GNC92H2 is an immunoglobuline G (IgG) with extended half-life that may sequester cocaine in blood and prevent its access to the brain. It appears that this vaccine has the capacity to redistribute cocaine from the brain to serum, within the restricted timeframe of cocaine overdose. Further research needs to be conducted to determine the medical safety and therapeutic utility of GNC92H2 for cocaine overdose (Treweek et al. 2011).

40.2.3 Methamphetamine Dependence

Immunotherapeutic approaches to methamphetamine and amphetamine dependence and overdose also appear promising (Gentry et al. 2009, 2010; Moreno et al. 2011; Duryee et al. 2009; Carroll et al. 2009). Gentry et al. reported that anti-methamphetamine monoclonal antibodies (mAb) are able to antagonize the locomotor effects of methamphetamine in rats and decrease meth-induced elevations in blood pressure and heart rate. Therefore, anti-methamphetamine mAb may prevent neurotoxicity and cardiovascular complications associated with methamphetamine overdose (Gentry et al. 2009). Recently, investigators began clinical trials of this mAb for the treatment of methamphetamine dependence.

EP54 is a methamphetamine vaccine that has been able to generate serum antibody titers against methamphetamine (Duryee et al. 2009). Efforts to systematic generate a series of haptens designed to target methamphetamine are ongoing. Vaccination of mice with meth immunoconjugates has shown high antibody titers and high affinity for three particularly promising formulations (Moreno et al. 2011).

40.2.4 Opiate Dependence

The development of biologics to treat opiate dependence is particularly challenging. The potentially efficacious vaccine should be able to bind to its target(s) with high specificity and avoid interfering with both the endogenous and any prescribed opiate medication. The ideal anti-opiate vaccine is one that can produce antibodies against heroin or the target opiate without blocking the pharmacotherapeutic effects of other opiates.

Currently, several groups are investigating anti-opiate vaccines (Anton and Leff 2006; Anton et al. 2009; Li et al. 2011; Pravetoni et al. 2012; Stowe et al. 2011). M-TT is being developed by a group of investigators in Mexico (Anton and Leff 2006; Anton et al. 2009). It has been reported that it is a highly immunogenic bivalent morphine/heroin vaccine that uses the tetanus toxoid as protein carrier. Studies conducted in rats have shown that the vaccine was able to prevent opiate use relapse.

M-KLH is a morphine (M) and oxycodone (OXY) haptens conjugated vaccine that may be useful for the treatment of poly-opioid dependence. A recently published study conducted in rats showed that M-KLH alone produced high titers of antibodies directed against heroin, 6-monoacetylmorphine (6-MAM), and morphine. Future studies are needed to determine the efficacy of bivalent anti-opioid vaccines that may simultaneously target multiple abusable opioids (Pravetoni et al. 2013).

40.3 Conclusion

Given the public health burden of the SUDs and overdose, there is an urgent need for safe and effective therapeutic interventions and biologics appear to be a promising approach. Development process include the anti-nicotine vaccine PF-05402536. With regard to biologics against cocaine, TA-CD and TV-1380 are the most advanced. Biologics to treat opiate and methamphetamine dependence are far behind.

As with any other psychiatric condition, the biologic treatments must be provided in conjunction with adequate psychosocial support. The ideal biologic-based therapy should be potent enough to block the access of the drug of abuse to the brain for a long period of time and should have good specificity for the target drug or class of drugs. The long-acting effect is important because individuals with SUDs usually have poor treatment adherence and extended effects will increase the probability of successful outcomes.

Biologics have the advantage of exerting their effect in the periphery. Unlike pharmacotherapies that work by altering brain functions, biologics do not cross the blood-brain barrier and therefore are unlikely to produce undesirable neuropsychiatric side effects. If necessary, biologics can be combined with pharmacotherapies which may result in boosting their therapeutic effect. Given that vaccines rely on the immune system for the production of antibodies, it is required that the immune system of the host will have capability of producing the antibodies.

Biologics are large molecules that may have unique metabolic characteristics and could cause a whole sort of possible adverse events such as kidney or liver problems. Also, because they are usually originated from living organisms, there is always a risk of anaphylactic complications. One of the drawbacks of vaccines is that they may be contraindicated in people with SUDs who have immunodeficiencies, poor nutrition, or chronic and debilitating medical conditions. The medical safety is an important issue in the development of treatments with biologics.

Currently, there is a great need of safe and effective biologics to treat SUDs. Research is needed to develop vaccines that can elicit high levels of antibody titers

and adjuvants that can improve their immunogenicity, as well as technologies to improve the specificity and efficiency of production of vaccines. Given the accelerated pace of this area of research, it is expected that in the near future there will be safe and effective biologics that health-care providers can use to treat their patients with SUDs.

Frank J. Vocci

Contents

Abstract

Encouraging findings are being reported in the development of drugs for the treatment of addictive disorders. This chapter reviews drug development for the treatment of alcohol, cannabis, cocaine, opiates, and methamphetamine dependence. Gabapentin, pregabalin, ondansetron, and sertraline have been investigated for the management of alcohol dependence in double-blind, placebo-controlled designs. Gabapentin has been shown in two studies to reduce the emergence and percentage of heavy drinking days following alcohol detoxification treatment. Pregabalin was shown to reduce withdrawal

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment: International Perspectives*, DOI 10.1007/978-88-470-5322-9_32,

symptomatology, craving, and relapse. Sertraline was reported to be efficacious in reducing drinking days and heavy drinking days in study participants with late-onset alcoholism. Ondansetron was shown to reduce drinks per drinking day and to increase the percentage of days abstinent in an alcohol-dependent population. Gabapentin has been shown to reduce cannabis use, withdrawal, and craving relative to a placebo group in one study. Nabilone has been shown to reduce marijuana withdrawal symptoms and self-administration in a clinical laboratory study, providing a rationale for an outpatient trial. A combination of mixed amphetamine salts and topiramate, compared to a placebo group, produced a greater percentage of cocaine-dependent participants achieving 3 weeks of continuous abstinence. Bupropion, methylphenidate, naltrexone, and topiramate have been evaluated for efficacy in facilitating abstinence in methamphetamine dependence. Bupropion has given the strongest signals of efficacy. Topiramate may have some utility as a relapse prevention agent but this needs to be confirmed.

Implantable and injectable forms of buprenorphine are being developed for the treatment of opioid dependence.

41.1 Introduction

The development of medications for the treatment of addictive disorders has had some successes in the treatment of alcohol dependence (acamprosate, oral and extended-release naltrexone, and disulfiram), nicotine dependence (nicotine replacement therapies and bupropion), and opioid dependence (methadone, oral and extended-release naltrexone, buprenorphine, and buprenorphine/naloxone), while there are no marketed pharmacotherapies for the treatment of cannabis, cocaine, or methamphetamine dependence. There are 26 medications in development for addictive disorders by the pharmaceutical industry (Pharmaceutical Research Manufacturers Association [PhRMA] report 2012). Some of these development projects are partially supported by funding from the US National Institutes of Health. Of these 26 medications, some are being investigated for multiple drug dependencies. Thus, there are seven medications being evaluated for each of cocaine, opiate, and nicotine dependencies, while there are five medications being developed for alcohol dependence treatment and three for methamphetamine dependence treatment. Additionally, the medications development programs of the National Institute on Drug Abuse and the National Institute on Alcohol Abuse and Alcoholism support clinical studies of investigational and marketed medications that are not on the list from the PhRMA. Reviewing all the medications on the PhRMA list is beyond the scope of this chapter. This review will survey developments for the treatment of alcohol, cannabis, cocaine, opiates, and methamphetamine dependence that were recently published in the medical literature.

41.2 Medications in Development for Treatment of Substance Use Disorders

41.2.1 Pharmacological Treatments for Alcohol Dependence

Gabapentin (GPN) is an antiepileptic medication that is also indicated for the treatment of post-herpetic neuralgia in the United States. It has been studied as a treatment for the prevention of alcohol relapse. It is often used in the immediate post-detoxification period. The results of the four randomized, double-blind studies are summarized in Table 41.1. The daily dose of GPN ranged from 600 to 1,500 mg in these studies. GPN has a salutary effect on the reemergence of heavy drinking days, the percentage of heavy drinking days, and often had a posttreatment effect that lasted weeks (Brower et al. 2008) or months (Anton et al. 2009).

Pregabalin is another GABA analog that has been studied as a relapse prevention agent in alcohol-dependent populations. Three studies have been conducted by Martinotti's group and are summarized in Table 41.2. Doses of 150–450 mg per day were tested in an open-label design (Martinotti et al. 2008), a randomized single-blind comparison to lorazepam and tiagabine (Martinotti et al. 2010a), and a double-blind comparison to naltrexone (Martinotti et al. 2010b). The following scales were used in the studies: Clinical Institute Withdrawal Assessment of Alcohol Scale-Revised (CIWA-AR), the Symptom Checklist 90-Revised, and the Obsessive-Compulsive Drinking Scale (OCDS). The studies show a consistent reduction in withdrawal symptomatology, craving, and relapse, with a greater effect on relapse seen in patients with an Axis I diagnosis. The results suggest that pregabalin has promise in the prevention of relapse in alcoholic patients and may be indicated for alcoholic patients with co-occurring psychiatric disorders. However, since there is only one double-blind study, further confirmation of the efficacy of pregabalin is needed, preferably by other clinical sites.

Two studies examined the interaction of medications with a single-nucleotide polymorphism of the serotonin transporter gene (5′-HTTLPR) and age of onset of alcoholism in order to resolve previous inconsistencies reported for serotonergic medications on drinking behavior and alcoholism treatment (see Kranzler et al. 2011). Kranzler evaluated the effect of sertraline on 134 patients with a diagnosis of moderate to severe alcohol dependence. An urn randomization procedure was used to balance the sertraline and placebo-treated groups on the following variables: age of onset of alcoholism (early-onset alcoholism [EOA] or late-onset alcoholism [LOA]), current age, gender, educational level attained, past diagnosis of major depressive disorder, and duration of abstinence prior to screening). All study participants were genotyped for the tri-allelic 5′-HTTLPR single-nucleotide polymorphism (SNP), designated as SS/LS/LL. Participants were initially treated with 50 mg of sertraline or matching placebo and then the dose was increased to a maximum of 200 mg of sertraline. Medication was provided for 12 weeks and then tapered over a 2-week interval. The dependent variables of interest were drinking days (DDs) and heavy drinking days (HDDs).

Table 41.1 Clinical studies of the efficacy of GPN in the treatment of alcohol dependence

Study design	Sample size	GPN dose and duration	Comparator medication	Results	Reference
Randomized, double blind	60 males	300 mg bid for 30 days	Placebo	GPN reduced the number of drinks per day, % heavy drinking days both ($p = 0.02$) and increased % days abstinent ($p = 0.008$)	Furieri and Nakamura-Palacios (2007)
Randomized, double blind	11 males and 10 females	Titration up to 1,500 mg per day. Dosed for 6 weeks	Placebo	GPN reduced onset to heavy drinking effect relative to placebo; effect persisted for 6 weeks ($p = 0.003$ at 12 weeks)	Brower et al. (2008)
Randomized, double blind	60	Titration up to 1,200 mg; dosed for 39 days. 2 doses of flumazenil (2 mg) on 2 successive days	Placebo GPN and placebo flumazenil	GPN differential efficacy: better modulation of withdrawal in those with more severe withdrawal, more % days abstinent and more time to first heavy drinking episode. Effects persisted for 8 weeks post-dosing	Anton et al. (2009)
Randomized, double blind	150; 119 male	Titration up to 1,200 mg per day with or without 50 mg naltrexone per day	Respective placebos	First 6 weeks: GPN/naltrexone group had longer delay to heavy drinking ($p = 0.04$) and less heavy drinking days than naltrexone only group ($p = 0.0002$) and less drinks/drinking day than naltrexone only group ($p = 0.02$) and placebo group ($p = 0.01$)	Anton et al. (2011)

One hundred thirty-four participants were randomized: 63 to sertraline (21 EOAs and 42 LOAs) and 71 participants received placebo (25 EOAs and 46 LOAs). Completion rates varied across the groups, being the lowest in the LL EOAs treated at 14.3 % with sertraline and highest in the LL EOAs who received placebo and LL LOAs who received sertraline (83.3 % in both groups). There was no significant difference noted in participants that possessed the S allele. The results for DDs and HDDs varied by age of onset in the homozygous L carriers. LOAs receiving sertraline had fewer DDs and fewer HDDs ($p = 0.011$) compared to LOAs receiving placebo whereas the EOA group had fewer DDs and HDDs when

Table 41.2 Effects of pregabalin on relapse to drinking in alcoholic patients

Study design	Sample size	Pregabalin dose and duration	Comparator medication	Results	Reference
Open label	31 enrolled (16 males 15 females), 20 received drug	150–450 mg/day; $X = 262.5$ mg 16 weeks dosing	None	10 of 15 completers were abstinent for the trial duration; significant reductions in craving on OCDS and VAS (both $p < 0.001$); statistically significant decreases CIWA alcohol score, Symptom Checklist 90-R and subscales rating obsessive-compulsive, hostility/anger, and psychoticism, General Severity Index, and Positive Symptom Total	Martinotti et al. (2008)
Randomized, multicenter, single blind	190 evaluated, 111 enrolled 69 males 42 females, $N = 37$/group	Up to 450 mg per day for 2 weeks	Lorazepam up to 10 mg/day for 14 days; tiapride up to 800 mg/day for 14 days	All groups had significant withdrawal score reduction on the CIWA alcohol scale with a greater effect of pregabalin on headache and orientation ($p < 0.001$); all groups reported less craving; less relapse in the pregabalin group ($p < 0.05$); less retention in the tiapride group ($p < 0.05$)	Martinotti et al. (2010a)
Randomized, double blind	71 enrolled 54 males, 59 detoxed $N = 31$ pregabalin, $N = 28$ naltrexone Both groups have had equivalent Axis I comorbid patients	Up to 450 mg/day, $X = 275.8$ mg/day for 16 weeks; 27/31 completed	Naltrexone 50 mg/day; for 16 weeks; 21/28 completed	No group differences in abstinence or craving scores; % of abstinent pregabalin patients with dual diagnosis was significantly higher than in the naltrexone group ($p < 0.05$); CIWA-AR scores reduced in both groups, with a greater reduction in the pregabalin group ($p < 0.05$)	Martinotti et al. (2010b)

treated with placebo. A follow-up study at 3 and 6 months post-medication discontinuation noted that the sertraline effect on DDs and HDDs was still evident in the LOAs at 3 ($p = 0.027$) but not 6 months (Kranzler et al. 2012). These provocative findings support further studies with sertraline for the treatment of alcohol dependence. A confirmatory study should also include EOAs as a negative control group.

Johnson and colleagues (2011) evaluated the effects of a low dose (4 μg/kg) of ondansetron (OND), a 5HT 3 antagonist, versus placebo on drinks per drinking day (D/DDs) and the percentage of days abstinent (DAb). Study participants were genotyped for the tri-allelic 5′-HTTLPR SNP, designated as SS/LS/LL, as well as a second SNP (T/G) rs1042173 in the 3′-untranslated region of the 5-HTT gene. Genotyping for the RS1042173 SNP was performed after randomization. An urn randomization procedure was used in this trial to assign participants to OND or placebo with respect to the LL, LS, and SS genotypes. Two hundred eighty-three DSM-IV diagnosed alcohol-dependent participants were enrolled. They were mostly white males (73 % white, 84 % male) and the rest were Hispanic. A placebo run-in was used in the first week. Thereafter, OND or placebo was supplied for 11 weeks to the study participants.

OND recipients possessing the LL genotype had a greater, statistically significant therapeutic response in terms of both D/DD and % DAb with effect sizes in the medium range (Table 41.3). LL carriers with the additional TT genotype had an enhanced, statistically significant response to OND when compared to all other OND recipients, all placebo recipients, LL/TT carriers who received placebo, and LL/G carriers. Effect sizes for D/DD were in the large range and for % DAb were in the medium range.

It has been previously reported that individuals with the LL genotype have a greater urge to drink (Ait-Daoud et al. 2009). The enhanced efficacy of OND blockade of 5-HT3 receptors in this group suggests that the 5-HT3 system may be sensitized in these individuals.

41.2.2 Pharmacotherapy of Cannabis Dependence

There are no currently marketed pharmacotherapies for the treatment of cannabis dependence. Two research groups have evaluated medications marketed for other indications in cannabis-dependent populations. The first study evaluated gabapentin (GPN) in 50 cannabis-dependent adults (88 % male) in a randomized, double-blind, placebo-controlled design (Mason et al. 2012). GPN was administered at a dose of 1,200 mg per day for 12 weeks in an outpatient setting. Cannabis use was determined by assaying delta-9 tetrahydrocannabinol (THC) concentrations in weekly urine samples and by self-report using the timeline followback interview procedure. Cannabis withdrawal was quantified using the Marijuana Withdrawal Checklist. The consequences of cannabis use were determined by the Marijuana Problems Scale. The last 38 enrollees were further assessed on three sub-tests of the Delis-Kaplan Executive Function Test: trail-making, color-word interference, and the verbal fluency tests.

Table 41.3 Effects of genotype on the response to OND

Group	Comparison	D/DD mean difference	*P* value	Cohen's d	% Dab mean difference	*P* value	Cohen's d
OND	LL vs. LS/SS genotypes	−1.53	0.005	0.47	9.73	0.03	0.29
LL genotype	OND vs. placebo	−1.62	0.007	0.56	11.27	0.023	0.41
LL genotype	LS/SS OND + LL placebo + LS/SS placebo combined	−1.45	0.002	0.45	9.65	0.013	0.32
LL/TT OND	All other OND recipients	−2.57	0.0002	0.92	15.50	0.008	0.62
LL/TT OND	All placebo recipients	−2.67	0.0001	0.86	17.98	0.002	0.65
LL/TT OND	LL/TT placebo	−2.06	0.015	0.72	12.52	0.079	0.51
LL/TT	LL/G carriers	−2.34	0.005	0.82	15.25	0.03	0.62

Relative to the findings in the placebo group, GPN reduced cannabis use as determined by weekly urine toxicology ($p = 0.001$) and self-report results ($p = 0.004$). GPN also significantly reduced withdrawal symptoms ($p = 0.001$), craving ($p = 0.001$), and Beck Depression Inventory scores ($p = 0.009$). Sleep was also improved in the GPN group as determined by the Pittsburgh Sleep Quality Index ($p < 0.001$). The GPN medicated group showed improvement, relative to their baseline scores, on the Marijuana Problems Scale score ($p = 0.02$). The GPN group also showed greater improvement relative to placebo on a composite score of the three executive function tests ($p = 0.029$). GPN is a promising candidate medication for the treatment of cannabis dependence. The results need to be replicated before GPN can be recommended as a treatment for cannabis dependence.

