drug Use and HIV/AIDS	Senior scientist involved in HIV-related research, with a minimum of 7 years of experience beyond the postdoctoral level and with a documented scientific record	Provides an 8-month professional development fellowship focusing on HIV and drug use at a leading research institute, for a well-established HIV scientist not currently active in the drug abuse field	Check NIDA website for details: www.drugabuse.gov/international/fellowships-landing

147.2.2 Professional Advantages of a NIDA International Program Fellowship

As of December 2013, there were more than 415 former NIDA International Program fellows representing 104 countries, from Afghanistan to Vietnam. These individuals play uniquely influential roles in the international drug abuse research community by participating in national, regional, and international research groups; publishing articles in peer-reviewed journals; directing university training and research programs; and leading policy initiatives. Former NIDA International Program fellows lead drug abuse research efforts in every part of the world: They direct academic drug abuse research centers in Brazil, China, Georgia, Indonesia, and Israel and coordinate NIH-supported regional research projects in Eurasia, Latin America, Russia and the former Soviet Union, and Southeast Asia. Former NIDA International Program fellows work for international organizations such as WHO, UNODC, Joint United Nations Programme on HIV/AIDS, and Colombo Plan Drug Advisory Programme in Southeast Asia. They hold positions in drug policy and nongovernmental organizations. Two former fellows work for NIDA.

A 2012 assessment conducted by Virginia Commonwealth University (VCU) found that 1 year after completing their fellowships, more than half (63 %) of the Hubert H. Humphrey Fellows who attended VCU from 2007 through 2010 had a new job; 71 % said their fellowship helped them obtain the new job, and 70 % reported that the new job represented a change in career goals. More than one-third (37 %) of the fellows reported having conducted research since completing their fellowship, and 33 % reported continuing collaborations with a US partner (Leonchuk et al. 2012). The 2010 VCU assessment of fellows from 2007 through 2009 found that most former fellows (40 %) managed or administered treatment or prevention programs. The former fellows began their research careers quickly. At the 12-month follow-up, 16 % reported publishing research results in a peer-reviewed journal and 50 % reported making a presentation at a scientific conference (Leonchuk et al. 2010).

A December 2011 internal NIDA review of the fellowship programs found that former fellows had been principal investigators or principal foreign investigators for 36 NIH grants, funded by NIDA as well as the National Institute on Alcohol Abuse and Alcoholism, National Institute of Allergy and Infectious Diseases, National Institute of Mental Health, and the Fogarty Center. Former NIDA Hubert H. Humphrey, INVEST, and INVEST/CTN Fellows had published nearly 1,000 articles indexed in PubMed, the National Library of Medicine database.

By combining academic study and mentored research, NIDA International Program fellowships can introduce physicians from other countries to drug abuse research careers and help them prepare to take the credentialing examination offered by the International Society of Addiction Medicine.

Major International Challenges in Addiction Treatment: The Experience of TreatNet and Beyond

148

Elizabeth Saenz, Anja Busse, Juana Tomas, and Nicolas Clark

Contents

Abstract

One of the three pillars of the UNODC strategy for the prevention and treatment of drug use disorders is the delivery of technical assistance, especially through training. A major initiative in this effort is the Treatnet program. The UNODC Treatnet I global project started in 2005 and was designed to improve the technical capacity of professionals for the delivery of evidence-based drug treatment and

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment: International Perspectives*, DOI 10.1007/978-88-470-5322-9_49,

rehabilitation, along with drug-related HIV/AIDS prevention and care. Treatnet I established a network of 20 resource centers, a comprehensive training curriculum, and a cadre of trainers prepared as expert trainers in the treatment of substance use disorders. From 2009 to 2012, Treatnet II provided advocacy, capacity building, and service improvement in 20 countries in four regions. Using a "training cascade" strategy, Treatnet II provided training to over 11,000 service providers throughout the four regions and the project evaluation indicated a very high rate of satisfaction by the program participants. The current program in this series is the UNODC-WHO Programme on Drug Dependence Treatment and Care. This program has a particular focus on low- and middle-income countries, with the goals of promoting and supporting evidence-based and ethical treatment policies, strategies, and interventions to reduce the burden caused by drug use and dependence. In order to ensure the sustainability of interventions in prevention, treatment, and health/social protection, particularly in low-income countries that need long-lasting and stable support, the continuous provision of significant resources is essential. To provide sustaining support for this effort, the UNODC has called for the creation of a fund to support member states in a systematic and reliable manner.

148.1 Introduction

Substance use disorders are a public health, economic, and security problem in both industrialized and developing countries (Degenhardt and Hall 2006; National Centre for Education and Training on Addiction 2006; UNODC 2003). They are associated with health problems, poverty, violence, criminal behavior, and social exclusion. A large body of science-based evidence concludes that drug dependence is a chronic multifactorial disease affecting the brain and that it is a result of complex mechanisms involving repeated exposure to drugs as well as biological and environmental factors. Both genetic and social elements create risk and resiliency factors that respectively trigger or moderate individual vulnerability to drug use and proneness to further use that may result in dependence.