Nabilone is a synthetic cannabinoid medication. It has been compared to THC (dronabinol) in a clinical pharmacology study of its subjective, cognitive, and cardiovascular effects in ten current adult marijuana smokers (Bedi et al. 2012). Nabilone (2 mg) decreased systolic blood pressure and higher doses (4, 6, 8 mg) produced cannabinoid-like subjective effects. Doses of 6 or 8 mg of nabilone decreased psychomotor speed. Nabilone had a slower time to peak effects than THC and its effects were more dose-related than THC. The authors speculated that the dose-relatedness might be due to nabilone having more reliable bioavailability that THC.

A second study evaluated nabilone's ability to affect marijuana withdrawal symptoms and a measure of relapse (Haney et al. 2013). Eleven marijuana smokers were administered three doses of nabilone (0, 6, and 8 mg) in a counterbalanced order during times of marijuana abstinence (three consecutive days of placebo marijuana) in the clinical pharmacology laboratory. Both active doses of nabilone decreased marijuana withdrawal-related irritability and sleep disruptions ($p < 0.05$).

Food intake was increased relative to placebo when 6 or 8 mg doses of nabilone were administered during the marijuana withdrawal period. Participants engaged in more eating sessions ($p < 0.01$) and increased the caloric intake during each eating session. Nabilone doses of 6 and 8 mg also reduced self-administration of marijuana puffs, a laboratory measure of marijuana relapse. Interestingly, nabilone did not produce "liking" or a desire to take the nabilone capsules.

The data from the two studies discussed above suggest that nabilone should be evaluated as a treatment for cannabis dependence. The clinical pharmacology studies provide a rationale and the dose range for a phase II outpatient study.

41.2.3 Pharmacotherapy of Cocaine and Amphetamine/Methamphetamine Dependence

A combination of extended-release mixed amphetamine salts and topiramate was evaluated for efficacy in the treatment of cocaine dependence by Mariani et al. (2012).

These investigators randomized 81 cocaine-dependent study participants to the combination of mixed amphetamine salts and topiramate or their respective placebos. The mixed amphetamine salts were titrated to a maximum dose of 60 mg daily over a 2-week period, while the topiramate was ramped up to a maximum dose of 150 mg bid over 6 weeks. The primary outcome was the proportion of participants per group that achieved 3 weeks of continuous abstinence during the 12-week trial period.

The mixed amphetamine salt and topiramate group had twice the number of participants achieving the 3-week abstinence criterion than the placebo group (33 % vs. 17 %, respectively). Moreover, the higher the baseline use of cocaine, the more effective the active treatment combination was ($p < 0.05$). The median time to onset of the first week of 3 weeks continuous abstinence was 5 weeks in the amphetamine/topiramate group and 3 weeks in the placebo group. The onset of abstinence in the amphetamine/topiramate group came near the end of the topiramate titration period. The positive signal from this initial trial suggests that the drug combination of extended-release mixed amphetamine salts and topiramate deserves further study.

Modafinil was reported to facilitate abstinence (3 weeks continuous abstinence criterion) in cocaine-dependent subjects in a randomized, double-blind, placebo-controlled trial (Dackis et al. 2005). Subsequently, two confirmatory studies were performed. The first was a double-blind, placebo-controlled, and multicenter trial evaluation of 200 and 400 mg doses of modafinil in 210 cocaine-dependent subjects with or without a history of or current alcohol dependence ($n = 70$/group; Anderson et al. 2009). Modafinil or placebo was to be taken as a daily dose for 12 weeks. All study participants received a manual-driven cognitive behavioral therapy. The primary outcome measure was the change in average weekly cocaine nonuse days across the study weeks, analyzed by a general estimating equations (GEE) approach.

There was no difference in cocaine usage across the three study groups by the GEE analysis. The study also replicated the analysis used by Dackis et al. (2005) wherein missing urines were counted as positive for cocaine. This analysis also did not reveal a treatment effect favoring the modafinil groups. A secondary analysis of participants who did not have an alcohol dependence history or current alcohol dependence ($n = 125$) revealed a significant increase ($p = 0.02$) in cocaine nonuse days for the 200 mg (8.9 %) and 400 mg (8.5 %) modafinil groups relative to placebo. These non-alcohol-dependent modafinil subgroups also had a greater number of consecutive nonuse days, relative to the placebo group ($p = 0.01$). Craving was reduced in the 200 mg modafinil group although the effect was not statistically significant when corrected for multiple comparisons.

The second trial was a randomized, double-blind placebo-controlled trial of 210 cocaine-dependent participants who were randomized to a 200 mg modafinil ($n = 65$), 400 mg modafinil ($n = 70$), or a placebo group ($n = 75$) (Dackis et al. 2012). Unlike the Anderson et al. 2009 trial, prospective participants were excluded if they had any other drug dependencies. Thus, this group was a better match for the patient population from the first Dackis et al. (2005) study. The primary outcome variable was cocaine abstinence inferred by urine drug screens. Missing urines were imputed as positive. Other outcome measures assessed were withdrawal signs and symptoms, cocaine craving, and study retention.

There were no significant differences in cocaine abstinence across the three groups. The only trend ($p = 0.06$) seen favoring modafinil was in males in the 400 mg group versus males receiving placebo. There were no significant differences across groups on the other variables of interest.

The results of these two studies must be viewed as a disappointment as neither provided a robust signal of efficacy. It is conceivable that a combined analysis of these data sets could boost the power to determine differences across treatment groups.

41.2.4 D3 Dopamine Receptors and Buspirone

D3 dopamine receptors are located in limbic areas associated with cue- and drug-induced drug reward (Micheli and Heidbreder 2008). Cocaine produces an increase in D3 receptor mRNA and D3 receptor density in the rodent brain. Increases in D3 mRNA and receptors have been reported following cocaine cue-induced locomotion in mice (Le Foll et al. 2002) and a course of cocaine self-administration in rats (Neisewander et al. 2004). Upregulation of D3 mRNA (Segal et al. 1997) and D3 receptors have been reported in cocaine overdose fatalities (Staley and Mash 1996). These cocaine-induced neurobiological changes in D3 receptor density (and presumably, sensitivity to dopamine) may be a major determinant of cocaine-seeking behavior, in that they may enhance the reinforcing effects of cocaine use. D3 dopamine antagonists can block cue-induced, drug-primed, and stress-induced reinstatement of cocaine self-administration in rodents (Heidbreder 2008).

Buspirone has effects at multiple dopamine receptors. In vitro tests showed it to be a potent D3 dopamine receptor antagonist and a moderate D2 dopamine partial agonist (Toll et al. 2008) and a D4 antagonist (Bergman et al. 2013). Its D3 antagonist activity is in the same nanomolar range in in vitro tests as its well-known 5HT 1A activity. Buspirone has also been shown to reduce cocaine self-administration in high-grooming rats in a progressive ratio schedule (Homberg et al. 2004) and to block stress-induced (Beardsley et al. 2010) and cue-induced reinstatement (Shelton et al. 2013) of cocaine intake in cocaine-trained rats. Acute buspirone dosing (0.032 mg/kg) reduced cocaine self-administration in rhesus monkeys (Bergman et al. 2013). Further experiments by this same group showed that chronic buspirone dosing (0.32 mg/kg/h, i.v.) significantly reduced cocaine self-administration and shifted the dose-response curve downward in rhesus monkeys (Mello et al. 2013). Thus, preclinical data suggest that buspirone's blockade of D3 dopamine receptors would be a reasonable test of the hypothesis of an effect of D3 receptor blockade on cocaine abuse in humans.

Buspirone has been tested in two small studies of cocaine abusers ($n = 32$; Giannini et al. 1993) and ($n = 18$; Moeller et al. 2001). Giannini et al. evaluated cocaine withdrawal. Buspirone has also been given to 18 methadone-maintained patients in which reduction of drug use was evaluated (McRae et al. 2004), although cocaine use was not specifically reported. None of these studies had sufficient power to detect an effect associated with buspirone administration. The NIDA Clinical Trials Network is currently running a pilot study of the safety and efficacy of buspirone (60 mg/day) for the treatment of cocaine dependence (Winhusen et al. 2012).

41.2.5 Medications for the Treatment of Amphetamine/ Methamphetamine Dependence

Two clinical trials have been conducted that suggest bupropion can reduce methamphetamine use in light users (Elkashef et al. 2008; Shoptaw et al. 2008). Both of these studies evaluated 150 mg bid versus a placebo. Although the primary endpoint of statistically significant reduction of methamphetamine use was not achieved in either study, Elkashef et al. showed that bupropion significantly reduced methamphetamine use ($p < 0.001$) in light to moderate users (1–18 days of use per month at baseline). Similarly, Shoptaw et al. reported that bupropion also significantly reduced methamphetamine use ($p < 0.001$) in light methamphetamine users (defined as having 0–2 positive urines uses out of a possible six during the baseline period). McCann and Li (2012) conducted an analysis of individuals within groups who achieved multiple weeks of abstinence. In this analysis, bupropion significantly facilitated abstinence ($p = 0.0176$). Brensilver et al. (2012) reanalyzed the data on light to moderate users in the Elkashef et al. and Shoptaw et al. trials. These authors concluded that the inability to achieve at least three methamphetamine negative urine samples predicted a greater than 90 % likelihood of treatment failure. Thus, the primary trials and their reanalyses

suggest a patient population that may be responsive to bupropion and the time frame that at least a partial response should be seen.

Methylphenidate has been evaluated as a treatment agent for amphetamine dependence in a study in Finland (Tiihonen et al. 2007). In this study 53 intravenous amphetamine users were randomized to aripiprazole (15 mg/day), methylphenidate (54 mg per day), or placebo. The medication portion of the trial was 20 weeks. The primary outcome measure was amphetamine use as measured by urine toxicology. There were fewer amphetamine positive urines in the methylphenidate-treated group.

A follow-up trial to assess the efficacy of extended-release methylphenidate was conducted in Finland and New Zealand (Miles et al. 2013). Seventy-nine participants were randomized to either the methylphenidate (54 mg/day) or placebo group. The trial duration of 20 weeks was identical to the initial Tiihonen et al. (2007) study. There was no difference seen in amphetamine use between the two groups although retention was superior in the methylphenidate group ($p < 0.05$).

Naltrexone (50 mg/day, po) was found to reduce relapse in amphetamine-dependent trial participants (Jayaram-Lindstrom et al. 2008). Although no direct confirmatory trials have been reported in the extant literature, there are two publications that utilized naltrexone implants. The first was a study that randomized 100 amphetamine and opiate dually dependent participants to a naltrexone or placebo rod (Tiihonen et al. 2012). The primary outcome variables were urines negative for amphetamine and opiates and retention in the study. Missing urines were imputed as positive for the analysis. The naltrexone group had more drug-free urines (38 %) versus the placebo group (16 %) ($p = 0.01$). The number of amphetamine free urines was not statistically different across groups in a weekly drug use analysis. However, the number of times used per week was almost statistically significant ($p = 0.06$) with less days of use in the naltrexone group. Retention was greater in the naltrexone group ($p = 0.01$). Kelty et al. (2013) conducted a retrospective review of amphetamine-dependent users who were treated with naltrexone implants in Australia. Forty-four patients who received naltrexone implants gave self-report data on their amphetamine use. Almost 70 % claimed to be abstinent for at least 1 month. Of the 29 patients claiming abstinence at 1 month, 14 claimed to be abstinent at 6 months. The authors correlated abstinence with naltrexone blood levels and reported a direct relationship between blood levels and abstinence: those with a blood level greater than 2 ng/mL, 1–2 ng/mL, and less than 1 ng/mL had reported abstinence rates of 91 %, 43 %, and 39 %, respectively. Future trials need to incorporate urinalysis confirming abstinence with blood levels above 2 ng/mL as a threshold target in future trials.

Elkashef and colleagues (2012) evaluated the potential efficacy of topiramate versus placebo in the treatment of methamphetamine dependence in a randomized, double-blind, multicenter trial. One hundred forty methamphetamine-dependent adults received topiramate in a titrating dose schedule. The initial dose of 25 mg per day was ramped up to a maximum of 200 mg per day by the end of week 6. Doses were then kept constant for the next 6 weeks. The primary outcome measure was negative "methamphetamine use week" during weeks 6–12, analyzed using a GEE method.

There were no differences in methamphetamine use in weeks 6–12 across the two groups. However, when those participants in each group whose last baseline urine before randomization was negative ($n = 13$ in both the topiramate and placebo groups) were analyzed, the topiramate group had less methamphetamine use ($p = 0.02$). This finding suggests that topiramate should be reevaluated as a relapse prevention agent in methamphetamine-dependent populations (Vocci 2012).

41.2.6 Medications for the Treatment of Opioid Dependence

Buprenorphine and buprenorphine/naloxone prescribing have been increasing in the United States since their approval in October 2002. In fact, buprenorphine/naloxone was the 36th highest prescribed medication in the United States in 2012 with sales of nearly 1.5 billion dollars (Drugs.com 2013). The success of buprenorphine and buprenorphine/naloxone has not only engendered the development of generic dosage forms for these medications but also new dosage forms that have advantages in terms of diversion potential (Dasgupta et al. 2010). The first of these dosage forms is Probuphine, an implantable rod (26 × 2.5 mm) containing 80 mg of buprenorphine per implant. White et al. (2009) explored the efficacy, pharmacokinetics, and safety of switching 12 opioid-dependent study participants maintained on sublingual buprenorphine to the buprenorphine implant. Participants maintained on an 8 mg dose of sublingual buprenorphine received two rods while those on 16 mg of sublingual buprenorphine received four implanted rods in the subdermal space. The participants were followed for 6 months. Opioid withdrawal was assessed by the Subjective Opioid Withdrawal Scale (SOWS) and the Objective Opioid Withdrawal Scales (OOWS). Craving was assessed by the use of a Visual Analog Scale. Scores on the SOWS and OOWS were minimal; e.g., the SOWS score averaged over the 6 month period was 0.97 ± 2.18 (note the scale has a maximum score of 64). Craving scores were also minimal, averaging 2.25 ± 6.44 over the 6-month period (note the scale has a maximum score of 100). Three participants in the two implant group and two participants in the four implant group received sublingual buprenorphine as a rescue medication for withdrawal for an average of 4.8 ± 5.1 days.

The percentage of opioid-free urines during this pilot study (59 %) was consistent with results previously reported (60 % opioid-free urines) in a 6-month buprenorphine study by Pani et al. (2000).

No serious adverse events occurred in the group. Seven participants reported adverse events associated with implantation or removal of the rods. Five of the 12 participants experienced adverse events that were attributed to Probuphine: dizziness ($n = 3$), constipation ($n = 2$), and abdominal pain, implant site reaction, flushing, and pallor ($n = 1$).

Plasma samples were obtained over the 6-month period for determination of buprenorphine levels. The four implant group had an average plasma level of buprenorphine of 0.72 ± 0.11 ng/mL, essentially equivalent to the trough level

seen during the screening period when buprenorphine dosing was administered sublingually (0.72 ± 0.30 ng/mL). The terminal plasma half-life of buprenorphine post-removal of the implants was 23.8 ± 8.6 h.

A multicenter trial of the buprenorphine implant was performed in 18 centers in the United States (Ling et al. 2010). One hundred sixty-three male and nonpregnant female opioid-dependent study participants were randomized under double-blind conditions to the buprenorphine rods (four implants) or placebo (four implants) in a 2:1 ratio. All study participants were inducted onto 12–16 mg of sublingual buprenorphine and had to be maintained at that dose for 3 days before randomization.

In this trial supplemental sublingual buprenorphine, up to 12 mg, was allowed if participants experienced significant withdrawal or craving. An additional implant was also permitted if participants required supplemental buprenorphine more than 3 days in 1 week or 8 days over a 4-week period. Sixty-four of the 108 buprenorphine-implanted participants received supplemental buprenorphine for a median time of 7.5 days, whereas 91 % of the placebo group was supplemented with buprenorphine for a median time of 19.5 days during the first 16 weeks. The implants were removed after 6 months.

In addition to urine toxicology to determine opiate use, the Clinician Opiate Withdrawal Scale (COWS), the SOWS, a visual analog scale for craving, and Clinical Global Impression Severity (CGI-S) and Improvement (CGI-I) were obtained at baseline, 16 and 24 weeks.

Participants in the buprenorphine implant group used less opiates (40.4 % opiate negative versus 28 % negative in the placebo group) as measured by urine toxicology results ($p = 0.04$). Additionally, the buprenorphine implant group had lower scores on the COWS ($p < 0.001$), SOWS ($p = 0.004$), and the visual analog craving scale ($p < 0.001$). Lower scores were recorded in the buprenorphine group on the CGI-S ($p < 0.001$) with a corresponding improvement on the CGI-I scale ($p < 0.001$). Retention favored the buprenorphine implant versus placebo groups with 67.5 % and 30 % retention, respectively ($p < 0.001$).

Two serious adverse events (SAEs) were reported in the buprenorphine group and four were reported in the placebo group. One of the SAEs in the buprenorphine group was thought to be possibly treatment-related: one participant with a history of chronic obstructive pulmonary disease and embolism experienced an exacerbation of these conditions. One placebo participant developed a cellulitis at the implant site that required hospitalization, debridement, and drainage. The other SAEs in either group were not treatment-related. Most of the adverse events in the buprenorphine group were implant site-related; three participants discontinued due to implant site pain ($n = 1$) or pain and infection ($n = 2$). No placebo participants discontinued due to adverse events.

A second, multicenter trial of the buprenorphine implants was conducted in 20 sites in the United States (Ling and Beebe 2013). Opiate-dependent, adult males and nonpregnant females ($n = 287$) were randomized in a double-blind fashion to a buprenorphine implant group (four implants) or a placebo group (four implants) and a sublingual buprenorphine group in an open-label fashion. The primary

outcomes were the comparison of the two implant groups and the comparison of the buprenorphine implant group to the open-label buprenorphine/naloxone group.

At the conclusion of the 6-month trial, all study completers were allowed to enroll in a 6-month open-label extension of the buprenorphine implants.

In the comparison of the implant groups, the buprenorphine implant group had a greater percentage of opiate negative urines ($p < 0.0001$) and greater retention (64 % vs. 25 %, $p < 0.0002$). The implant group response was also shown to be non-inferior to the sublingual buprenorphine group response at a pre-specified non-inferiority level of −15 %.

A long-acting, injectable preparation of buprenorphine is being developed by Camurus (2013). Depending on the lipid composition of the controlled-release matrix, an injection could produce therapeutic blood levels last for 1 week or 1 month. A safety, efficacy, and pharmacokinetics study of the 1-week preparation in 41 opiate-dependent individuals was reported on the company's website. Dose-proportional and dose-linear kinetics were observed after a single injection of buprenorphine (CAM2038). SOWS and COWS assessments were "well controlled for up to 10 days after single dose injection of CAM2038." These results obviously need to be published in a peer-reviewed journal but, if verified, would give clinician's another option to treat opioid dependence with minimal concern about diversion.

Methadone is available as a racemic mixture for treatment of opioid dependence. Besides an effect on respiratory depression, racemic methadone has effects on cardiac repolarization by virtue of its ability to block the inwardly rectifying K^+ channel (IKr) in the myocardium. The human ether-a-go-go-related (HERG) gene encodes the potassium channel current. Methadone blocks the HERG channel at Cmax concentrations seen in human populations (Katchman et al. 2002). The delayed repolarization produced by methadone (and other medications that block the IKr channel) results in a prolongation of the QT interval in the ECG. There are numerous case reports in the literature of methadone's ability to prolong the QT interval (Andrews et al. 2009) along with cohort studies (Maremmani et al. 2005; Ehret et al. 2006; Fanoe et al. 2007). The QT interval associated with chronic methadone treatment at a fixed dose has been reported to increase (Andrews et al. 2009). Martell et al. (2005) reported that methadone increased the QTc by an average of 12 ms and the increase was correlated to both trough and peak methadone serum levels. Roy et al. (2012) reported that 11.1 % of 180 patients enrolled in a methadone clinic had QTc intervals greater than 450 ms. In the cohort reported by Ehret et al. (2006), 16 % of the group has a QTc >500 ms, and 3.6 % developed torsades de pointes (TdP). Fanoe et al. (2007) calculated that each 1 mg increase in methadone dose increased the QTc by 0.14 ms. Thus, methadone may produce toxicity through both respiratory and cardiac mechanisms (QT prolongation that could lead to TdP).

The R-isomer (l-methadone or levomethadone) has been reported to be ten times more potent at mu receptor binding sites than the S-isomer (Kristensen et al. 1995) and twice as potent as racemic (R,S) methadone. The S-isomer has been reported to be 3.5 times more potent than the R-isomer in blocking the HERG channel (Eap et al. 2007). Thus, the S-isomer is likely to be a greater contributor to QT prolongation than the R-isomer when the racemic mixture is given. In 39 patients

receiving R,S-methadone for treatment of opioid dependence, Ansermot and colleagues (2010) reported the QT interval was significantly reduced by 3.9 ms per week when the patients were switched to a half-dose of the R-isomer ($p = 0.04$). Verthein and colleagues (2005) enrolled 75 patients to test the hypothesis that switching from R-methadone to R,S-methadone was associated with more withdrawal symptoms and side effects than switching from R,S-methadone to R-methadone. These investigators employed a stratified, randomized, 2 × 2 cross-over study design over a period of 8 weeks. Every second patient was switched from the pre-study medication to the other medication and the switched back after 4 weeks of dosing. Although no significant differences in withdrawal symptoms or side effects were noted between the two medications, patients treated with l-methadone reported fewer withdrawal symptoms. An open-label substitution of R-methadone for the (R,S) methadone in a multi-clinic setting, at half the dose of the R, S mixture, resulted in successful transition to the R-isomer in 91.8 % of the 1,552 study participants (Soyka and Zingg 2009). Less than 1 % of the patients dropped out due to adverse events. Moreover, patients switched to the R-isomer for 4 weeks reported fewer withdrawal symptoms ($p < 0.001$), less craving (reduced from 69.3 % to 36.8 % of patients reporting craving), fewer side effects ($p < 0.001$), and less illicit drug use. In fact, 98 % of the patients did not report any side effects. The number of illicit drug screens dropped from 61.2 % prior to transfer to 39.8 % 4 weeks after the switch to R-methadone. Compliance with R-isomer treatment was rated as "very good" or "good" for 85.8 % of the patients compared to 60.1 % prior to the switch ($p < 0.001$). Seventy-nine percent of the participating clinicians felt that the R-isomer was tolerated by the patients "better" or "much better" and only 1 % of the clinicians felt that the patients tolerated the R-isomer "worse" or "much worse" than the R,S-racemate. These data suggest the following benefits of R-methadone compared to the R,S-racemate: (1) lesser degree of QT prolongation with a lesser propensity for development of TdP, (2) better management of withdrawal symptoms, (3) less craving for opiates, (4) less illicit drug use, (5) fewer side effects, and (6) greater compliance with the treatment regimen. Thus, a rational strategy to reduce the morbidity and mortality of methadone is to switch patients who are on the racemate to the levo-isomer.

Currently, the R-methadone is only marketed in Germany and Austria. Consideration should be given to expanding the availability of this medication.

41.3 Conclusion

Gabapentin, pregabalin, sertraline, and ondansetron have demonstrated efficacy for the management of alcohol dependence. The efficacy of gabapentin has been confirmed in several studies; a posttreatment effect slowing the onset of return to heavy drinking has been seen in two studies (Brower et al. 2008; Anton et al. 2009). Although confirmatory studies will be needed for pregabalin, sertraline, and ondansetron, the alcohol treatment field has reason to be optimistic about this group of medications.

Gabapentin and nabilone have emerged as possible pharmacotherapies for the management of cannabis dependence. These findings are relatively new and require confirmation in the case of gabapentin and determination of efficacy in at least two phase II trials for nabilone.

The amphetamine salts and topiramate combination for the treatment of cocaine dependence needs confirmation in a longer clinical trial. Although the 3 weeks of continuous abstinence is a clear signal of efficacy that merits publication in the literature, FDA regulatory authorities want trials of 6-month duration with abstinence measured at the end of the trial to demonstrate efficacy (Winchell et al. 2012).

The potential efficacy of buspirone is now being investigated in a clinical study (Winhusen et al. 2012). Studies performed in rats (Beardsley et al. 2010; Shelton et al. 2013) and rhesus monkeys (Bergman et al. 2013; Mello et al. 2013) give a solid rationale for testing buspirone in cocaine dependence. Any studies performed with buspirone should measure plasma levels so that adherence can be measured and the levels can be compared to plasma levels in rhesus monkeys that suppressed cocaine self-administration (Mello et al. 2013).

New medications in testing for the treatment of opioid dependence are currently variations on a theme. Longer-acting dosage forms of buprenorphine reduce the risk of diversion and, in the case of the implant, appear to be equally efficacious to sublingual buprenorphine/naloxone. These medications may be particularly useful in nonadherent patient populations and in rural areas where patients have to travel great distances to receive medical care. The development of R-methadone would likely be a safer version of methadone administration with equal efficacy to the racemic mixture (Soyka and Zingg 2009).

Evaluating the Therapeutic Utility of Hallucinogens for Substance Use Disorders

42

Elias Dakwar

Contents

Abstract

Hallucinogens represent a promising but controversial treatment for substance use disorders. Research into their efficacy and clinical feasibility has been hampered, however, by legal, cultural, and political restrictions since the late 1960s, when many of these substances were criminalized. In light of these substantial limitations, this chapter evaluates what is known about the uses of hallucinogens in the treatment of substance use disorders. First, the neurobiological and psychoactive effects of hallucinogens are summarized. The relevance

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment: International Perspectives*, DOI 10.1007/978-88-470-5322-9_33,

of these effects to therapeutic mechanisms is explored, with special attention given to recent findings that elucidate the prefrontal effects of hallucinogens. Set and setting are defined and discussed, and consideration is given to how the cultural use of hallucinogens, in developed as well as preindustrial societies, can inform how they might be used appropriately in medical settings. A variety of hallucinogen-oriented therapeutic strategies are reviewed, including behavioral, psychedelic, psychodynamic, and neurobiological models. A review of the available research subjects that while the therapeutic utility of hallucinogens may be highly promising, the evidence is far from conclusive. The chapter concludes with a discussion of future directions for research.

42.1 Introduction

Like heroin, hallucinogens were initially regarded as possible medicines before concerns over their risks led them to be classified as nontherapeutic drugs of abuse. Unlike heroin, however, hallucinogens have demonstrated therapeutic feasibility, as well as safety and tolerability, in various treatment contexts (Bakalar and Grinspoon 1997; Galanter and Kleber 2008; Malleson 1971). Numerous case studies and several controlled trials have suggested that classical hallucinogens, and specifically lysergic acid diethylamide (LSD), can be administered in appropriate therapeutic settings to certain psychiatric populations, such as alcohol-dependent or depressed individuals, with minimal risk and with apparent benefit (Malleson 1971; Vollenweider and Kometer 2010). Given these promising findings, it is important to understand how these compounds came to be classified as dangerous drugs of abuse with no medical value. This will provide some background to the deficits in our knowledge concerning their therapeutic utility.

Believed at one time to herald a new paradigm in the treatment of mental illness (Hoffer 1970), but criminalized in most Western countries in the late 1960s and early 1970s due to reports of widespread misuse and abuse (Leuner 1994), hallucinogens have for decades now been condemned by mainstream psychiatry as too high risk to merit further investigation. Accordingly, funding for clinical research with classical hallucinogens had rapidly dwindled in the late 1960s from millions of dollars annually in the United States alone, despite promising early findings, particularly with severe alcoholism (Bakalar and Grinspoon 1997; Leuner 1994). This abrupt halt to clinical research has left many important questions unanswered and has severely restricted our capacity to appropriately assess their clinical effectiveness.

In light of these limitations, this chapter reviews what is known about the uses of hallucinogens in the treatment of substance use disorders. First, we summarize the neurobiological and psychoactive effects of hallucinogens, and provide a brief overview of the various cultural contexts in which their use has occurred. Then, we explore several models proposed for how they might be effective for substance use disorders and examine the research conducted to date assessing their therapeutic

efficacy. When appropriate, popular preconceptions about these compounds, pertaining to both possible risks and benefits, are evaluated based on the available evidence. We conclude with a discussion of future directions for clinical research.

42.2 Classifications, Properties, and Historical Uses

42.2.1 Classifications and Mechanisms

The term "hallucinogen" designates a diverse group of substances whose primary effects are changes in perception, experience, and consciousness comparable to the alterations that characterize non-ordinary mental states such as dreaming, meditation, psychosis, dissociation, or mystical experience (Galanter and Kleber 2008; Vollenweider and Kometer 2010; Hoffer 1970). It is worth noting that hallucinogens, despite their name, rarely engender hallucinations (or sensory phenomena that are experienced as real though lacking a referent in reality). This has led other names to be proposed for this drug class, such as psychedelic (mind manifesting), phantasticant (inducing fantasy), and oneirogen (dream generating). Hallucinogen (from the Latin *alucinor*: mental wandering or dreaming) remains the most widely used term for these substances in medical settings, and we will employ it here, despite its limitations.

Hallucinogens encompass many distinct substances, some with quite different neurobiological and psychoactive effects. These various agents can be organized either by their immediate neurobiological effects or by their molecular structure. The two broadest molecular subgroups are the indoleamines and phenethylamines (Fig. 42.1). The indoleamines include LSD, dimethyltryptamine (DMT), psilocybin, ibogaine, and harmaline. Phenethylamines include naturally occurring compounds such as mescaline but also an ever-expanding number of synthetic compounds, e.g., 2-CB, MDMA, MDA, and DOM.

Classical hallucinogens are widely believed to exert their psychoactive effects by direct agonism of the 5HT2A serotonin receptor, though other serotonin receptors may also be involved. Classical hallucinogens include psilocybin, LSD, mescaline, and DMT. These compounds, though sharing neurobiological activity, come from quite diverse sources: psilocybin can be isolated from a mushroom, for example, and mescaline derives from a cactus in the American Southwest.

Hallucinogens may also exert their psychoactive effects by *nonclassical* mechanisms. These mechanisms include serotonin release or nonspecific serotonin receptor activation, as in the case of MDMA ("Ecstasy" or "Molly") and other phenethylamines; *N*-methyl-D-aspartate receptor (NMDAr) or glutamatergic modulation, as with ketamine and phencyclidine; cannabinoid receptor activation; and κ-receptor agonism, as occurs with *salvia divinorum*. These mechanisms are by no means exhaustive; there are other compounds (e.g., nitrous oxide, the fly agaric mushroom) that work by different mechanisms (Bakalar and Grinspoon 1997; Galanter and Kleber 2008; Malleson 1971). Interestingly, recent research suggests that classical hallucinogens and dissociative anesthetics, despite their apparent

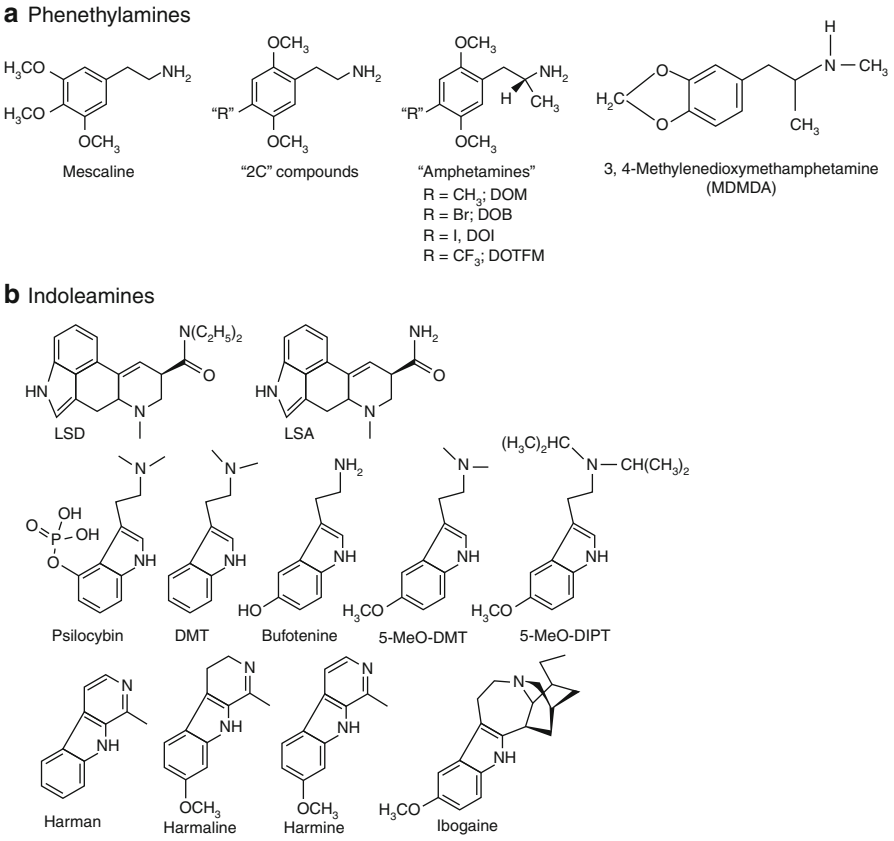

Fig. 42.1 Hallucinogens by molecular group

differences in immediate neurobiological activity, work by a common final pathway of prefrontal glutamatergic modulation (Vollenweider and Kometer 2010).

The effect of classical hallucinogens on cerebral blood flow (CBF) and brain activity is currently a matter of some controversy. Previously demonstrated to increase blood flow to and activity in the prefrontal areas when administered orally (Vollenweider and Kometer 2010; Schreckenberger et al. 1998; Gouzoulis-Mayfrank et al. 1999), recent research by a single group has suggested that psilocybin may *decrease* CBF to certain prefrontal areas by functional magnetic resonance imaging (fMRI), when administered as a bolus dose by the intravenous (IV) route, as well as reduce prefrontal activity (Carhart-Harris et al. 2012b). These changes in CBF and activity appear to correlate with certain psychoactive effects. Further, IV psilocybin has been shown by the same group to attenuate functional connectivity, synchronize anti-correlated networks, and reduce resting-state default mode network (DMN) activity, which is thought to correspond to self-referential processing and the structuring of experience (Carhart-Harris et al. 2012a, b). These latter effects on the DMN

and functional connectivity are consistent with brain activity associated with other altered states, such as meditation and psychosis, as well as with the subacute effects of sub-anesthetic ketamine (Scheidegger et al. 2012). The diminution in prefrontal CBF and activity found with IV psilocybin, however, has yet to be replicated by other groups. It is also unclear whether this effect on CBF is indeed crucial to the psychoactive effects of psilocybin or whether it is an epiphenomenon of tryptamine-like vasoconstriction.

42.2.2 Psychoactive Properties and Risks

The psychoactive effects of hallucinogens can be markedly different depending on the type of drug and its route of administration. Even agents from the same subgroup (e.g., mescaline and MDMA) can be quite dissimilar. Here, we will aim to describe all *potential* hallucinogenic effects. Classical hallucinogens are the subgroup that typically exhibits the widest range of these alterations (Bakalar and Grinspoon 1997; Galanter and Kleber 2008; Malleson 1971; Vollenweider and Kometer 2010).