Prevention and treatment are essential strategies of significant public health importance, as they help prevent drug-related harm and they reduce the severe health and social consequences associated with drug use. Unfortunately, despite the evidence, in many countries, people affected by drug use disorders continue to be stigmatized, criminalized, and deprived of their right to receive adequate, science-based, and humane drug-dependence treatment and care.

148.2 Description

148.2.1 Global Dimension of the Problem

The United Nations Office on Drugs and Crime *World Drug Report* (UNODC 2012) estimates that globally, between 149 and 272 million people (or 3.3–6.1 % of the

population aged 15–64) used illicit substances at least once in the previous year. Although prevalence rates of illicit drug use have remained generally stable over the last decade, the estimate of the number of problem drug users ranges from 15 to 39 million people, equivalent to 0.3–0.9 % of the abovementioned population (UNODC 2012).

148.2.2 UNODC Work in Practice: Treatnet and Beyond

The UNODC's response to its Drug Demand Reduction mandate is based on a three-pillar strategy consisting of:

(a) Advocacy to counteract stigma and discrimination:

The UNODC disseminates information on the benefits of investing in the prevention and treatment of drug use disorders and invites UN member states to consider drug dependence as a preventable and treatable disease within their public health system. To help create the conditions for an evidence-based approach, UNODC programs work with governments' ministries of health and social affairs, as well as justice and interior, in areas including legal and regulatory framework, system and service organization, and financial and human resource investment.

(b) Technical assistance, especially through training:

The UNODC disseminates evidence-based methodologies and capacity-building trainings of professionals in the delivery of services for people who use drugs. By involving country agencies, it tailors the methods toward local conditions, emphasizing the development of country and regional networks of national authorities, academic institutions, and service providers, which then act as resource centers offering sustainable training and dissemination of good practices.

(c) Low-cost, evidence-based, mainstreamed services:

The UNODC promotes a model that envisages two levels of service provision: (i) basic drug-dependence treatment services mainstreamed into the health system, i.e., low cost, decentralized, and thus more accessible and affordable, and (ii) specialized drug-treatment centers at the district/province level that include a multidisciplinary approach for dually diagnosed patients by offering mental health services and inpatient facilities.

A comprehensive approach is used in the scaling-up of treatment services including pharmacological and psychosocial interventions and the building of a rehabilitation-oriented continuum of care ranging from outreach activities to a wide variety of clinical programs.

148.2.2.1 Treatnet I

The UNODC Treatnet I global project, which started in 2005, improved the technical capacity of professionals in the delivery of evidence-based drug-dependence treatment and rehabilitation, along with its important role in drug-related HIV/AIDS prevention and care. Its main approach was the development of knowledge transfer strategies and mutual support between treatment professionals worldwide through a network of drug-dependence treatment centers.

Twenty resource centers were identified through a systematic process aimed at assessing their potential to become leading centers in their respective regions.

For 2 years, the project supported the exchange of knowledge and experience in order to identify best practices and develop four topic-oriented review documents based on state-of-the-art practices and field-based experience on drug-dependence treatment and rehabilitation.

The capacity-building component has been structured on the basis of its own achievements and lessons learned. During the project phase I, a training package was developed through the work of an international consortium of experts on the basis of the training needs identified by the network's members at the time (National Centre for Education and Training on Addiction 2006). The training package is a comprehensive tool consisting of four volumes covering key topics of addiction medicine and aimed at a multidisciplinary audience of drug-treatment service providers.

148.2.2.2 Structure of Treatnet Training Package (UNODC 2007)

Volume A: Screening, Assessment, and Treatment Planning

Module 1:	Screening and brief intervention using the ASSIST
Module 2:	Addiction Severity Index (ASI)
Module 3:	Treatment planning M.A.T.R.S.: utilizing the ASI

Volume B: Elements of Psychosocial Treatment

Module 1:	Drug addiction and basic counseling skills
Module 2:	Motivating clients for treatment and addressing resistance
Module 3:	Cognitive behavioral and relapse prevention strategies

Volume C: Addiction Medications and Special Populations

Module 1:	Addiction basics: alcohol and benzodiazepines; psychostimulants, volatile substances, and cannabis
Module 2:	Opioids: basics of addiction; opiate agonist, partial agonist, and antagonist therapies
Module 3:	Special populations: individuals with co-occurring disorders, women, and young people

Volume D: Administrative Toolkit

Topic 1:	Improving client access and retention (NIATx)
Topic 2:	Clinical supervision techniques
Topic 3:	Program evaluation methods
Topic 4:	Reducing the harm of drug use and dependence and HIV risk reduction

More than 20 trainers were trained to deliver training to staff members at their respective treatment centers. Building upon the human and material resources of phase I, training plans were prepared in phase II to tailor each country's training content to the needs identified through a needs assessment which also included training needs in all participating countries. This process was facilitated by a "Training Coordination Group," consisting of health and academic authorities in

each country. These groups were responsible to organize all training activities under the coordination of the project's regional management team.