Hallucinogenic alterations can be grouped into three categories, all of which can be experienced concurrently (Vollenweider and Kometer 2010; Studerus et al. 2011). The first and most basic are *perceptual changes*. These include an intensification of sensory phenomena; greater sensitivity to latent phenomena (e.g., patterns or textures that are ordinarily overlooked); changes in the perception of time or space; conflation of sensory modalities, as in synesthesia; the production of eidetic imagery, such as spirals, shapes, and arabesques; greater aesthetic appreciation; illusions; pseudohallucinations (with intact reality testing); and an altered sense of the body.

The second category of alterations is *experiential*. These changes include alterations in mood (euphoria, hilarity, terror, or anxiety), altered relatedness to others or to objects (empathy, alienation, connectedness, or merging), philosophical/existential concerns, increased insight, dissociation, emergence of pseudo-delusional or overvalued ideas (e.g., the world will end in the near future), suggestibility, and a reliving of past memories or a resurgence of apparently resolved conflicts.

Mystical or transpersonal experiences constitute the third category. These are alterations characterized by heightened spirituality or mysticism, similar to experiences described by mystics, philosophers, or religious figures in historical accounts. They can include a struggle or conflict of archetypal dimensions; a sense of life's absurdity or lack of purpose; an experience of complete oneness with all that is; near-death or birth-like experiences; immersion in a total void; ego diffusion, as in so-called oceanic boundlessness; ego dissolution; a sense of the sacred; spiritual ecstasy; spatiotemporal transcendence; nondiscursive or ineffable understanding (e.g., knowledge beyond the pale of language); overwhelming sense of finiteness or sinfulness; identification with the divine; reincarnation; reevaluation of values; redemption; and metaphysical/cosmological speculation. Recent research with psilocybin suggests that the personal significance of such experiences can be enduring,

with individuals continuing to report 1 year later that the experience was among the most important in their lives (Griffiths et al. 2006, 2008).

As we will see later, these various alterations in consciousness are believed by some treatment models to serve as the psychological mechanisms by which clinical improvement for addictive disorders occurs. However, these same alterations also represent the greatest source of toxicity, especially when the hallucinogen is consumed by unprepared or unstable individuals, or in the absence of a supportive, responsive framework. In such circumstances, hallucinogens may lead to acute behavioral disturbances or persistent distress that may require emergency treatment. Common adverse effects of hallucinogens include anxiety or dysphoria, generally circumscribed to the period of intoxication; loss of behavioral control during acute intoxication, including passivity, disorganization, indecision, and suboptimal functioning; and more rarely, precipitation of persistent anxiety, affective, or psychotic disturbances in vulnerable individuals (Bakalar and Grinspoon 1997; Vollenweider and Kometer 2010; Johnson et al. 2008; Imperi et al. 1968).

The criminalization of hallucinogens was buttressed by various claims of risk that are now recognized as false, but which have managed to persist despite no supportive evidence (Bakalar and Grinspoon 1997). These unsubstantiated claims include concerns that classical hallucinogens cause chromosomal damage (Cohen and Shiloh 1977–1978); that they lead to suicide, murder, or debauchery, even when used in appropriate clinical settings (Malleson 1971; Studerus et al. 2011); or that they engender schizotypal personality changes or lasting psychotic disturbances in individuals without a preexisting vulnerability (Malleson 1971; Studerus et al. 2011; Vardy and Kay 1983).

Though hallucinogens may be used irresponsibly or abused (e.g., repeatedly ingested despite the emergence of behavioral distress or other adverse effects), classical hallucinogens do not present a risk for dependence according to animal models; they are not self-administered, do not create conditioned place preference or physiological dependence, and do not lead to dopamine release from reward pathways (Fantegrossi et al. 2008).

Recent polls in the United States parallel these findings and strongly suggest that hallucinogens are infrequently used and do not create dependence phenomena. Hallucinogens are used most commonly in late adolescence and young adulthood, with up to 11 % of 12th graders having used at least once, and their use is generally sporadic, clustered, or infrequent. Even heavy users do not use more than two or three times a week, and it is uncommon for hallucinogen use to persist beyond young adulthood. Barring atypical substances such as ketamine, nitrous oxide, certain phenethylamines (i.e., MDMA), and cannabis, hallucinogens do not create physiological dependence or tolerance, and dependence phenomena, such as an inability to stop using, are rarely seen (Galanter and Kleber 2008; Fantegrossi et al. 2008; Passie et al. 2002).

Research suggests that the behavioral and psychoactive risks associated with hallucinogens may be effectively minimized and managed by the context in which the agents are administered. It has been recognized that hallucinogenic alterations are shaped, to an extent, by the past experience, expectations/intentions, preparation,

and attributes of the individual (the *set*), as well as by the context (including other individuals, medical staff, or a guide) in which the experience occurs (the *setting*) (Bakalar and Grinspoon 1997; Malleson 1971; Vollenweider and Kometer 2010; Imperi et al. 1968; Studerus et al. 2012). The set and setting may play a primary role in whether the hallucinogen experience is pleasant and enriching or dysphoric and upsetting. Most importantly, the set and setting also constitute the most salient modifiable variables affecting whether or not hallucinogen-related toxicity occurs. Many reports from the heyday of hallucinogen research – the 1950s and 1960s – have consistently shown that with appropriate patient selection, preparation, guidance, and follow-up care, hallucinogens can be safely administered in medical settings, with minimal reports of behavioral toxicity or persistent adverse effects (Bakalar and Grinspoon 1997; Malleson 1971; Vollenweider and Kometer 2010; Studerus et al. 2011). Indeed, most accounts of behavioral toxicity or persistent distress occur outside of medical settings, when these substances are used irresponsibly. These findings are now being replicated by more recent investigations as human-oriented hallucinogen research carefully resumes (Johnson et al. 2008).

42.2.3 Historical Use

Set and setting also provide a valuable lens by which to understand the historical use of hallucinogens. As is the case with many psychoactive substances, hallucinogens have been accorded an important, and sometimes sacramental, place in various cultural traditions. The use of the hallucinogen might be ritualized or ceremonialized, symbolically integrated into the group's beliefs and traditions, or invested with supernatural importance (Fig. 42.2). The unique psychoactive profile of hallucinogens, and particularly their capacity to engender mystical-type experiences, has made them especially well suited to religious, initiation, or healing ceremonies (Bakalar and Grinspoon 1997; Hofmann and Schultes 1979).

Indigenous groups in the Americas have a robust and diverse history of incorporating hallucinogens into their rituals and ceremonies, likely because of the wealth of naturally occurring psychoactive substances in these continents. The Aztecs ritualized the use of psilocybin-containing mushrooms for millennia; peyote (mescaline) and salvia are used by groups in Mexico; and DMT, in the form of ayahuasca or yage, is central to Shamanic or religious ritual in various indigenous and syncretic Amazonian traditions. Despite DMT and mescaline being illegal in the United States, they can be licitly used in their naturally occurring forms by members of certain religions that are recognized by the US government as requiring these substances for proper worship. Of note, both DMT (as ayahuasca) and mescaline (as peyote) are used by their respective communities to promote health and address certain ailments, such as addiction. The spiritually oriented set and setting implicated in the therapeutic use of hallucinogens have led some researchers to propose that psychospiritual mechanisms account for their putative benefits. Researchers have accordingly proposed hallucinogen-based treatment models that aim to elicit mystical states similar to those cultivated in hallucinogen-oriented rituals (Bakalar and Grinspoon 1997;

Fig. 42.2 Various mushroom stones. These stones, dating from 1,000 BC to 500 CE, are approximately 1 ft in height. They suggest the religious and cultural importance accorded to psychoactive mushrooms by groups that consume them sacramentally, ritually, or ceremonially (Image adapted from *Plant of the Gods* by Schultes and Hofmann)

Hofmann and Schultes 1979). (These will be discussed in greater detail in the next section, alongside other hallucinogen-based treatment models.)

The widespread use of hallucinogens in the United States and Europe among the young during the 1960s is also worth discussing. Alongside being privileged for their potent ability to alter and enhance sensory experience, hallucinogens (and primarily LSD) were celebrated by the counterculture as tools for self-discovery, direct mystical communion, and transcendence from ordinary, consensus experience. This attitude towards hallucinogens, fueled by such popular figures as Aldous Huxley, Timothy Leary, and Alan Watts among many others, gained particular momentum in the context of the social problems and generational conflicts that characterized the late 1950s and 1960s, with many people, and particularly the young, disillusioned by the belligerent imperialism, consumerism, materialism, and conformity that had come to shape their societies. In this troubled time, hallucinogens came to represent, much as in some indigenous cultures, a means by which to access deeper truths and initiate communal renewal. Unlike these indigenous cultures, however, the United States and other Western countries lacked the cultural framework to effectively incorporate hallucinogen use, support those who sought to use them, and respond creatively to the powerful experiences occasioned by them. Instead, unsupervised and irresponsible use proliferated; traumatic or sensational adverse events made headlines; and the substances were condemned as dangerous and bereft of benefit. The importance of a supportive and guided framework that adequately screens and prepares the individual before hallucinogen administration

cannot be overstated and should guide both the clinical and cultural use of these compounds to minimize the risks associated with them, as well as optimize their benefits (Bakalar and Grinspoon 1997; Leuner 1994).

42.3 Hallucinogen-Based Treatment Models

The majority of addiction-oriented treatment models incorporating hallucinogens are aimed at utilizing their unique psychoactive effects for therapeutic ends. As the acute and downstream neurobiological effects of these agents have begun to be elucidated, new models have emerged that emphasize biological mechanisms of therapeutic efficacy. We will examine each of these models in turn.

42.3.1 Negative Reinforcement

The earliest hallucinogen-based model for the treatment of alcohol dependence in a medical setting originated with the observation that individuals who had undergone delirium tremens (DTs) were more likely to pursue abstinence from alcohol than those who had not (Bakalar and Grinspoon 1997; Hoffer 1970; Abramson 1967). It was also believed that hallucinogens can engender delirium and suffering, as well as nightmarish reflections on the ravages of alcohol, that were comparable in phenomenology to DTs. Thus, much like DTs, hallucinogen-generated suffering was thought to lead individuals to abandon drinking.

This model is predicated on the *negative reinforcement* hypothesis of learning, whereby a certain behavior is reinforced (such as maintaining abstinence) by the negative consequence that would occur if the behavior were *not* performed (such as a resurgence of DTs and alcohol-related distress). As such, a behavior comes to be performed in order to avoid a certain adverse outcome. Agents that were used in this model include antimuscarinic agents such as scopolamine and belladonna and LSD. The therapeutic framework was primarily oriented around accentuating the horrors of alcohol and shoring up motivation to stop using. A similar strategy was used in an early form of ketamine psychedelic therapy (KPT) wherein the horrors of the problem drug (alcohol or opioids) were reinforced using cues or props while the patient was actively intoxicated with a sub-anesthetic dose of intramuscular ketamine (Krupitsky and Grinenko 1997).

42.3.2 Psycholytic Therapy

Hallucinogens were believed to facilitate psychoanalysis by weakening ego defenses; increasing the capacity for free association and memory retrieval; and creating more detachment from habitual thought patterns. They were also believed to accelerate the interpretative process by heightening transference reactions and engendering fantasy and pseudo-dream states within the session (Fig. 42.3).

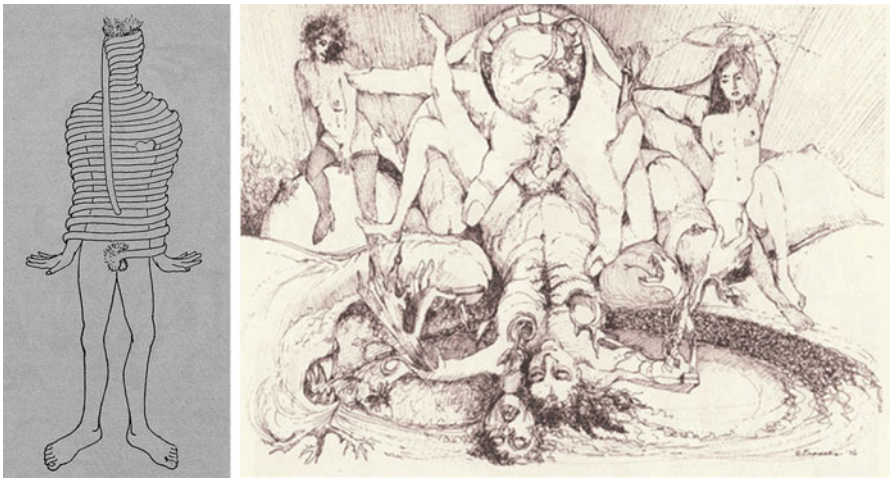

Fig. 42.3 These drawings by trained artists are visual representations of experiences that occurred during LSD-assisted psychotherapy. They demonstrate the psychological depth and intensity of the conflicts that might emerge during psychedelic experience, as well as how readily these conflicts might lend themselves to psychodynamic exploration. In these images, the artists may be depicting their conflicted attitude towards sexual desire, and anxieties about how sexual desire and union may threaten individual identity (Adapted from *LSD Psychotherapy* by Stanislav Grof)

LSD was thought to be most effective at a low dose for these purposes. The therapeutic framework was the typical one of psychoanalysis, with sessions occurring several times a week and with the analyst seated out of sight of the generally supine patient so as to facilitate transference reactions, free association, and fantasy. Frequency of LSD administration varied from a few times weekly to monthly, and the goal was to raise to conscious reflection the unconscious processes that perpetuate addictive behaviors. This model was primarily used, however, to address depressive and anxiety symptoms, not substance use disorders (Bakalar and Grinspoon 1997; Malleson 1971; Vollenweider and Kometer 2010; Hoffer 1970; Abramson 1967).

42.3.3 Psychedelic Therapy

Psychedelic therapy refers to the variety of therapies aimed at using hallucinogens to provoke "psychedelic" states and that provide a therapeutic framework to allow the individual to integrate the experience(s) into a healthier worldview and lifestyle. While the phenomenology of the target experience might vary – one approach might aim for a near-death experience, for example, while another a mystical communion with the cosmos – the common goal is to produce experience with potent *transformative* potential, such that it provides the patient with opportunity for existential reappraisal, a beneficial shift in perspective, and refreshed creativity. Such hallucinogen-based experiences are comparable to the mystical states occasioned

during the indigenous ceremonies discussed earlier. Furthermore, they are similar to the spontaneous experiences described by addicted individuals who undergo a transformative experience, be it "hitting rock bottom" or "having a moment of clarity," that serves to provide an experiential foundation for subsequent abstinence (Hoffer 1970; Abramson 1967; Krupitsky and Grinenko 1997; Miller and C'de Baca 2001).

Psychedelic therapy involves a high level of rapport, preparation, guidance, and post-session integration. It is typically carried out over many encounters, with several sessions occurring before the hallucinogen is administered so as to ensure that the participant is adequately prepared and comfortable with his/her treatment team. In current psychedelic therapy models, the team is generally composed of a male and female who engage with the patient as a dyad during the hallucinogen session. The role of the dyad is to provide gentle support and reassurance throughout the session, particularly when distressing phenomena may occur (Johnson et al. 2008).

Psychedelic therapy with high-dose LSD became the dominant hallucinogen-based model for treating alcohol dependence in the 1960s, and enough comparable controlled studies were completed as to produce sufficient data for a recent meta-analysis, which will be discussed later. KPT, mentioned above, was used in Russia in the 1980s and 1990s and was intended to trigger near-death and rebirth experiences with ketamine to treat opioid or alcohol dependence. Ibogaine is found in the root bark of an African shrub *iboga* and continues to be used by the Bwiti for healing, pleasure, initiation, and spiritual communion. Ibogaine as a treatment for opioid dependence emerged from the psychedelic/experiential model in the 1950s, but was investigated preclinically with government funding in the 1980s and 1990s with greater emphasis on neurobiological mechanisms. Ayahuasca (a brew composed of plants containing DMT and an MAOI, which serves to inhibit first-pass DMT metabolism) is beginning to be investigated in small pilot studies in Spain and Brazil for treating various addictive disorders. More recently, researchers in the United States are testing the feasibility of embedding psychedelic therapy using psilocybin in more conventional addiction-oriented therapies, such as cognitive-behavioral therapy (CBT) or motivational enhancement (ME), to treat nicotine and alcohol dependence (ClinicalTrials.gov Identifier: NCT01534494) (Bakalar and Grinspoon 1997; Malleson 1971; Hoffer 1970; Abramson 1967; Krupitsky and Grinenko 1997; Alper and Glick 2001).

42.3.4 Hallucinogen-Facilitated Therapies

Another emerging model involves utilizing hallucinogens to facilitate psychotherapies beyond psychoanalysis or the psychedelic framework. An ongoing controlled trial investigating sub-anesthetic ketamine and mindfulness training for cocaine dependence represents an example of this approach (ClinicalTrials.gov Identifier: NCT01535937). Other strategies might include embedding the hallucinogen in a framework of 12-step facilitation or group psychotherapy. The pilot studies with psilocybin mentioned above represent a mixed model where the psychedelic therapy is intended to produce a transformative experience that, in turn, leads to

increased engagement with more conventional addiction-oriented psychotherapies, such as CBT or ME.

42.3.5 Neurobiological Approaches

Recent research has served to clarify the neurobiological effects associated with hallucinogens and has broadened the scope of clinical research with these compounds by suggesting that they might target some of the neural, synaptic, or functional deficits associated with addiction as well as other psychiatric disorders. While classical hallucinogens and their nonclassical counterparts initiate their psychoactive effects by different mechanisms, they may have comparable downstream effects, particularly on prefrontal regions. These effects include the promotion of neural plasticity, improvement of prefrontal glutamate homeostasis, modulation of glutamatergic neurotransmission, attenuation of problematic cortical excitation, and regulation of DMN activity and functional connectivity (Vollenweider and Kometer 2010; Carhart-Harris et al. 2012a; Scheidegger et al. 2012). Many of these mechanisms have direct relevance to the deficits associated with substance use disorders.