Pre- and post-training data was collected and systematized in all countries with training outcomes indicating an increase in knowledge among trainers and practitioners as well as a high level of training satisfaction. The cascaded training of trainers approach facilitated sustainability of knowledge and skills transfer while reaching a high number of professionals.

Treatnet I and II lessons learned and recommendations with respect to the training component can be summarized as follows:

- While the training cascade approach can provide a broad base of knowledge and attitude change, stronger emphasis on follow-up, booster sessions, mentoring, and in-service training would be required for full acquisition of skills.
- Stronger linkages with national academic and training institutions as well as professional networks would facilitate integration of training in professional training programs, sustainability, and ongoing professional exchange and support.
- Additional capacity to train trainers at regional level is required to respond to increasing demand for training.
- While Treatnet I and II assessed trainee satisfaction and knowledge change, an assessment of the training impact on service provision in future training rounds would be required (Tomás-Rosselló et al. 2010).

148.2.2.3 Treatnet II

Following the successful completion of Treatnet I, UNODC developed a scaling-up strategy through a second phase of the project. This phase emphasized intensive involvement and direct participation of national authorities in the creation, consolidation, and expansion of their drug-dependence treatment and care systems. Treatnet II promotes high-quality treatment and care services that are diversified and accessible, including HIV/AIDS prevention and care. It aims to attain a wide range of health and social services for all whose lives are impaired by drug dependence, by working with national counterparts with the ultimate goal to create universal access to evidence-based, comprehensive, and ethical drug-dependence treatment and care.

The project's strategy consists of three pillars:

- Advocacy: Raising awareness that addressing substance use disorders requires a multidisciplinary and comprehensive approach
- Capacity Building: Providing training to health and social service providers using a training-of-trainers approach
- Service Improvement: Creating community-based treatment networks involving health and social services

From 2009 to 2012, Treatnet II was implemented in 22 countries[1] in four regions, where it has contributed to improved quality of drug-dependence treatment services

[1]Brazil, Colombia, Haiti, Nicaragua, Peru, Ivory Coast, Kenya, Nigeria, Mozambique, Sierra Leone, Tanzania, Zambia, Afghanistan, Kazakhstan, Kyrgyzstan, Tajikistan, Turkmenistan, Uzbekistan, Cambodia, Myanmar, Vietnam, Ukraine.

and increased access to drug treatment for people in need. A major achievement of Treatnet II has been the successful implementation of a knowledge-sharing mechanism called the "training cascade," through which more than 11,000 service providers from various disciplines have received training on evidence-based interventions.

The project has also supported the development and strengthening of drug-treatment services, as well as creating networks of services within a continuum of care. In particular, project support has (1) expanded communities' ability to provide integrated and comprehensive responses to drug use and dependence and/or improve the quality and intensity of services; (2) made drug-dependence treatment and related services more available, accessible, and affordable at selected locations; (3) developed opportunities for social integration and rehabilitation; and (4) supported local organizations, including grassroots, community-based programs and community-based recovery organizations, in linking services and delivering them in a manner consistent with continuum-of-care principles.

The treatment systems for drug use disorders in most countries where Treatnet has been/is being implemented are fragmented and uncoordinated, poorly linked to the overall health system, high threshold, or mostly residential, therefore costly and ineffective, stigmatized, and poorly staffed (numbers and capacity). Given this situation, Treatnet has proposed a community-based treatment "model" referring to a specific integrated model of treatment in the community, which provides a continuum of care from outreach and low-threshold services, through detoxification and stabilization to aftercare and integration, including maintenance pharmacotherapy. The model involves the coordination of a number of health, social, and other nonspecialist services needed to meet the patient's needs. Strong support is also given to the patient's family and the community to address the drug and alcohol problems in their complexity and to ensure efficient and long-term results.

Community-based treatment services are designed to:

- Help patients develop the skills to manage their drug and alcohol dependence and related problems in the community
- Stop or reduce the use of drugs and alcohol
- Respond to a wide range of needs and ensure the best possible outcomes
- Actively involve local organizations, community members, and target populations in the establishment of an integrated network of community-based services in a manner that is empowering
- Facilitate access to a larger number of people in need
- Reduce the need for and use of residential treatment and custodial services for people with drug and alcohol problems

The tasks of promoting, raising awareness, and technically supporting countries toward the implementation of the community-based treatment approach have not been easy or straightforward. In Southeast Asia, community-based treatment services, a new modality for the three participating countries (Cambodia, Myanmar, and Vietnam), have been initiated. This involved a progressive change of attitude toward drug use, people who use drugs, and the understanding of drug dependence as a health disorder. The project has also supported the development of treatment models, guidelines, and standards of care in these three countries. These are a

contributing step in moving away from compulsory centers for drug users, the current dominant response to drug use and dependence in the region, and improving access to HIV prevention. In Cambodia, the Treatnet project has contributed to strengthening the Government's Community Based Drug Treatment Programme (CBTx) through the provision of staffing, technical assistance, capacity building, facilitating meetings among stakeholders, and supporting the delivery of services to people who use drugs at eight sites in Banteay Meanchey province. This has allowed for developing an innovative approach, building relationships and strengthening coordination mechanisms, and planning for future activities with National Government counterparts (at the National Authority for Combating Drugs and the Ministry of Health), subnational authorities (such as the Provincial Drug Control Committee and the Provincial Health Department), and civil society organizations that have partnered with CBTx.

An evaluation conducted in 2011 indicated that Treatnet II training had been useful in increasing the knowledge of staff as well as their use of new approaches toward service provision for drug users. Other findings included:

- More than 95 % of trainees reported that training had been helpful for their work.
- More than 98 % of respondents found the "training packages and manuals useful," and almost 97 % of all therapeutic staff indicated that their relationships with patients had improved as a direct result of the trainings.
- Almost 90 % of respondents reported that their service agency had a better reputation because of the project.
- Three quarters of staff reported observed "positive consequences of Treatnet."
- There were mixed results regarding access to care: the number of individuals waiting for treatment had grown; however, overall, the number of days that patients waited to be admitted fell overall.
- Retention in care improved dramatically: retention in detoxification improved by 42 %, inpatient long-term retention improved by 44 %, outpatient medication-assisted treatment (MAT) improved by 90 %, and outpatient drug-free treatment improved by 145 %.

148.2.3 UNODC-WHO Programme on Drug Dependence Treatment and Care: "Nothing Less than what Is Expected for the Treatment and Care of Any Other Disease"

Building on previous initiatives such as Treatnet I and II, UNODC and the World Health Organization (WHO) launched their Joint Programme on Drug Dependence Treatment and Care in 2009 at the 52nd session of the Commission on Narcotic Drugs in Vienna. With a particular focus on low- and middle-income countries, their goal was to promote and support worldwide, evidence-based, and ethical treatment policies, strategies, and interventions to reduce the burden caused by drug use and dependence. UNODC and WHO have complementary mandates, experience, competencies, and networks and through this program sought to strengthen their collaboration on drug-dependence treatment and care and build

on their respective strengths. As of 2013, the UNODC-WHO Programme is being implemented in 17 countries in five regions (Southeast Europe, Latin America and the Caribbean, Southeast Asia, West Africa, and the Middle East). Its comprehensive approach includes activities at the global, regional, and national level.

148.2.4 Partnership in Action

The UNODC-WHO Programme promotes the recognition of drug dependence as a multifactorial mental health disorder and advocates the need to follow the same quality standards applied to any other chronic disease. The program also seeks to counteract stigma and discrimination against people who suffer from drug dependence. The implementation is guided by the following UNODC-WHO principles of drug-dependence treatment and care[2] (UNODC-WHO 2009):

- Availability and accessibility
- Screening, assessment, diagnosis, and treatment planning
- Evidence-informed drug treatment
- Drug-dependence treatment, human rights, and patient dignity
- Targeting special subgroups and conditions
- Providing addiction treatment within the criminal justice system
- Community involvement and patient-oriented treatment
- Clinical governance of drug-treatment services
- Developing treatment systems: policy development, strategic planning, and coordination of services

148.2.5 Results

Implementation of the UNODC-WHO Programme started in 2010 in Albania, Haiti, Pakistan, and Serbia, building on the existing UNODC Treatnet project and WHO initiatives. The program is currently active in Albania, Serbia, Cambodia, Lao PDR, Vietnam, Brazil, Haiti, Pakistan, as well as countries within Africa, the United Arab Emirates, and the Middle East. Brief summaries of the program's work in Serbia and Haiti follow.

148.2.5.1 Serbia

An existing Coordination Committee was activated at the interministerial and intergovernmental levels, followed by the training of 487 practitioners from four regional centers, support of treatment services at the primary health center level, and the expansion of a primary health-care unit in Belgrade that resulted in a 20 % reduction of patients on waiting lists.

[2]For further details please see https://www.unodc.org/documents/drug-treatment/UNODC-WHO-Principles-of-Drug-Dependence-Treatment-March08.pdf

148.2.5.2 Haiti

After the 2010 earthquake, 27 professionals received training using the Treatnet materials (psychologists, psychiatrists, social assistants, and medical doctors) from the Ministry of Health, APAAC (L'Association pour la Prévention de l'Alcoolisme et autres Accoutumances Chimiques), Mars and Kline Psychiatric Hospital, Defilée de Beudet Hospital, Grace Children's Hospital, Hedo-Haiti, Unique, CONALD (Commission Nationale de Lutte contre la Drogue), and HUEH (Haiti's University and Educational Hospital).

148.2.6 Emerging Themes and Lessons Learned from the Initial Implementation of the UNODC-WHO Programme

Several themes have emerged from the first years of the UNODC/WHO Programme that warrant highlighting:

1. The importance of collaboration between drug control and health agencies at the national and subnational levels.

   In all countries, responsibility for drug-treatment policies and the resources to implement these policies are shared between health and other sectors, including drug control, social welfare, justice, police, and security. Facilitated by the UNODC and WHO links with both the health and crime/security sectors, staff in participating countries are increasingly engaging in multisectoral dialog, collaboration, and decision-making.
2. The challenge of obtaining reliable data on treatment needs and outcomes as basis for sound decision-making on treatment policies.