Ibogaine was investigated in this way for opioid dependence, with the hypotheses that NMDAr effects were implicated in its anti-addictive properties and reduction in withdrawal symptoms (Vollenweider and Kometer 2010; Alper and Glick 2001). However, an analog iboga compound with less toxicity, 18-methoxycoronaridine (18-MC), has been found to exert comparable anti-addictive effects but with negligible NMDAr activity, suggesting that the main mechanism of action may not be what was thought previously (Glick et al. 2000). Similarly, the NMDAr antagonist ketamine is being investigated along neurobiological lines as a treatment for various substance use disorders.

42.4 Evidence for Efficacy

42.4.1 Clinical Evidence

Most of the clinical research conducted with hallucinogens for substance use disorders occurred in the 1950s and 1960s, focused on LSD for alcohol dependence, and lacked the rigorous design characteristics that have come to characterize modern research methodology. It is therefore not possible to draw conclusions from these early preliminary studies, though there may be some promising signals. A literature search, for example, reveals many clinical anecdotes, case studies, and trials of varying degrees of scientific rigor that suggest the feasibility of LSD as an antidipsotropic agent.

Case studies and open trials, however, cannot establish efficacy on their own. The gold standard in clinical research is widely recognized to be randomized controlled trials (RCTs). As such, a recent meta-analysis pooled results from seven comparable studies conducted in the 1960s that best approximate modern standards of RCT design (Krebs and Johansen 2012). The authors found that LSD,

at varying doses and in various psychotherapeutic contexts, was superior to the control conditions in promoting short-term abstinence. The authors note that while some of the analyzed trials were negative independently (perhaps because they were underpowered), the trials in aggregate demonstrated some promise. Without delving too deeply into a discussion of the study's limitations, it is important to emphasize that the favorable meta-analysis should not be interpreted to mean that LSD is effective for alcohol dependence, especially given the heterogeneity of study design, of population, and of LSD dosage in the analyzed trials. Research that adheres to rigorous and uniform randomized controlled design – employing effective blinding procedures, adequate controls, independent evaluations, appropriate outcome measures, and so on – is needed to clarify whether this promising intervention is indeed effective. Unfortunately, various legal and social obstacles make it unlikely that LSD will be investigated in a well-designed and adequately powered RCT in the near future.

Inconclusive evidence exists for other hallucinogens as well. Animal and preliminary human research indicated that ibogaine may be effective in reducing opioid self-administration and ameliorating withdrawal phenomena, but government funding stopped short of standardized clinical investigations due to concerns over its hallucinogenic effects and possible cardiotoxicity (Alper and Glick 2001). 18-MC, an iboga congener associated with less toxicity, has demonstrated promising effects on drug self-administration in animals, but has yet to be tested in humans. It is also unclear to what extent 18-MC has hallucinogenic properties, as its developers believe that its profile of neurobiological effects render it less likely than is ibogaine to produce alterations in consciousness (Glick et al. 2000). It is therefore unclear until it is tested in humans whether or not 18-MC should be grouped with hallucinogens.

Ketamine administered intramuscularly in the context of KPT has been found effective in preliminary controlled trials in producing abstinence from opioids and alcohol (Krupitsky and Grinenko 1997) and is currently being investigated, administered intravenously at sub-anesthetic doses for under an hour, as a treatment for cocaine dependence in individuals receiving mindfulness-based psychotherapy. There is insufficient evidence at present, however, to draw conclusions about the efficacy of ketamine for substance use disorders, even though it is one of the few hallucinogens, like LSD and ibogaine, that have been studied in RCTs for this purpose. This is in contrast to ayahuasca, psilocybin, and mescaline, for which only dramatic clinical anecdotes, community studies, and favorable open trials are available. Systematic RCTs need to be conducted in order to establish the efficacy of these promising compounds.

42.4.2 Mechanism-Oriented Evidence

In the absence of large-scale RCTs, researchers have turned to more modest laboratory studies to investigate how hallucinogens may impact on outcomes relevant to addiction. These studies have thereby sought to elucidate the

mechanisms by which hallucinogens, and ketamine and psilocybin in particular, might benefit substance use disorders. In a recent series of studies with healthy volunteers (Griffiths et al. 2006, 2008), orally administered psilocybin in the context of psychedelic therapy has been shown to occasion spiritually significant experiences whose importance persists up to 1 year after the session. Alongside being subjectively important to participants, these psilocybin-occasioned experiences may have been associated with increased openness, as assessed by a personality test (MacLean et al. 2011), and improved functioning, according to accounts of family and friends. These improvements appear to correlate with the mystical intensity of the experience, such that experiences were more likely to be associated with beneficial changes in character and functioning the more they approached a mystical state. These findings have some relevance to the management of substance use disorders in that they suggest that psychedelic experience leads to behavioral and characterological changes that might ameliorate addictive behaviors. These findings also appear to lend credence to the main hypothesis of psychedelic psychotherapy – namely, that psychedelic states may lead to beneficial psychological and behavioral effects. It remains to be determined, however, if psilocybin effectively produces such changes in addicted individuals.

Recent studies by several groups have shown that sub-anesthetic ketamine has powerful antidepressant effects that might implicate downstream mechanisms such as prefrontal neural remodeling and modulation of glutamate homeostasis (Mathew et al. 2012; Li et al. 2010). These findings are relevant to the management of substance use disorders insofar as addiction has been long recognized to involve glutamatergic prefrontal disruptions (Kalivas 2009; Goldstein and Volkow 2002; Kosten et al. 2006; Goldstein et al. 2007). These disruptions are thought to be associated with such deficits as the attenuated salience of natural rewards and increased sensitivity to stress and drug cues. Animal studies have further shown that glutamatergic modulators consistently decrease the reinforcing effects of powerful substances of abuse, such as cocaine, even as human studies with comparable glutamate-oriented compounds have been disappointingly unsuccessful (Collins et al. 1998; Bisaga et al. 2010). A recent laboratory study investigating sub-anesthetic ketamine at doses comparable to the antidepressant dose found that, in cocaine-dependent nontreatment-seeking volunteers, ketamine was superior to the control condition in increasing motivation to stop use and decreasing cue-induced craving (Dakwar et al. 2014). These findings suggest that the potent prefrontal effects of sub-anesthetic ketamine may serve to target addiction-related deficits that have eluded other glutamatergic modulators. The clinical safety and efficacy of sub-anesthetic ketamine is currently being investigated in a RCT (NCT01535937).

42.5 Conclusion

In the United States, classical hallucinogens are classified as Schedule I; this classification is reserved for substances of high abuse liability and with no known

medical benefit. Inasmuch as hallucinogens can be associated with substantial risks and are not established to be effective for any medical conditions, this classification is appropriate. However, the classification is problematic because it a priori dismisses agents with hallucinogenic effects as without medical benefit (ketamine being the sole exception). This has led to difficult cultural, legal, and financial obstacles being placed in the way of investigators who aim at better understanding the clinical utility, or lack thereof, of these compounds.

In light of the findings discussed above, it is not unreasonable for investigators to be interested in carefully and responsibly evaluating the efficacy of these promising but high-risk agents. Enough encouraging signals and important unanswered questions exist as to merit further clinical and mechanism-oriented research. Yet, it is exceedingly difficult at present to marshal the requisite financial and institutional resources to conduct appropriate clinical investigations (particularly with Schedule I substances such as LSD or psilocybin) to determine anti-addiction efficacy. Financial and cultural restrictions thereby continue to undermine the ability of researchers to appropriately investigate efficacy, while the lack of research establishing efficacy serves to reinforce those very restrictions. Thus the pursuit of science is stymied.

Governmental agencies or industry may be unwilling to fund such studies for cultural and political reasons, but research has managed to resume over the past decade, albeit at a much slower pace than in the 1950s and 1960s. Modern clinical research with Schedule I hallucinogens, such as psilocybin, MDMA, or ayahuasca (DMT), has been largely funded by foundations, such as Heffter, Beckley, and the Multidisciplinary Association for Psychedelic Studies (MAPS), that aim to sidestep some of the restrictions mentioned above by soliciting funds from private donors. In this way, clinical research with hallucinogens has received some modest financial support in the absence of conventional funding, and small pilot studies for nicotine and alcohol dependence are currently approaching completion at two independent academic centers. But in the absence of the millions of dollars necessary to effectively conduct large-scale RCTs, these foundations are ill equipped to bear the financial burden on their own. It may be that governmental or industry funding may be ultimately necessary to adequately assess the clinical utility of these compounds. It is unlikely, in the absence of a political sea change, that these types of funding will be available to fund clinical research for a compound already criminalized; instead, government or industry may be most likely to fund compounds under development or in preclinical investigation, as is the case with 18-MC.

42.5.1 Medicine, or Drugs of Abuse?

A question related to classification is whether hallucinogens should be designated as "medicines" or "drugs of abuse." These compounds are undoubtedly *drugs of abuse* insofar as they carry a high risk for problematic use and serious adverse consequences. These risks, as discussed earlier, are most probable when hallucinogens are used irresponsibly, by unprepared or unsuitable individuals, and in settings

without appropriate levels of support or guidance. Any investigative approach that does not adequately consider these dangers or makes light of them would be irresponsible. But does it follow that because hallucinogens might be used as drugs of abuse, they cannot possibly be medicines?

This chain of reasoning is shown to be based on a false dichotomy when one considers other high-risk medical treatments. It is difficult to find in the history of medicine another intervention where risks associated with nonmedical applications have been interpreted to indicate a lack of utility in clinical settings. The aim in clinical research is to investigate interventions in appropriate *medical* settings: a surgical procedure is tested in the operating room, for example, and pharmacotherapy in the clinic. To classify hallucinogens as Schedule I based primarily on risks emerging in nonmedical settings is tantamount to outlawing an experimental surgical procedure because it is associated with high morbidity and mortality when attempted at home with crude implements. Whatever the intervention might be and no matter how preliminary the clinical research, risks emerging from its nonmedical uses should not be given undue emphasis when drawing conclusions about medical utility in appropriate contexts. This is especially the case for intervention where a proper medical setting is crucial, as with hallucinogens. From a clinical research perspective, it is therefore appropriate to tentatively group hallucinogens alongside other high-risk interventions, such as surgery, opioids, or anesthetic agents, which necessitate various precautions, well-delineated treatment contexts, and careful screening procedures so as to minimize risk and optimize therapeutic efficacy. Whether hallucinogens ultimately take a place next to such effective but high-risk interventions remains to be determined by the appropriate research.

With a binary conceptualization of these compounds as drugs of abuse *or* medicines clearly inadequate, it is reasonable to suppose instead that hallucinogens are drugs *and possibly* medicines. This allows for an appreciation of their risks and complexities, as well as for recognition that scientific inquiry into their efficacy is promising but incomplete. While the current schedule does not brook such nuances, particularly when substances of known risk are concerned, this conceptualization can help investigators frame their research approach, especially when it comes to determining set/setting and testing procedures. Further, it may assist in transforming entrenched political and cultural attitudes towards these compounds.

The most pressing question is ultimately an empirical and straightforward one: Do hallucinogens have a role in the treatment of substance use disorders or not? As discussed above, this is a question that builds on decades of research and that addresses important gaps in our understanding. Further, it is a question that deserves to be answered, having been left unresolved for nearly half a century. Addiction is too severe a disorder, and too often resistant to available treatments, for the continued neglect of these promising compounds to be justified. We have come to realize that hallucinogens can be abused as drugs; perhaps, it is time to determine whether they can be used as medicines as well.

Markos Emmanouel

Contents

Abstract

The National Acupuncture Detoxification Association auricular acupuncture protocol is used around the world to help people deal with and recover from substance abuse. The NADA protocol has been shown in a variety of clinical settings to be beneficial in the process of detoxification from substance abuse as well as to help with the emotional, physical, and psychological attributes involved in addictions. The NADA protocol has been effective in a wide range of addictive disorders that include opiates, alcohol, cocaine, cannabis, methamphetamine, and benzodiazepines. Clinical reports have indicated that the NADA protocol has been effective for dually diagnosed patients. Patients report a decrease in anxiety and depression and a reduction in violence, improvement in compliance with medication protocols, and reduction of adverse reactions to psychotropic medications. Since the beginning of the new millennium, in the age of evidenced-based medicine, the use of this modality has increased significantly worldwide, despite the lack of a large amount of randomized controlled trials indicating its efficacy.

43.1 Introduction

Acupuncture is a modality of treatment practiced in China for the past 2,500 years. In 1972, Dr. H. L. Wen, a neurosurgeon from Hong Kong, discovered that one of his patients reported reduced withdrawals and cravings for opiates following auricular acupuncture utilized for analgesia. Dr. Wen and Dr. Cheung published their results of treating 40 heroin and opium addicts with electropotentiated ear acupuncture in the Asian Journal of Medicine.

The following year Dr. Michael Smith, medical Director of the Lincoln Hospital Detox Program, began using acupuncture as an adjunct treatment for their patients, following a 10-day methadone detoxification cycle. Clients reported less malaise, feeling more relaxed, and a reduction of opiate withdrawal symptoms. It was accidentally discovered that simple manual needling produced a more prolonged effect compared to electric stimulation. In 1978, the clinic discontinued the use of methadone as a part of its detoxification protocol. During the crack cocaine epidemic of the 1980s, the protocol was utilized with some success to treat these patients as well.

43.2 Acupuncture Applications

43.2.1 The NADA Ear Protocol

Chinese medical theory, though scientific in its own right, is built on the foundation of ancient philosophical thought. The theory of the yin and yang is one such philosophy. The basic premise of this theory is that in nature there is constant change. Yin and yang represent two broad categories of opposite yet complementary concepts. More specifically, yin is what maintains and endures, is nourishing, and supports growth. Some examples of yin are earth, autumn, cold, and moisture. On the other hand, yang is what is creative and generating. Some examples of yang are heaven, spring and summer, heat, and dryness.

Auriculotherapy is a therapeutic modality of acupuncture in which external ear stimulation is utilized to treat health conditions in other parts of the body. The needling takes place with five thin, sterile, stainless steel needles under the surface of the skin of the outer ear. The practice of ear acupuncture is based on the fact that there is an anatomical arrangement of points on the external ear that represent an inverted homunculus. More specifically, the head is represented in the lower part of the ear, the hands and feet towards the top, and the internal organs within the depressions of the outer ear.

The NADA five points are the sympathetic, shen men (spirit gate), kidney point, liver point, and lung point. These were chosen based on Chinese medical theory and clinical indication, as well as lower electrical resistance and pain sensitivity.

They are located on the deep, dark, cavernous parts of the ear, i.e., the yin side. The combination of all five points has the result of a yin tonification, restoring the calm inner qualities akin to serenity.

The needling of the sympathetic and shen men points produces calming, relaxing, and centering effects. The kidney, liver, and lung points correspond to yin organs. The yin organs are deemed as nourishing, restorative, and supportive. In modern Western medicine, these organs are the organs of elimination in the body and, hence, relate to detoxification and cleansing.

Dr. Michael Smith at the Lincoln Recovery Center developed sleepmix tea which is used in prior to the NADA protocol. It contains three parts chamomile and one part each peppermint, yarrow, hops, skullcap, and catnip. It is believed to calm and soothe the nervous system, stimulate circulation, and eliminate waste products.

43.2.2 Research and the NADA Protocol

Dr. H. L. Wen was the first physician to report successful treatment of withdrawal symptoms with acupuncture in 1973. He initially observed an opiate addict receiving electroacupuncture for presurgical analgesia and, as a result, reported relief of withdrawal symptoms.

In 1987, Bullock studied 54 patients with alcohol dependence in an inpatient program that were randomly assigned to either the NADA treatment protocol or needling at nearby ear points (the "sham" group). The receivers of the NADA protocol treatment showed better outcomes for cravings of alcohol and subsequent relapses. These results were replicated by the same group in 1989 during which 80 patients were divided randomly in two groups, 40 in the NADA group and 40 in the "sham" group. After 8 weeks, 21 patients in the first group remained in the program compared to one in the latter group.

Washburn in 1993 reported that opiate addicts receiving the NADA treatment protocol had better program attendance than subjects receiving acupuncture on placebo sites.

Konefal in 1995 conducted a study during which 321 subjects were randomly assigned to three groups: a one-needle shen men point, the NADA protocol five-point treatment, and a NADA protocol five-point treatment plus selected body points for self-reported symptoms. All three groups showed a reduction in the percentage of positive urine drug screens, with the latter two groups showing the largest reduction.

Shwartz, Saitz, Mulvey, and Brannigan in 1999 published a retrospective cohort study of 8,000 clients discharged from detoxification programs in Boston, MA. Outpatients that received acudetox treatment had statistically significant lower rates of readmission than residential patients who did not receive acudetox treatment.

A pilot study in 2000 by Russell, Sharp, and Gilbertson of 86 subjects with a history of addiction and multiple arrests found a statistically significant increase in program retention and positive trend towards fewer arrests and fewer positive urine toxicology results of the group that received acudetox treatment compared to the group that did not.

Avants in 2000 conducted a study in which 82 cocaine-dependent methadone-maintained subjects were randomly assigned to three groups. The results found 58 % of the acudetox group versus 24 % of the sham group, and 9 % of the relaxation video group had cocaine-free urines. A large six-state nationwide study published in JAMA by Margolin et al. in 2002 found no statistically significant difference between the acudetox and control groups.

Bier et al. in 2002 studied the effect of acudetox in nicotine cessation. They found that in 1 month 10 % of receiving acudetox were not smoking compared to 22 % of those receiving sham acupuncture with education counseling and 40 % of those receiving acudetox and clinical intervention.

43.2.3 Applications and Outcomes

While originally intended for use in opioid abuse and dependence, the NADA protocol has been effective in a wide range of addictive disorders that include opiates, alcohol, cocaine, cannabis, methamphetamine, and benzodiazepines. For the most part, this form of treatment has been effective as adjunctive to standard treatment protocols.