   Reliable estimates of the size of the population who need services for drug use disorders can be difficult to obtain, even for high-income countries, posing obstacles for countries to plan specific treatment services. Lack of data on available resources, in particular, the organization of services that best match the problem faced by each country, impairs a country's ability to obtain funding from international donors and successfully implement interventions. To assist countries in bridging this gap, WHO and UNODC are developing specific tools such as the Substance Abuse Instrument for Mapping Services (SAIMS), which is used to assess, monitor, and evaluate treatment systems for substance use disorders.
3. The need for standards of care in treatment of drug use disorders.

   In some countries, there are no accepted standards defining treatment of drug use disorders, how it should be provided, and who should provide it. In response, the UNODC-WHO Programme uses a range of methods, including trainings and visits from experts, as well as support for the establishment of a "best practice" treatment facility in the country following UNODC-WHO Principles of Drug Dependence Treatment and Care.
4. The interaction between treatment for people with drug use disorders and criminal justice systems (WHO in press).

   Treatment as an alternative to punishment and other areas of interaction between the criminal justice and health-care systems are often complex but

key areas for intervention. Investing in drug treatment, in preference to the use of criminal or administrative sanctions for people with drug dependence, is not only cost effective but also consistent with human rights principles and the Drug Control Conventions.

5. The coordination of treatment of drug use disorders and treatment of frequent comorbidities.

   Drug dependence is often associated with mental disorders and complicated by physical health problems. In many countries, the epidemics of drug (in particular opioid) injection, HIV, hepatitis B and C, and tuberculosis are highly correlated.

6. The confirmation and reminder of a well-known axiom in the provision of services for substance use disorders: "Not one size fits all."

   Countries differ in drug use extent, patterns, and trends. Legal frameworks, conceptualizations of drug use and dependence, sectors responsible for their management, health system structures, and financing modalities determine the type, quality, appeal, and coverage of services available. Further, the overall perception or level of awareness among the general population, health professionals, and drug-treatment service providers in particular regarding the nature of drug use disorders creates the context in which any initiative for change needs to navigate and influence in order to progress toward a sustainable, comprehensive, human- and science-based response.

7. The main challenge ahead is represented by the perception still firmly rooted in society of drug use and dependence as a moral failure, and therefore a consistent effort is needed to change this attitude and reach an understanding of drug dependence as a chronic health disorder.

148.2.7 International Considerations

Three major debates are occurring regarding the best strategies for dealing with the world drug problem. Long-term polarized discussions about punishing options versus the legalization of drug use have captured public attention, ignoring the fact that people who use and are dependent on drugs are in need of reliable prevention measures and health and social care instead of repressive policy or legalization measures. In addition, the debate about pharmacological versus psychosocial/educational approaches that has dominated the scene in regard to policy for treatment of drug use disorders does not take into account the fact that such a complex disease requires comprehensive and articulated interventions, including differentiated, complementary, and integrated treatment methods. A conflict between advocates of measures to reduce the health and social consequences of drug use and those who favor treatment and recovery has unproductively consumed the time and efforts of policy makers, while neglecting the needs of people who use drugs and patients in all stages of their disease for a full, uninterrupted continuum of care.

148.2.8 Conclusions and the Way Forward

Translating research into practice is a major challenge. The current lack of adequate services and limited access to treatment for people with substance use disorders are compounded by the absence of political prioritization of and commitment to the identification and implementation of solutions to this situation. Because drug dependence is a stigmatized condition, people suffering from drug use disorders are deprived of resources, discriminated against, and excluded from the general health-care mainstream.

UNODC aims to raise awareness among its member states and international organizations regarding the need for creating systematic, large-scale action in the field of prevention and treatment of drug use and dependence; providing care, treatment, and rehabilitation for people who use and are dependent on drugs; reducing the adverse health and social consequences of drug use; integrating supply and demand reduction interventions; and mainstreaming these activities in the broader development of education and health opportunities.

Treatment of drug dependence should be based on effective scientific methods with similar quality standards to those applied in the treatment of any other disease (UNODC 2012). The development of treatment services, starting from low-cost initial-stage facilities, should progress in parallel with other health-care system components – not in isolation. Training for professionals in the field of drug treatment, starting with university curricula for nurses, social workers, counselors, psychologists, medical doctors, and psychiatrists, and building on for those who work in specialized treatment services for drug use disorders, is a critical area, particularly in developing countries.

The UNODC-WHO Programme on Drug Dependence Treatment and Care is a milestone in the development of a comprehensive, integrated health-based approach to drug policy aimed at reducing demand for illicit substances, relieve suffering, and decreasing drug-related harm to individuals, families, communities, and societies. The initiative intends to send a strong message to policy makers to develop services that address drug use disorders in a pragmatic, science-based, and humanitarian way, replacing stigma and discrimination with knowledge, care, recovery opportunities, and reintegration.