43.2.3.1 Opiate Addiction

It has been reported from the Lincoln Recovery Center that acudetox provides nearly complete relief of observable acute opiate withdrawal symptoms in 5–30 min and lasts for 8–24 h. The duration of the effect of treatment has been subjectively reported by patients as increasing with every subsequent treatment. It has also been reported that patients that are intoxicated prior to initiating the treatment session feel less intoxicated following treatment. During treatment of acute opiate withdrawal, the NADA protocol is administered 2–3 times daily. In conjunction with methadone or buprenorphine, it is administered once daily. In addition to the above, the NADA protocol in an opiate detoxification program typically results in a 50 % increase in retention. In methadone maintenance programs that utilize this form of adjunctive treatment patients report a decrease of methadone side effects and a decrease in positive urine toxicology results (Margolin 1993).

43.2.3.2 Alcohol Addiction

Retention in alcohol detoxification programs increase up to 50 % when an acudetox component is incorporated as an adjunctive treatment. Woodhull Hospital in Brooklyn, New York, reported that 94 % of the patients in the acudetox group remained abstinent compared to 43 % of the control group.

43.2.3.3 Cocaine Addiction

Acudetox recipients report calmness and decreased craving to use cocaine as soon as following the first treatment. A study of patients enrolled in a methadone maintenance program with concurrent cocaine dependence, after receiving

8 weeks of auricular acupuncture treatments, had a 44 % abstinence rate. Overall, the subjects reported decreased craving and increased aversion to cocaine-related cues (Margolin 1993). At the Lincoln Recovery Center, 80 % of 226 patients with a history of cocaine dependence had negative toxicology results. Women in Need, a program for crack-addicted women in New York City, reported an average of 3 visits per year for patients receiving conventional outpatient treatment, 27 visits per year for acudetox with conventional treatment, and 67 visits per year for those receiving acudetox, conventional treatment, and an educational component.

43.2.3.4 Methamphetamine Addiction

The Hooper Foundation, a public detoxification program in Portland, Oregon, reported a 5 % retention of methamphetamine-addicted patients without acudetox versus a 90 % retention rate of patients that received the treatment.

43.2.3.5 Marijuana Addiction

Anecdotal reports indicate a reduction in craving and an improved subjective sense of well-being following acudetox.

43.2.4 Special Populations

Substance abuse treatment programs that treat groups such as adolescents; elderly; women; culturally defined populations; gay/lesbian/transgender patients; homeless; veterans; incarcerated patients; patients with significant medical comorbidities such as HIV/AIDS, hepatitis, and mental illness; and trauma survivors have found the NADA protocol particularly helpful. These groups have more trouble maintaining their sobriety due to added stressor of discrimination and marginalization. In pregnant women, acudetox has been an effective alternative to treatment especially when medication-based treatment is not indicated or available. The Lincoln Recovery Center has been treating more than 100 pregnant cocaine users per year.

Clinical reports have indicated that the NADA protocol has been effective for dually diagnosed patients. Patients report a decrease in anxiety and depression, and programs a reduction in violence, improvement in compliance with medication protocols, and reduction of adverse reactions to psychotropic medications.

43.2.5 International Perspectives

Currently, the National Acupuncture Detoxification Association protocol is utilized in 2000 drug and alcohol treatment centers in 40 countries. It is used in 130 prisons in England. This program was expanded because of an 80 % reduction in violent incidents. In New York City following the terrorist attacks on 9/11/2001 and in New Orleans following Hurricane Katrina in 2005, posttrauma treatments were given to community members, and treatments for firemen have been established in both cities. Ear acupuncture or stress has been used by thousands of military

personnel in India. In Northern Europe, 3,000 nurses have been trained in 100 different government facilities. The Drug Abuse Resistance Education (D.A.R.E.) program in Thailand has provided ear acupuncture for Burmese tribes in border camps.

In May 2008, at the Kiryandongo Refugee Settlement Camp in Uganda, 21 former healthcare worker refugees were trained in the NADA protocol to treat the Kenyan refugee population that fled their country and entered Uganda due to the postelection violence that erupted in Kenya. Over 500 refugees were treated, with improvements in mood and sleep, decreased aggression and grief, and decreased substance abuse (mostly alcohol and tobacco use), and in children a decrease in bedwetting. Within a week, the temporary camp was moved to a permanent camp where the Kenyan refugees joined Sudanese and Ugandan refugees. Acudetox treatments continued at the camp with the participation of all three national groups. The community leaders reported that issues such as domestic abuse, stress, and alcoholism were significantly reduced since the implementation of acudetox treatments. In a period of 18 months, over 29,000 acupuncture treatments were provided.

43.3 Conclusion

Auricular acupuncture is a very effective adjunctive form of addiction treatment. This is evident in the large number of anecdotal reports from both clinicians and patients that attest to its effectiveness. What makes it even more attractive as a form of treatment is its low risk of side effects and low cost. Since the beginning of the new millennium, in the age of evidenced-based medicine, the use of this modality has increased significantly worldwide, despite the lack of a large amount of randomized controlled trials indicating its efficacy.

Transcraneal Magnetic Stimulation (TMS) as Treatment for Substance Addiction

44

David A. Gorelick

Contents

Abstract

Transcranial magnetic stimulation (TMS) is a rapidly developing noninvasive physical approach to psychiatric treatment, including substance use disorders. It involves projecting a fluctuating magnetic field (magnetic pulses), usually repetitively (rTMS), through the skull into the brain, which generates electrical currents in brain tissue and, thus, modulates neuronal firing. TMS treatment of addiction is still in an early stage and must be considered experimental. The mechanism of TMS therapeutic action in addiction is not definitively established, but may include modulation of neurotransmitter activity (especially dopamine and glutamate) in brain regions mediating addiction, such as the dorsolateral prefrontal cortex (Hayashi et al. Proc Natl Acad Sci USA 110:4422–4427, 2013), and disruption of cue-induced drug craving. Most, but not all, studies found reduced drug craving in the active TMS group vs. the sham group. TMS does appear well tolerated by individuals with addiction; there are no reported serious or unexpected adverse events. Research is being conducted to evaluate the safety and efficacy of this novel intervention.

44.1 Introduction

Transcranial magnetic stimulation (TMS) is a rapidly developing noninvasive physical approach to psychiatric treatment which involves projecting a fluctuating magnetic field (magnetic pulses), usually repetitively (rTMS), through the skull into the brain (Kluger and Triggs 2007; Rossini and Rossi 2007). This generates electrical currents in brain tissue (via electromagnetic induction) which modulate neuronal firing. In general, low-frequency ($\leq$1 Hz) TMS inhibits neuronal activity, while higher-frequency TMS stimulates activity, although exceptions have been noted. Because of synaptic connections, there are distal effects (both cortical and subcortical, ipsilateral and contralateral) on neural activity (Bestmann et al. 2008; Denslow et al. 2005; Li et al. 2004; Paus et al. 2001), regional cerebral blood flow (Speer et al. 2003), and neurotransmitter activity (Cho and Strafella 2009). TMS can be thought of as targeting brain circuits, rather than specific brain chemicals (e.g., neurotransmitters). Because it is applied directly to the brain, it may be better tolerated than systemic medications by some patients, e.g., pregnant women, the elderly, or those with severe medical conditions such as heart disease. rTMS is being studied as treatment for a wide variety of psychiatric disorders (Fitzgerald 2011; Kammer and Spitzer 2012), including depression, schizophrenia, bipolar disorder, obsessive-compulsive disorder, post-traumatic stress disorder, and autism, and is already approved by many national regulatory authorities as treatment for major depressive disorder.

44.2 TMS Treatment of Addiction

TMS treatment of addiction is still in an early stage and must be considered experimental (Bellamoli et al. 2013). There are only about a dozen human studies in the published literature, all dealing with nicotine (tobacco) (Table 44.1), cocaine (Table 44.2), or alcohol (Table 44.3) use disorders. A majority are single-session experimental laboratory studies and appear well designed (e.g., using single- or double-blind sham TMS), but only three measured actual drug use in addition to drug craving. Only two studies (both with nicotine addiction) are outpatient-controlled clinical trials, the longest of 4-week duration. All but two studies targeted TMS pulses to the dorsolateral prefrontal cortex (DLPFC), a brain region considered important in mediating addiction which is also targeted in depression treatment. All but three studies used high-frequency (5–20 Hz) rTMS, which is considered to stimulate neuronal activity.

Most, but not all, studies found reduced drug craving in the active TMS group vs. the sham group. However, there are too few studies and substantial heterogeneity in study characteristics (except for the target brain region, which is almost always the DLPFC), making it difficult to definitively identify common factors associated with a beneficial treatment response. For example, the optimal TMS characteristics (e.g., frequency, number of pulses), duration of treatment, and combination with other smoking cessation treatments (medication and

psychosocial) remain unknown. Thus, no particular TMS application can be recommended for addiction treatment at this time. TMS does appear well tolerated by individuals with addiction; there are no reported serious or unexpected adverse events.

The mechanism of TMS therapeutic action in addiction is not definitively established, but may include modulation of neurotransmitter activity (especially dopamine and glutamate) in brain regions mediating addiction, such as the dorsolateral prefrontal cortex (Hayashi et al. 2013), and disruption of cue-induced drug craving.

44.2.1 rTMS and Nicotine (Tobacco) Addiction

We identified five published studies using rTMS to treat nicotine addiction (Table 44.1), including two which were double-blind, sham-controlled clinical trials with nicotine-dependent outpatients (Amiaz et al. 2009; Wing et al. 2012).

Table 44.2 Studies of rTMS and cocaine craving

[a]Deep (H) coil generating bilateral TMS pulses
[b]Comorbid dysthymic disorder, treated with antidepressants and anxiolytics

Both trials applied high-frequency rTMS pulses (10 or 20 Hz, respectively) to the DLPFC (either left or bilaterally) for multiple daily sessions (2 or 4 weeks). In the first trial, active rTMS (compared to sham) significantly reduced both cue-induced craving and cigarette smoking (Amiaz et al. 2009). In the second trial, involving participants with comorbid schizophrenia, active rTMS significantly reduced spontaneous craving only during the first (of four) week of treatment, with

no effect on cigarette smoking (Wing et al. 2012). Thus, the effectiveness of TMS for smoking cessation in a realistic clinical setting remains uncertain.

44.2.2 rTMS and Cocaine Addiction

We identified two published and one unpublished study using rTMS to treat cocaine addiction (Table 44.2), including one small, open-label outpatient trial (Politi et al. 2008) and one double-blind, sham-controlled outpatient clinical trial (Ribeiro et al. 2013). Both trials applied high-frequency rTMS pulses (10 or 20 Hz, respectively) to the left DLPFC for multiple daily sessions (2 or 4 weeks). Both trials reported significantly decreased spontaneous craving – developing only in the second week of treatment in the open-label trial and linearly over time in the controlled clinical trial. The controlled clinical trial also reported significantly decreased cocaine use, verified by urine drug testing (drug use wasn't reported by the open-label trial). Thus, there is limited clinical trial evidence that at least one week of high-frequency TMS applied to the left DLPFC reduces cocaine craving and use.

44.2.3 rTMS and Alcohol Addiction

We identified six published studies using rTMS to treat alcohol addiction (Table 44.3), including one single-blind, sham-controlled trial involving inpatients no longer in severe acute withdrawal (Mishra et al. 2010). That trial reported significantly decreased spontaneous craving after ten sessions of high-frequency (10 Hz) rTMS applied to the right DLPFC.

44.3 Conclusion

High-frequency (5–10 Hz) rTMS applied to the DLPFC is a noninvasive physical approach to addiction treatment that has seen limited evaluation in controlled clinical trials for nicotine, cocaine, and alcohol addiction and is not approved for this indication by any national regulatory authority. Two outpatient-controlled clinical trials in nicotine addiction gave conflicting results, with the negative trial involving outpatients with comorbid schizophrenia. Two outpatient clinical trials (one open-label) in cocaine addiction both found decreased craving, with the controlled trial (unpublished) also reporting decreased cocaine use. One inpatient controlled clinical trial in alcohol addiction reported decreased craving. In summary, the clinical trial evidence supporting rTMS as treatment for addiction is very limited. Therefore, while rTMS is well tolerated, it cannot be recommended at this time as a first-line treatment for addiction.

Nutrients, Phytomedicines, and Mind-Body Treatments for Substance Abuse

45

Richard P. Brown and Patricia L. Gerbarg

Contents

Abstract

Substance abuse programs continue to search for nonpharmacological treatments to assist patients during withdrawal and for relapse prevention. The craving, dysphoria, insomnia, and discomfort that drive addictions cannot be adequately treated with pharmacological agents which may be addictive or contraindicated due to comorbid conditions. The treatment of addictions is often complicated by physical pain; poor nutrition; emotional disorders such as depression, anxiety disorders, and posttraumatic stress disorder; and medical problems such as traumatic brain injury, neurological deterioration, lung disease, liver disease, and HIV. Nutrients, herbs, and mind-body practices that ameliorate physical and psychological aspects of addiction as well as its medical complications are gaining acceptance commensurate with their growing evidence base.

45.1 Introduction

Nutrients, including vitamins, minerals, omega-3 fatty acids, and metabolites, can be beneficial in the treatment of substance abuse and its many comorbidities. Among the advantages of using nutrients, herbs, and mind-body practices are the following: little or no risk for dependence or withdrawal symptoms; fewer and less severe side effects than most prescription drugs; beneficial effects on comorbid conditions; and less risk of exacerbating abuse-related disorders such as alcoholic cirrhosis, hepatitis, or HIV. Furthermore, vitamins and nootropics (cognitive enhancers) may improve brain functions that have been compromised by substance abuse, poor nutrition, and traumatic brain injuries. Nutrients also have a role in the prevention and treatment of fetal alcohol syndrome. Dysphoria, anxiety, depression, and anger are major factors that contribute to substance abuse. Certain mind-body practices can rapidly reduce the effects of such negative emotions, improve emotion regulation, and provide new tools for dealing with stress.

This chapter focuses on treatments supported by an evidence base and by plausible physiological mechanisms of action. The relatively small scale of research on many natural treatments reflects the imbalance of funding and the difficulty of patenting natural products. In contrast, patentable, synthetic pharmaceuticals can be sold at a large profit to offset the costs of high-quality research. Taking into consideration that the playing field for research is far from level and that nutrients, herbs, and mind-body treatments tend to have fewer side effects, the evidential threshold for trying natural treatments could be lowered, particularly for patients who do not respond well or who are unable to tolerate standard treatments.

The same principles used in treatment with prescription medications apply to the use of nutrients and phytomedicines. Documentation of physician-patient discussion of risks, benefits, and the pros and cons of both standard and alternative approaches is advisable (Brown et al. 2009). The risk of adverse effects can be minimized by starting with lower doses in patients who are elderly, frail, or sensitive to medications and monitoring for side effects while increasing doses over a period of days to weeks, depending on tolerance. Herbs and nutrients can be strategically combined for synergistic effects.

45.2 Nutrients, Phytomedicines, and Mind-Body Treatments

45.2.1 Nutrients

Vitamins, minerals, fatty acids, amino acids, and metabolites have been shown to be beneficial in all phases of substance abuse treatment. In addition to reducing craving and relapse, many supplements prevent or ameliorate adverse effects of drinking on the liver, brain, and other organ systems. Vitamin B12 and folate are important for the antidepressant effects of *S*-adenosylmethionine (SAMe) and prescription medications (see below). Vitamin B6 is essential for SAMe hepatoprotection.

45.2.1.1 Vitamin B1 (Thiamine)

Vitamin B1 (thiamine) supplementation has become a standard complementary treatment for neurological sequelae, including Korsakoff psychosis, polyneuropathy, and myopathy, associated with thiamine deficiency in chronic alcohol abusers. In therapeutic doses, B vitamins rarely cause adverse reactions. A combination of B6 and B12 vitamins and folate reduces homocysteine levels (elevated homocysteine correlates with increased risk of cardiovascular disease) but may slightly increase the risk of restenosis of cardiac stents in men only whose baseline homocysteine level is less than 15 μmol/l (Lange et al. 2004).

45.2.1.2 Magnesium

Acute alcohol administration can cause sudden severe vasoconstriction and decreased cerebral blood flow. Alcohol use, particularly "binge drinking," is associated with headaches, strokes, sudden death, and worse outcomes in patients with brain injury. Low levels of intracellular and extracellular magnesium modulate a cascade of events involved in cerebrovascular constriction. In animal studies, magnesium infusion attenuated alcohol-induced vasoconstriction. In humans, intravenous magnesium sulfate relieved alcohol-associated headaches (Altura and Altura 1999; Barbour et al. 2002).

In a 12-week randomized controlled trial (RCT), magnesium-l-aspartate 723 mg/day given to heroin addicts undergoing treatment with methadone decreased the percentage of positive urinary tests and the rate of relapse to heroin use during methadone maintenance. Preclinical in vitro and animal studies point to a role for Mg^{2+} in reducing the intensity of dependence on nicotine, cocaine, amphetamine, ethanol, and other drugs. Magnesium has moderate stimulative effects on the reward system and reinforcement without causing dependence (Nechifor 2008). It is thought to reduce caffeine and nicotine dependence by release of dopamine and glutamate. A 4-week RCT found that magnesium enabled heavy smokers to reduce the number of cigarettes smoked per day (Nechifor et al. 2004). Cocaine-dependent patients given mg-L-aspartate 732 mg/day in a 12-week RCT showed decreased cocaine craving and cocaine use (Margolin et al. 2003).

45.2.1.3 Taurine and Acamprosate

Taurine, an amino acid and antioxidant, prevented toxic damage to the liver during alcohol withdrawal in rats by reducing acetaldehyde levels (Watanabe et al. 1985). Supplementation with taurine 1–4 gm/day reduced alcohol withdrawal symptoms better than placebo in an RCT study of 60 patients (Ikeda 1977). Taurine has also been used to reduce alcohol craving. Acamprosate, a medication derived from taurine, is more effective than taurine for reducing alcohol craving in clinical practice. For this reason and because medical insurance will cover the cost of acamprosate, few patients will require taurine.

45.2.1.4 Acetyl-L-Carnitine (ALCAR)

Alcohol abuse is associated with low serum carnitine levels. Abstinent alcoholics treated with acetyl-L-carnitine (ALCAR) 2,000 mg/day for 3 months showed better

performance on neuropsychological testing than control subjects (Tempesta et al. 1990). Several rat studies have shown that ALCAR protects against alcohol-induced metabolic abnormalities, including glutathione (major antioxidant) depletion (Calabrese et al. 2000, 2002). Acetyl-L-carnitine may have a role in the prevention and treatment of cognitive deficits associated with alcohol abuse. One rodent study found that ALCAR protected against tremor during alcohol withdrawal and reduced alcohol consumption (Mangano et al. 2000).

45.2.1.5 *N*-Acetylcysteine

Animal studies have indicated that *N*-acetylcysteine (NAC) inhibits cocaine-seeking behavior. In a double-blind randomized placebo-controlled (DBRPC) cross-over trial, 15 hospitalized nontreatment-seeking patients with cocaine dependence were given four doses of either NAC (600 mg) or placebo. In rating their responses to watching slides depicting cocaine and cocaine use, subjects reported less interest and less desire to use cocaine while they were taking NAC. This study suggests that NAC may reduce cocaine cue reactivity (LaRowe et al. 2007).

A 4-week open pilot study in 23 treatment-seeking cocaine-dependent patients tested NAC in doses of 1,200 mg/day, 2,400 mg/day, or 3,600 mg/day. The two higher doses of NAC were associated with better retention rates. A majority of the 16 subjects who completed the study either terminated use of cocaine completely or significantly reduced their use of cocaine during NAC treatment. All three doses were well tolerated. These findings support the value of further trials of NAC as an adjunct for treating individuals with cocaine dependence (Mardikian et al. 2007).

Reducing marijuana use may be more appealing to young adults than giving it up completely, as demonstrated in a pilot trial of NAC. Men (n=18) and women ($N = 6$) ages 18–21 years, who wanted to reduce marijuana smoking, but not stop it entirely, took NAC 1,200 mg b.i.d. for 4 weeks. The subjects reported significant reductions in three out of four domains on the Marijuana Craving Questionnaire. Semiquantitative urine cannabinoid levels did not change (Gray et al. 2010). In an 8-week DBRPC study of 15–21-year-old marijuana users, the treatment group received NAC 1,200 mg/day with a contingency management intervention and brief weekly cessation counseling. During treatment participants receiving NAC had more than twice the odds of having negative urine cannabinoid tests compared to the placebo group (odds ratio = 2.4, 95 % CI = 1.1–5.2) (Gray et al. 2012).

45.2.1.6 Omega-3 Fatty Acids from Fish Oils

Ethanol (alcohol) reduces n-3 PUFAs (polyunsaturated fatty acids) in nerve cell membranes and depletes the liver of these essential fatty acids. Low n-3 PUFA levels have been associated with anxiety, depression, and cognitive dysfunction. In a DBRPC 3-month study of substance abusers with anxiety, 13 patients were given 3,000 mg/day of fish oils versus 11 patients given placebo. Those taking capsules containing 3 g of n-3 PUFAS (eicosapentaenoic acid + docosahexaenoic acid) showed a significant progressive decrease in anxiety compared to those given placebo ($p = 0.01$). The decrease in anxiety scores remained significantly lower in the n-3 PUFA treatment group versus placebo at 3- and 6-month follow-ups

(Buydens-Branchey and Branchey 2006). Considering the known health benefits of omega-3 fatty acids, one could recommend their use while waiting for further studies to validate these encouraging results.

45.2.1.7 *S*-Adenosylmethionine

S-adenosylmethionine (SAMe) has significant potential as a valuable treatment for all stages of alcoholism because it has both antidepressant and hepatoprotective effects. Many alcoholics suffer from depression. SAMe is as effective as prescription antidepressants, but it has fewer side effects. Unlike prescription drugs, it does not burden liver metabolic systems and does not cause liver enzyme elevations (a common side effect of SSRI's). SAMe has been shown to improve liver function and to reduce alcohol-induced liver toxicity through several mechanisms. First, SAMe reduces serum alcohol levels, but does not increase serum acetaldehyde levels. Second, SAMe protects liver mitochondria from damage by alcohol (Lieber 2002). Third, SAMe maintains supplies of the body's primary antioxidant, glutathione. The US Department of Health and Human Services Research and Quality Assessment report (AHRQ 2007) concluded that SAMe was as effective as prescription antidepressants but with fewer side effects and that it improved indicators of hepatic dysfunction (for reviews of SAMe, see Brown et al. 2002; Bottiglieri 2002, 2013).

SAMe, Folate, and B12: Metabolic Pathways

S-adenosylmethionine (SAMe) is produced primarily in the liver and secondarily in the brain by the condensation of methionine and adenosyl triphosphate (ATP), catalyzed by the enzyme methionine methyltransferase (MAT). Methyltransferase enzymes catalyze methylation, the process in which SAMe avidly donates methyl groups to DNA bases, proteins, phospholipids, neurotransmitters (serotonin, norepinephrine, and dopamine), and many other cellular components. It also donates sulfate groups, for example, in the synthesis of glutathione, the primary endogenous antioxidant. Methylation controls gene expression, turning "on" or "off" transcription of proteins; posttranslation modifications of proteins that affect enzyme activity; the ability of phospholipids to maintain cell membrane integrity; and the functioning of receptors in the lipid membrane bilayer (Bottiglieri 2013).

Methylation by SAMe for production of major neurotransmitters involved in mood regulation requires cofactors B_{12} (methylcobalamin) and folate. Low levels of these cofactors are associated with severe depression. The antidepressant effect of SAMe and other antidepressant medications is often enhanced by adding 1,000 mcg/day B_{12}, 800–1,000 mcg/day folate, and 50–100 mg/day B_6.

Effects of Alcohol on Hepatic Functions and Levels of SAMe and Glutathione

- Decreased SAMe content has been found in liver biopsies from cirrhotic patients.
- Hepatic SAMe deficiency is the result of the loss of MAT activity.
- Ethanol (alcohol) consumption decreases SAMe synthesis, intracellular SAMe levels, and the enzymatic activity of MAT II (Halsted 2013; Halsted and Medici 2012).

- SAMe blocks CYP2E1 effects on alcohol oxidation and the associated increase in reactive oxygen species (ROS).
- SAMe prevents alcohol upregulation of Toll-like receptor (TLR) signaling pathways that mediate proinflammatory response, fibrogenesis, and carcinogenesis in alcoholic liver disease (ALD) and other chronic liver diseases in animal models (Oliva et al. 2011).

The mechanisms of SAMe hepatoprotection against injury by alcohol and CYP2E1 have been reviewed (Cederbaum 2010). Dehydrogenase oxidizes most of the alcohol that is ingested, but at elevated ethanol concentrations and with chronic consumption, CYP2E1 has a greater role in oxidizing ethanol and generates acetaldehyde and hepatotoxic ROS. SAMe is a reversible, noncompetitive inhibitor of the catalytic effect of CYP2E1 on ethanol oxidation. Thus, SAMe blocks CYP2E1 oxidation of alcohol, reducing production of ROS that damage mitochondria and membranes.

Chronic alcohol consumption by baboons for 18–36 months significantly depleted hepatic SAMe and glutathione and increased circulating levels of the mitochondrial enzyme glutamic dehydrogenase. SAMe attenuated the ethanol-induced increase in plasma glutamic dehydrogenase and was associated with a decrease in the number of giant mitochondria (Lieber et al. 1990).

In a 30-day DBRPC study of 64 subjects with at least a 6-year history of alcohol abuse, those given SAMe 200 mg IM/day (equivalent to 400 mg p.o.) showed significant improvements in anxiety, depression, liver function tests, fatigue, anorexia, insomnia, nausea/vomiting, treatment compliance, and abstinence compared to placebo. The group given SAMe had lower gamma-GT levels and lower serum alcohol levels compared to no change in the placebo group (Cibin et al. 1988).

A review of 17 clinical studies (Osman et al. 1993) found that SAMe improved biochemical markers (e.g., serum bilirubin, liver enzymes, cysteine, taurine, and hepatic glutathione) and symptoms (e.g., pruritus, fatigue, and jaundice) of liver disease regardless of etiology (alcoholic, nonalcoholic, infectious hepatitis, cirrhosis, cholestasis, metabolic disorders, and hepatotoxicities).

Mato and colleagues (Mato et al. 1999) conducted a 2-year DBRPC study of 123 patients with alcohol-induced liver cirrhosis reporting that patients with Child-Pugh class A or B given oral pharmaceutical-grade SAMe (AdoMet) 1,200 mg/day for at least 1 year had a mortality/liver transplantation rate of 12 % versus 29 % ($p = 0.025$) in the placebo group. At 2-year follow-up, the SAMe group continued to have lower mortality/liver transplantation rates ($p = 0.046$). In Child-Pugh C, the more severe cases, there was a trend toward reduced mortality/liver transplantation that did not reach significance. These results indicate that long-term treatment with SAMe may improve survival or delay liver transplantation in patients with alcoholic liver cirrhosis, especially in those with less advanced liver disease.

In contrast, a 24-week DBRPC study of SAMe treatment in 37 outpatients with alcoholic liver disease (ALD) included baseline liver biopsies in 24 subjects. The group given 400 mg t.i.d. of SAMe (SD4 by Abbot Laboratories) found SAMe to be no more effective than placebo in reducing liver function tests (LFTs) or fibrosis on

liver biopsy (Medici et al. 2011). The authors acknowledged that the absence of SAMe effects observed in this study may be due in part to the following limitations. The small number of completers, 13 in each group, was marginally adequate to detect meaningful effects. The number of posttreatment biopsies was even smaller (n=14). Although an attempt was made to exclude patients with severe ALD, the biopsies showed a high level of fibrosis. The authors noted that this would result in a smaller number of potentially responsive hepatocytes. Therefore, the effectiveness of SAMe would depend upon its transport, retention, and metabolism by damaged hepatocytes. Furthermore, glutathione production requires vitamin B6. The ALD subjects had subnormal B6 levels throughout the study which were not corrected. Moreover, sobriety was not guaranteed in outpatients. Subjects admitted relapse to drinking, and those whose drinking exceeded the protocol limit were dropped from the study. The reported alcohol abuse and the possibility of unreported drinking would reduce the effectiveness of SAMe and the validity of the findings. Finally, the short duration of this study, 24 weeks, may not have allowed sufficient time for SAMe benefits in patients with fibrosis of ALD. The study by Mato and colleagues (Mato et al. 1999) reported significant results after 1 year of SAMe treatment for alcoholic liver cirrhosis.

A review of 8 RCTs of ALD did not find sufficient evidence to support or refute treatment with SAMe (Rambaldi and Gluud 2006). Overall, the evidence suggests that SAMe is beneficial to liver function and repair but that in more severe cases, it requires augmentation for effectiveness. One of the weaknesses of research is the predominance of single-agent trials even when it is known that essential cofactors are deficient, for example, low B6 levels. Liver protection and repair require the rehabilitation of multiple metabolic pathways and cellular structures. Expecting a robust response to SAMe monotherapy in patients with serious ALD may be unrealistic. Further SAMe research on hepatic diseases should include more complex regimens (see below). Current treatments for ALD are quite limited, and the morbidity, mortality, and costs of hepatic disease are high. In this context, clinicians can offer patients with ALD low-risk treatments that will improve their chances for recovery by using higher doses of SAMe as the treatment foundation. The benefits of SAMe can be augmented with vitamin B6 and the nutrients and herbs discussed below.

Augmenting SAMe for the Treatment of Substance Abuse and Hepatic Dysfunction Using Dilinoleoylphosphatidylcholine, B6, and Bupleurum

Dilinoleoylphosphatidylcholine (PLPC), a polyunsaturated phospholipid, is the active antioxidant constituent of polyenylphosphatidylcholine (PPC). PLPC attenuates early effects of alcohol toxicity, partly by reducing mitochondrial injury. These benefits at the initial stages of alcoholic liver injury may prevent or delay progression to more severe forms of ALD. In alcohol-fed rats, chronic administration of a soybean-derived PLPC prevented development of cirrhosis, ethanol-induced fatty liver, and hyperlipidemia (Navder et al. 1997). Also, PLPC prevented alcohol-induced fibrosis in baboons and opposed the associated oxidative stress. Studies showed that the combination of SAMe with dilinoleoylphosphatidylcholine (PLPC)

had antifibrinogenic effects in hepatic stellate cells, effects that could be explained by the inhibition of collagen-producing mRNA and other mechanisms. In addition, SAMe blocked the generation of H_2O_2 (free radical) and restored the reduced glutathione (GSH) levels (Cao et al. 2006).

To date, no clinical trials of SAMe with PLPC augmentation have been published. In clinical practice, one of the authors (RB) finds that the addition of PLPC and Chinese herbal combinations containing Bupleurum (see below) to higher doses of SAMe (1,200–2,400 mg/day) substantially increases the benefits of SAMe in the treatment of patients with mild to severe alcohol-induced liver disease. Correction of subnormal B6 levels is also important. In future studies of patients with alcohol-related hepatic dysfunction, including fibrosis, it would be worthwhile to supplement SAMe with PLPC, B6, and Bupleurum-containing preparations.

45.2.1.8 SAMe Treatment During Pregnancy

Treating women for substance abuse-related problems during pregnancy is a challenging problem. Depression, cholestasis of pregnancy, hepatitis, and other hepatic dysfunctions are not uncommon among substance abusers. SAMe has been the standard treatment for cholestasis of pregnancy in Italy for over 20 years. Eight studies showed SAMe to be safe and effective for relief of pruritus and for reducing elevated serum bilirubin levels associated with cholestasis of pregnancy. None of the eight clinical trials reported adverse effects on mothers or children during or after they were treated with SAMe. In an RCT of pregnant women with chronic hepatitis B and elevated liver function tests (LFTs), SAMe improved liver functions in 21 % of 18 subjects. At birth and 1-year follow-up, all of the children were physically normal (Sun et al. 2010).

SAMe in the Treatment of Methamphetamine Abuse

Methamphetamine reduces dopamine and SAMe levels contributing to damage to brain functions (Cooney et al. 1998). Improvements in depression and extrapyramidal symptoms in patients with Parkinson's disease treated with SAMe suggest that SAMe may improve dopaminergic function (Di Rocco et al. 2000; Brown et al. 2009). Dr. Richard Brown has observed anecdotally that SAMe accelerated recovery in methamphetamine addicts (without bipolar disorder). Based on preclinical data, mechanisms of action, positive effects in Parkinson's disease, the low level of risk, and the known health benefits and limited standard treatment options, SAMe could be considered as an augmentation to the treatment of methamphetamine abuse.

SAMe Effects on Depression

In European countries, SAMe has been a first-line prescription antidepressant for over 25 years. The US Food and Drug Administration (FDA) approved SAMe as an over-the-counter nutraceutical in 1998 based on its very low profile of side effects. SAMe proved to be a safe and effective treatment for major depression in 16 open trials, 13 DBRPC studies, and 19 RCTs in comparison to standard antidepressants (Brown et al. 2002). SAMe protects the liver from toxic

effects of prescription drugs and does not have adverse interactions with medications (Torta et al. 1988).

SAMe has been shown to be useful as a monotherapy and as an adjunct to other antidepressants. An open trial of SAMe (800–1,600 mg/day) augmentation to antidepressant treatment for 30 depressed patients who had failed to respond to either SRIs or venlafaxine yielded a response rate of 50 % and a remission rate of 43 % (Alpert et al. 2004). In a 6-week DBRCT of 73 serotonin reuptake inhibitor (SRI) nonresponders with major depressive disorders, adjunctive SAMe (800 mg b.i.d.) significantly improved response rates and was well tolerated (Papakostas et al. 2010). The US Agency for Healthcare Research and Quality Assurance report based on a systematic review of SAMe research found no statistically significant difference in outcomes between patients treated with SAMe compared to prescription antidepressants, but SAMe caused fewer side effects (AHRQ 2007).

In an 8-week DBRPC study of 18 schizophrenic patients, oral SAMe (800 mg/day) significantly improved depression and ameliorated aggressive symptoms (Strous et al. 2009). Oral SAMe treatment for 8 weeks also significantly reduced depressive symptoms in 20 HIV-seropositive patients with a history of drug abuse and a diagnosis of major depressive disorder (Shippy et al. 2004). The evidence for antidepressant effects of SAMe is compelling (Brown et al. 2009; Bottiglieri 2013). Considerable evidence indicates hepatoprotective effects. Although the one small recent study cited above did not corroborate hepatoprotection, this may have been due to the short term of treatment, low B6 levels, patient selection, or the lack of SAMe augmentation. At the very least, SAMe does no harm to the liver and, in that regard, is superior to other antidepressants. Although further studies of oral SAMe in the treatment of alcoholism are needed, the evidence base is sufficient to justify its use treating depression, anxiety, and hepatic dysfunction in alcoholics.

SAMe and Immune Function

Substance abusers are at risk for compromised immune function due to poor nutrition, self-neglect, infections from needles, lung damage from smoking, and sexual indiscretions.

SAMe is vital for the activation and proliferation of T helper CD4(+) lymphocytes. MAT II catalyzes the synthesis of SAMe from methionine and ATP. Ethanol impairs immune function by decreasing MAT II and SAMe (Hote et al. 2008). The reduction in SAMe and MAT II may have additional adverse effects on mood and cognitive function. Supplementation with oral SAMe can reverse these deficits.

Safety of SAMe and SAMe Side Effects, Risks, and Benefits

Compared to prescription antidepressants, SAMe has a low side effect profile. It does not cause any weight gain or sexual dysfunction. The most common side effects of SAMe are nausea and loose bowels, which usually do not require discontinuation. Less common are vomiting, abdominal discomfort, overactivation, and rarely anxiety, agitation, or insomnia. As with most antidepressants, the induction of manic symptoms is a serious risk. SAMe is the only antidepressant demonstrated to be safe in patients concurrently taking MAO inhibitors (n=60) and

in alcoholics taking antidepressants or anticonvulsants (n=18). Not only were there no adverse reactions, but SAMe also reversed or prevented liver toxicity and normalized elevated gamma-glutamyl transpeptidase (GGT) in all patients taking MAOIs, anticonvulsants, or antidepressants (Torta et al. 1988).