148.2.9 The Need for a Large-Scale/High-Level Awareness Process

The international community needs to prioritize the development and implementation of effective interventions to prevent and treat substance use disorders, thus reducing the health and social consequences of these diseases. The first step should be the mobilization of public opinion, the media, and high-ranking politicians for an understanding of substance use disorders as a health condition and stopping the discrimination faced by those who suffer from substance use disorders (UNODC 2010). A large-scale mobilization of civil society, academics, the media, and high-ranking personalities could restore the dignity of people who use and are dependent

on drugs, protect the human rights of individuals vulnerable to substance use disorders, and contribute to reducing the burden of substance use disorders on communities' health, security, and economy.

Such a mobilization should walk hand in hand with the adoption of effective strategies tested through reliable trials and/or national experiences and adaptation of these strategies to various sociocultural environments. Cost-effective prevention and treatment tools exist and should be systematically used, along with measures of outreach, health-care, and social services that alleviate the consequences of substance use and dependence.

148.2.10 A Permanent Fund

Following political commitment to an understanding of substance-related disorders as a health condition and to the implementation of evidence-based interventions, the development and maintenance of responses in prevention, treatment, and health/social protection in low-income countries require at this point long-lasting and stable support. Therefore, the continuous provision of significant resources is essential. UNODC has called for the creation of a fund to support member states in a systematic and reliable manner. The fund should operate for 10 years, providing grants for training and improvement of services and supporting low-income countries in building their prevention, treatment, and health/social protection systems, which, in the long term, should become self-sustainable. For this purpose, chiefs of state and governments should urgently consider this issue at the next meeting of the G20.

Pain Education Curriculum in Medical Schools

149

Bridin Murnion

Contents

Abstract

Increasing prescription opioid misuse defines a need for medical practitioners to have pain assessment and management skills. Pain education should commence in undergraduate programs. This chapter describes pain curricula, focussing on the IASP curriculum, and describes methods of delivery of pain education.

149.1 Introduction

There are few human experiences as universal as that of pain. It is the presenting symptom in 70 % of emergency department presentations. Eighty percent of postoperative patients complain of pain (Vadivelu et al. 2012). Approximately 20 % of the population have chronic non-cancer pain, and 30 % of these are unable to function in their work role (IASP 2013). Not only does this cause a personal burden of suffering and financial hardship, there is a societal economic impact as well.

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment: International Perspectives*, DOI 10.1007/978-88-470-5322-9_87,

Pain management is a diverse discipline encompassing acute operative, acute nonoperative, chronic non-cancer pain and cancer pain. Pain management is multimodal and includes medications, interventional procedures, psychological approaches, and physical strategies. Effective pain management requires skills from many disciplines such as medical, nursing, physiotherapy, occupational therapy, and psychology.

In the last decade there has been an explosion in opioid prescription for pain, with a concomitant explosion in prescription opioid misuse. In response to this increase in prescription opioid misuse, there has been advocacy for enhancing healthcare practitioners' skills in recognizing and managing opioid misuse (UNODC 2011). There has also been increasing recognition that all healthcare practitioners, not just addiction specialists, need adequate pain management skills to reduce inappropriate opioid prescribing and improve pain management. The addiction specialsit has a particular interest as not only is opioid misuse increasingly an iatrogenic problem, but also many of the patients with prescription opioid misuse have underlying chronic pain which needs to be addressed concurrently and may also have intercurrent acute pain. The assessment and management of acute pain in the context of opioid dependence and chronic pain presents specific challenges.

The evolution of pain medicine as a specialty has allowed some focussed development of educational initiatives, both at undergraduate and postgraduate level. There is widespread acceptance that most medical practitioners should have pain management skills and that responsibility and skills for pain management cannot rest solely with pain specialists. Expert consensus agrees that pain education should begin in medical schools (IASP 2013). This chapter will provide an overview of current medical school pain curricula, the resources available, and some curriculum delivery models.

149.2 Curricular Features

Over the last 20 years, there has been significant progress in our understanding of the science of pain, both acute and chronic (IASP 2013). This has occurred in both basic and clinical science. Our understanding of the neuroanatomy and neuropharmacology of pain has expanded dramatically. We have enhanced knowledge of clinical treatment paradigms, whether pharmacological, surgical, psychological, or physical-based therapies. With the advent of computerized tomography, magnetic resonance imaging, and positron emission tomography, our capacity to image both experimentally and in routine clinical practice has advanced beyond what could have been imagined 30 years ago.

The International Association for the Study of Pain (IASP) is the professional body for scientists, educators, and clinicians working or researching in pain. Membership is open to any individual working or researching in pain and is drawn from over 130 countries. IASP defines its role as to support and advocate for pain research and practice, such that pain management is improved globally. There are a number of local chapters throughout the world and a developing countries' project (IASP 2013).

Some 25 years ago, the IASP recognized the need for and developed an undergraduate/prelicensure pain curriculum. Since that time, there have been a number of revisions, the most recent in 2012. This is available for free download on the IASP website (IASP 2013).

Despite our expanding knowledge and a freely available curriculum, there has not been paralleled by increased education about pain in medical school curricula.

Mezei and Murinson (2011) reviewed the curricula of 117 medical schools in Canada and the USA between 2009 and 2010 and identified that 80 % of medical schools in the USA and 92 % in Canada have some requirement for pain education. However, dedicated time was limited although Canada fared better than the USA. Curriculum content was inadequate and much of the core undergraduate curriculum of the International Association for the Study of Pain was not covered adequately if at all. The authors conclude that pain education in medical schools in North America is "limited and fragmentary."

Vadivelu et al. (2012) have reviewed curriculum across a number of different countries and regions. In medical schools in the UK, an average of 13 h is allocated for pain teaching and, similar to the North American experience, is considered inadequate and fragmented. Alarmingly veterinary science and physiotherapy have the greatest time allocation for pain education. Elsewhere in Europe, medical schools in Finland provide reasonable coverage of the IASP curriculum, although the delivery of this curriculum is perhaps suboptimal. Undergraduate pain education appears to be in a parlous state in the developing world. Although there are very limited data looking at the extent of pain education in these countries, the data that are available suggest very limited undergraduate exposure, poor understanding of the risks of opioid analgesics medications for treatment of pain, low prioritization of pain, and inadequate outcomes in pain treatment (Vadivelu et al. 2013).

Thus, it is evident that despite the high prevalence of pain in the population, the clear need for all medical practitioners to have pain management skills, and a readily available curriculum, pain does not have adequate coverage in most medical school curricula. Likely reasons for this include resources, both human and educational, busy curricula with multiple competing demands, and lack of coordination of fragmented pain teaching. Pain is a relatively new specialty so may well be fighting with more established groups for curriculum space. In addition, having adequate pain management skills is important in most areas of medicine (e.g., surgery, palliative care, pediatrics, geriatrics). Integration of pain teaching across multiple specialties is challenging.

149.2.1 IASP Curriculum and Its Derivatives

The IASP has developed a number of curricula for the various craft groups within healthcare (e.g., medicine, dentistry, nursing). In addition, in 2012, an interdisciplinary curriculum was developed. The IASP recognizes that changing medical school curricula is complex. One of the goals in developing the medical curriculum was to try and engage curriculum leaders in discussion round the importance of

adequate pain education and to give a guideline as to what should be included (IASP 2013). In this context, both the medical school and the interdisciplinary curriculum warrant further examination.

149.2.2 Medicine Curriculum

The prelicensure medicine curriculum is one of the seven uniprofessional curricula developed by IASP. The objectives of the curriculum outline for medicine are that after completing the course, the student should appreciate the importance of pain medicine in clinical practice, understand the basic science of pain, be able to diagnose in acute and chronic pain effectively, understand the biopsychosocial model of pain and its management, understand pharmacological treatment, and begin to develop the capacity to work in the multidisciplinary team of pain medicine.

There are four key domains of the curriculum which are:

1. Multidimensional nature of pain
2. Pain assessment and measurement
3. Management of pain
4. Clinical conditions

Each of these domains is further expanded. Domain 3, for example, includes subheadings of general principles of management, clinical pharmacology, neurostimulation, psychological therapies, nerve blocks, surgical techniques, and physical therapies. These subheadings are further elaborated, e.g., surgical techniques are expanded to nerve decompression, neurosurgical, and orthopaedic techniques.

The IASP suggests that the curriculum is delivered as basic, clinical, and social science early in the medical degree, with a pain medicine course later in the degree. Beyond that it makes no recommendations regarding delivery, nor does it supply educational resources. It however directs the reader to the German model as an example of content delivery (IASP 2013).

The European Federation of IASP Chapters, EFIC, provide a comprehensive medical school curriculum developed from the IASP curriculum. This provides a clear curriculum framework, guiding principles, curriculum domains, and very detailed educational objectives. A detailed timetable for delivering the content is provided. This again is based on the German model and is updated biannually (EFIC 2013).

149.2.3 Interprofessional Curriculum

Pain is multidimensional and treatment of pain is optimally provided in multidisciplinary teams. In recognition of this, in 2012 IASP published an interprofessional curriculum (IASP 2013). This was developed over a number of years by an expert group from a variety of health science backgrounds. The curriculum was developed in a manner to ensure that it was relevant to all professions and cross-referenced to

the individual healthcare professional curriculum to ensure inclusion of common themes. It was then sent for further evaluation through review by members of the special interest group in education of the IASP. It is anticipated that further development will occur iteratively as feedback after use will be generated to assist in further refining the curriculum.

One of the major goals of the interprofessional curriculum is to facilitate shared learning and enhance understanding of roles and competencies of the different disciplines within the pain management team. While all disciplines should understand the core components, the depth of understanding will be defined by the professional group to which an individual student belongs.

As an implementation strategy, the IASP suggests core lectures with small group work around common themes. It advocates that students return to their "home" discipline for curriculum areas that require specific focus for their professional group.

The four key domains of the curriculum remain the same as in the uniprofessional curricula, i.e., the multidimensional nature of pain, pain assessment and measurement, management of pain, and clinical conditions.

The objectives of the curriculum, not unsurprisingly, are somewhat different. It is expected that the student completing the curriculum should understand methods of pain assessment and treatment common to all health professionals, as well as have an understanding of the common misbeliefs. They should understand the complex multidimensional nature of pain and its impact on patients and families. The student should understand how all professions individually and collaboratively develop and provide pain management plans and how outcomes of this are monitored. It is also expected that they have a sophisticated understanding of the individual and societal issues around inadequate pain treatment.

This curriculum is much more comprehensive and for the most part more explicit than the uniprofessional medical curriculum. Looking again at domain 3 "management of pain," this is subdivided into:

1. Goals of pain management
2. Pain management planning decisions
3. Treatment considerations
4. Pharmacological methods
5. Non-pharmacological methods
6. Evaluation of outcomes

The sub-domain 2 of pain management planning decisions in the interprofessional curriculum is illustrative of the differences between the two curricula. This sub-domain identifies as core content that treatment plans should be developed and implemented as an interprofessional or multiprofessional team. Patients and families should be involved in setting goals which are realistic and clear and that they should have information regarding treatment options and side effects. Treatment should be multimodal where appropriate. Pain management planning decisions are not included in the uniprofessional medical curriculum, although understanding of the multidisciplinary pain clinic, psychological interventions, and physical therapies are included in different domains.

While the subheading of non-pharmacological methods includes surgical techniques, these are not specifically defined as nerve decompression, neurosurgical, and orthopaedic techniques that are identified as core content for the medicine curriculum.

The IASP also offers education grants to countries in the developing world for the development of pain education in medical schools. EFIC can award financial assistance to eastern European countries for pain curriculum implementation, recognizing that specific local factors may need to be addressed during implementation.

Most recently, interdisciplinary pain competencies have been proposed (Fishman et al 2013). An expert working party derived 21 competencies over four domains that prelicensure students across healthcare disciplines could be expected to achieve. The four domains are again the multidimensional nature of pain, pain assessment and measurement, pain management, and clinical conditions. The developers' intent is that these competencies are used to define and refine pain curricula.

149.2.4 Curriculum Delivery

A number of methods of delivering pain education are described. Murinson et al. (2011) describe the process and outcomes of an intensive 4-day course in pain medicine to first year medical students at Johns Hopkins University. The School of Medicine underwent curriculum redesign, providing an opportunity for integration of pain education. Pain is a "horizontal strand" that continues throughout the 4-year course. The 4-day course during first year is the foundation for subsequent learning. This is comprised of some didactic lecture teaching, but predominantly delivered as small group discussions, team-based learning, and laboratory sessions. The assessment tasks, done on day 4 of the short course, include multiple choice questions, an assessment task, and a short pain portfolio. The goal of the portfolio was to enhance understanding of the emotional aspects of pain. Outcome assessment identified learner satisfaction and knowledge acquisition and good participation in the portfolio exercise. However, course implementation was labor intensive requiring over 60 staff for delivery.

Hartrick et al. (2012) integrate pain basic science into first year pharmacology teaching, using pain neuroscience and pharmacology to illustrate principals of pharmacology (e.g., buprenorphine as a partial agonist, patient-controlled analgesia, and volume of distribution).

Since 2002, the University of Toronto has iteratively developed an interfaculty pain curriculum with students from medicine, dentistry, pharmacy physiotherapy, and occupational therapy (Hunter et al. 2008). A number of settings such as large groups and small groups are used to deliver content. Groups may be uniprofessional, multiprofessional, or interprofessional. Written material has been developed to support both students and facilitators. Prior to participation, facilitators attend a 3 h training workshop. Outcomes were measured by assessing

students' pain knowledge and beliefs pre- and post course, assessment of content and processes via a questionnaire to students and facilitators, and the assessment of the students' ability to develop a comprehensive pain management plan. The course performed well in all domains. Again, this course is human resource intensive.

149.3 Conclusion

It is evident that excellent uniprofessional and interprofessional pain curricula with comprehensive content are freely available. A significant barrier is the failure to adequately include pain or allocate appropriate time in medical school curricula. Continuing advocacy from IASP, local chapters and postgraduate bodies are needed to improve this. Other challenges include effective implementation in countries with limited resources and how to integrate pain education into other specialties in a curriculum. Ensuring pain curricula are delivered in a manner that allows development of the humanistic aspects of pain management such as empathy and compassion, rather than just acquisition of knowledge and skills, is important. These problems, however, are not insurmountable. It is to be hoped that with the continuing advocacy and commitment of IASP, its local chapters, postgraduate bodies, pain academics, and consumer groups, pain medicine will continue to gain momentum.