SAMe Product Quality

Each SAMe tablet must be kept in an individual blister pack to prevent the rapid oxidation from exposure to air that would occur in bottled products. In addition, tablets must be carefully manufactured and enterically coated to delay metabolism by digestive enzymes. Inactive SAMe isomers have been found in bargain brands marketed on the web. Therefore, it is strongly recommended that patients use only pharmaceutical-grade SAMe in products that have been tested for efficacy and shelf life (effects of time on potency) (Brown et al. 2009).

45.2.2 Herbal Medicines

Phytomedicines have been used widely in the treatment of substance abuse to reduce craving, withdrawal symptoms, and hepatotoxic effects. Traditional use, animal studies, and clinical trials of mixed quality support the use of certain herbals and indicate a need for rigorous controlled trials to explore their potential efficacy. This section will focus on clinically useful herbal medicines with adequate levels of evidence for mechanisms of action, efficacy, and safety.

The following herbs reduced alcohol intake by rats bred to prefer alcohol but require more study in humans: Hypericum perferatum (St. John's Wort), *Salvia miltiorrhiza* (Red sage, Chinese sage), *Galanthus nivalis* (snow drop), *Trigonella* foenum-graecum (fenugreek).

Tabernanthe iboga (ibogaine) (see ▶ Chap. 42, "Evaluating the Therapeutic Utility of Hallucinogens for Substance Use Disorders"), *Hovenia dulcis* (raisin tree), and Asian, Chinese, and Ayurvedic herbal compounds. Although St. John's Wort (SJW) reduced alcohol craving in animal studies and has antidepressant effects, it can interfere with the metabolism of many drugs. Also SJW can cause photosensitivity and, at higher doses, side effects similar to sertraline. For a review that includes herbs supported only by preclinical studies or those that have potentially severe adverse effects, see Tomczyk et al. (2012).

45.2.2.1 Passionflower (*Passiflora incarnata*) and Lemon Balm (*Melissa officinalis*)

Passionflower extract was found to reduce tolerance and dependence on morphine, alcohol, diazepam, and delta-tetrahydrocannabinol in mouse studies (Dhawan et al. 2003). A DBRPC study of 65 opioid-dependent patients comparing clonidine augmented with passionflower versus clonidine plus placebo showed no difference in effects on withdrawal symptoms. Passionflower significantly accelerated the clonidine effects and reduced psychological symptoms of withdrawal (Akhondzadeh et al. 2001). Side effects are generally minimal at therapeutic doses but may include dizziness, confusion, ataxia, sedation, or prolonged QT intervals.

45.2.2.2 Kudzu (*Pueraria lobata*)

Kudzu root extract, containing active ingredients, diadzin, daidzein, and puerparin, was shown to reduce alcohol intake by rodents. In a small 1-month DBRPC study in veterans with alcoholism, kudzu showed no significantly greater effects on craving or sobriety compared to placebo (Shebek and Rindone 2000). In another DBRPC trial involving heavy drinkers, those taking kudzu significantly reduced the number of beers consumed and the volume of each sip (Lukas et al. 2005). Minimal side effects have been reported in studies of kudzu.

45.2.2.3 Herbs to Augment SAMe for the Prevention and Treatment of Hepatic Dysfunction

Bupleurum kaoi, *Bupleurum Chinense* (*Synonym Bupleurum Falcatum*), and *Bupleurum scorzonerifolfium*

In Asia, *Bupleurum kaoi* is widely used, often in multi-herbal products to treat liver diseases. Preclinical studies have demonstrated hepatoprotection against dimethylnitrosamine (DMN-induced fibrosis in rats). Various fractions of Bupleurum extracts demonstrated anti-inflammatory and antifibrotic action followed by increased glutathione production with antioxidant effects and decreased malondialdehyde (MDA), enhanced liver cell regeneration, and markedly increased interferon gamma. Hepatoprotective effects were higher in *Bupleurum kaoi* grown in Taiwan than in *Bupleurum chinense* from China (Yen et al. 2005). A combination of *Scutellaria baicalensis* and *Bupleurum scorzonerifolfium* induced interleukin-6-related signal transducer and activator of transcription 3 (STAT3) in rat liver after partial hepatectomy (Lee et al. 2011). Further studies are needed to determine whether these findings prove relevant to the regeneration of hepatocytes in humans.

In clinical practice, the authors (RB and PG) have found that multi-herbal preparations, Ease-2 and Ease Plus (Crane Herb) containing Bupleurum, reduce elevated LFTs in patients with mild liver disease. In more severe cases, Ease-2 or Ease Plus can be added to SAMe and other hepatoprotective herbs and nutrients.

Milk Thistle (*Silybum marianum*)

Antioxidant, antifibrotic, and hepatoprotective effects of milk thistle have been documented in many in vitro and animal studies. However, a review of 18 RCTs in patients with alcoholic and/or hepatitis B or C liver diseases noted that in the high-quality trials, milk thistle did not improve liver-related mortality or liver histology (Rambaldi et al. 2007).

Asian Ginseng (*Panax ginseng*) and American Ginseng (*Panax quinquefolius*)

Based on animal studies, *P. ginseng* may have a potential role in reducing dependence and tolerance for cocaine, amphetamines, and morphine. In animal studies, both Asian and American ginseng reduced blood alcohol levels by decreasing gastrointestinal absorption (Tomczyk et al. 2012). Clinical studies are needed to assess the potential benefits for treatment of alcohol intoxication syndrome.

In a multicenter RCT involving 212 heroin addicts, *P. ginseng* root extract containing ginsenosides was as effective as lofexidine in reducing symptoms of

withdrawal (Ward et al. 2011). *P. quinquefolius* contains an active ingredient called pseudoginsenoside F11 (PF11). In a DBRCT in 43 heroin addicts, a formula called WeiniCom or Xian Xu Qudu Jiaonang, containing *P. quinquefolius* and kratom, relieved opioid craving more quickly than buprenorphine and reduced withdrawal symptoms (Ward et al. 2011). Side effects of these herbal preparations were low compared to lofexidine.

Kratom (*Mitragynia speciosa korth*)

Kratom (*Mitragynia speciosa korth*) produces alkaloids (mitragines) only when it grows in Southeast Asia. Traditionally it has been used to treat opium withdrawal, cough, diarrhea, and musculoskeletal pain and to attain euphoria in higher doses. Mitragines bind to opium receptors. In animal studies, kratom led to tachyphylaxis and cross-tolerance with morphine. Kratom use was associated with tonic-clonic seizure in two cases, and long-term users have experienced anorexia, weight loss, constipation, and facial hyperpigmentation (Ward et al. 2011). Kratom is used in combination with other herbs, but to date there are no human studies published. Unfortunately, it is becoming a substance of abuse and has a mild abstinence syndrome similar to that of opioids. However, kratom does not cause respiratory depression and has fewer serious side effects than methadone. In areas where methadone maintenance programs are not readily available, such as in Asia, kratom may be a reasonable alternative that is less expensive and more culturally acceptable.

Mentat

Mentat is a traditional Ayurvedic formula containing ashwagandha (*Withania somnifera*), Bacopa (*Bacopa monnieri*), gotu kola (*Centella asiatica*), Indian Valerian (*Valeriana jatamansi*), Triphala churna, and other medicinal herbs. One small open series suggested it reduced relapse in abstinent alcoholics (Trivedi 1999). In animal studies, ashwagandha decreased opiate withdrawal symptoms (Kulkarni and Ninan 1997).

45.2.3 Mind-Body Practices in the Treatment of Substance Abuse

The desire to avoid or escape from negative thoughts, feelings, and painful sensations is a key factor in substance abuse and relapse. Difficulty regulating affects such as anxiety, fear, and anger is a common finding in substance abusers. Mind-body practices which are known to improve affect tolerance and affect regulation have the potential to help patients deal with difficult emotions without resorting to substance abuse. The treatment of addictions is often complicated by physical pain; emotional problems such as depression, anxiety disorders, and posttraumatic stress disorder; and medical conditions such as traumatic brain injury, neurological deterioration, lung disease, liver disease, and HIV. Studies indicate benefits of mind-body practices in recovery from substance abuse, anxiety, depression, physical injuries, and pain syndromes. Key neurophysiological mechanisms that underlie addictions are targeted by therapeutic mind-body practices.

Compounding the problem, chronic substance abuse compromises areas of the brain involved in affect regulation, attention, inhibitory control, and the ability to observe and moderate responses to intense emotions. Deficits in affect regulation increase vulnerability to relapse, particularly in early stages of recovery. Mind-body approaches can improve affect tolerance, affect regulation, and stress response during the withdrawal, early recovery, and maintenance phases of treatment.

In this discussion, the rubric, mind-body practices, encompasses all forms of yoga, qigong, zen, meditation, and breathing modalities. Although there are thousands of specific techniques, these practices share a few basic elements: movement, breathing, meditation, and often visualization. Traditional psychoanalysis, psychotherapy, and cognitive therapies support the observing ego and strive to reduce the judgmental activity of the archaic superego. Similarly, many Eastern practices cultivate detached nonjudgmental observation and letting go of thoughts, emotions, and sensations. During recovery, such practices may help put a distance between the impulse to take substances of abuse and the compulsion to act on the impulse. For example, dialectical behavior therapy (DBT) includes mindfulness and affect tolerance in the treatment of substance abuse (Dimeff and Linehan 2008). Following detoxification, patients continue to experience anxiety, depression, and often severe psychosocial and financial stress – conditions that promote relapse. Sedatives, anxiolytics, and some sedating antidepressants may be contraindicated due to high risks of abuse, dependence, overdose, or medical complications. Mind-body practices can be valuable, low-risk adjunctive treatments with standard rehabilitation, counseling, and self-help groups such as Alcoholics Anonymous and Narcotics Anonymous. Considering the complexity of substance abuse, a multimodal approach using compatible, synergistic treatments is likely to best serve the patient.

45.2.3.1 Neurophysiology of Mind-Body Practices and Substance Abuse

Evidence suggests that dysfunctions in higher regulatory centers, particularly the prefrontal cortex (PFC), and impaired inhibitory control are associated with substances of abuse. Mind-body practices may correct the disruptions in emotion regulatory systems and reward processing (Witkiewitz et al. 2012). Drawing from the literature on respiratory physiology, neuroanatomy, and brain imaging, Brown and Gerbarg (Brown and Gerbarg 2005) described a model for the neurophysiological effects of yoga breathing. The model was extended to include recent research on the inhibitory neurotransmitter, gamma-aminobutyric acid (GABA), and the hypothalamic-pituitary-adrenal (HPA) axis (Streeter et al. 2012). Briefly, it is hypothesized that changes in the pattern of breathing send different interoceptive messages through vagal afferents to influence brain structures involved in emotion regulation, stress response, mood, bonding, and cognitive function. These pathways project to the amygdala, hippocampus, hypothalamus, thalamus, prefrontal cortex, insular cortex, and the anterior cingulate. Evidence was provided that slow gentle breathing, particularly at rates between four and six breaths per minute with equal inspiration and expiration (coherent or resonant breathing) for most adults,

increases parasympathetic tone (as indicated by HF-HRV), reduces sympathetic arousal, optimally balances the stress response system, increases top-down GABA inhibitory activity from higher centers (prefrontal cortex and insular cortex) to the amygdala, and thereby improves emotional and behavioral control. Increased HF-HRV is associated with enhanced self-regulation.

Low levels of heart rate variability (HRV) are associated with anxiety, depression, and nicotine dependence (Libby et al. 2012). A study of 15-h abstinent smokers (n=32) exposed to script-driven imagery of stressful and relaxing scenarios assessed the ability to resist smoking, and subsequent ad-lib smoking was related to the vagal reactivity to stress (HF-HRV). Stress and ad-lib smoking additively decreased HF-HRV and increased LF/HF (increased sympathetic and decreased parasympathetic response). Blunted stress-induced HF-HRV responses reflecting decreased vagal reactivity were associated with less time to initiate smoking and increased craving relief and reinforcement from smoking. The findings that stress-precipitated decreased vagal reactivity predicts the ability to resist smoking suggest that interventions that normalize vagal reactivity in early abstinent smokers may improve smoking cessation outcomes (Ashare et al. 2012).

Heavy alcohol use as well as alcohol dependence has been associated with dysregulation of the hypothalamic-pituitary-adrenal axis and the autonomic nervous system. Alcohol abuse may contribute to vagal neuropathy. In a study of 70 chronic alcoholics, vagal neuropathy was reversed in most of those who were able to maintain abstinence from alcohol, (Villalta et al. 1989).

Heroin users show decreased cardiac vagal activity, and methadone therapy immediately facilitates vagal regulation in patients with a recent lapse (Chang et al. 2012). Methamphetamine has been associated with decreased HRV and impaired vagal function, which may be related to cardiotoxic or neurotoxic effects of prolonged methamphetamine use (Henry et al. 2012).

Slow yoga breath practices can improve emotion regulation and increase HRV (Gerbarg 2008; Brown and Gerbarg 2009). Breathing gently at a rate between four and six breaths per minute, found in most mind-body traditions, reduces anxiety within minutes. One factor that is often overlooked is that simply putting attention on one's breath can reduce the respiratory rate. During meditation, practitioners often breathe at three to six breaths per minute. Thus, it may not be possible to separate the effects of meditation from all the effects of slow breathing. Activation of the parasympathetic system is emotionally soothing; increases GABA, serotonin, and norepinephrine; enhances mood and bonding; and reduces pain.

Pain is an important cause of substance abuse. Many people who begin using alcohol or analgesics for pain control progress to dependence and abuse. Fear of pain or of being unable to sleep generates anxiety, further exacerbating the problem. Anxiety is a major factor in the subjective experience of pain. Mind-body techniques such as hypnosis, relaxation, yoga breathing, and guided meditation that alleviate anxiety have been used to reduce pain. An additional mechanism by which yoga breathing may reduce or block pain perception is through stimulation of the vagus nerve which is involved in nociception (discrimination of painful stimuli). The vagus also affects baroreceptors which modulate pain awareness. Slow yoga

breath practices (4.5–6 breaths per minute) such as coherent breathing, ujjayi (ocean breath), and alternate nostril breathing reduce anxiety and induce a state of calm alertness (Brown and Gerbarg 2009, 2012). Preliminary neurophysiological data are consistent with improvements in attention, cognitive integration, and learning.

45.2.3.2 Qigong in the Treatment of Substance Abuse

Qigong includes movement, breathing exercises, guided imagery, concentration, and meditation. Mind-body practices that integrate body, breath, mind and spirit into oneness from a Chinese perspective are forms of qigong, whereas from an Indian perspective, they are forms of yoga. The word *qi* or *chi* meaning breath of life or vital energy is similar in meaning to the Sanskrit word, *prana*. *Gong* means "the skill to work with." The awareness of *qi* sensations in the body is a prelude learning how to guide the flow of qi as a means of physical, mental, and spiritual healing. Qigong masters develop the ability to emit energy (external *qi*) from their hands. This energy, like an electric current, is used for healing.

Qigong in the Treatment of Opiate Withdrawal

Eighty-six male heroin addicts (DSM-IIIR) admitted for mandatory treatment to the Changzhou Drug Treatment Center in the People's Republic of China were assigned in the order of their admission to one of three treatment groups. One group practiced qigong (PanGu) together 2–2.5 h/day and was treated with emitted qi for 10–15 min/day by a qigong master. The second group was detoxified with tapering doses of lofexidine, physical exercise, and group counseling. The third group received only emergency care for acute pain, diarrhea, or insomnia (diazepam or methaqualone). After 1 day, the qigong group showed significantly lower mean scores on the Chinese Standard Evaluation Scale of Withdrawal Symptoms. All groups had comparable mean Hamilton Anxiety Scores (Ham-A) at baseline. By day 5, mean Ham-A declined from 37.4 ± 7.5 to 8.2 ± 4.9 in the qigong group, from 33.5 ± 8.5 to 13.6 ± 6.4 in the lofexidine group, and from 35.0 ± 4.7 to 21.3 ± 11.4 in the nontreatment group (Li et al. 2002). Although there are methodological limitations, this study suggests that qigong practices may ameliorate anxiety and reduce withdrawal symptoms during opiate withdrawal.

Qigong in the Treatment of Cocaine Craving

Cocaine-dependent subjects ($n=101$) were randomly assigned to either real external qigong therapy (EQT) or sham EQT for four to six sessions over 2 weeks. Cue-elicited craving and depression decreased significantly in the real EQT versus the sham control (Smelson et al. 2012).

Qigong in the Treatment of Drug Addiction

A study evaluating the acceptability, feasibility, and effects of qigong on a non-Chinese population in an American residential drug addiction treatment center allowed clients to choose to participate in either a twice-daily qigong meditation (breathing, relaxation, inward attention, guided imagery, and mindfulness) or the

stress management and relaxation training (SMART) for up to 4 weeks. Two-thirds opted to participate in qigong, and 248 completed questionnaires. Treatment completion rate was higher (92 % in the qigong group versus 72 % in the SMART group). Within the qigong group, those who were better meditators reported greater reductions in craving, anxiety, and withdrawal symptoms. Compared to men, women meditators reported the greatest improvements (Chen et al. 2010). Limitations of this study included non-randomization, self-selection, difficulties assessing quality of meditation, and lack of reporting on the specific drugs of addiction.

45.2.3.3 Yoga in the Treatment of Substance Abuse

Hatha Yoga in the Treatment of Opioid Addiction

In a 6-month RCT, 61 patients treated for opioid addiction in a methadone maintenance program received either conventional weekly group psychotherapy or a weekly hatha yoga group. No significant differences were found between the two groups on psychological, sociological, and biological measures after 6 months (Shaffer et al. 1997). Most studies of mind-body practices schedule between two and five sessions per week to achieve substantive change. This study suggests that once-a-week Hatha yoga was as effective as once-a-week group psychotherapy as an adjunct to methadone maintenance. A once-weekly mind-body intervention, particularly in individuals under stress of detoxification, would be analogous to a subtherapeutic dose of a medication. It would be worthwhile to evaluate the effects of more frequent yoga sessions with standard treatment for methadone maintenance.

Hatha Yoga in the Treatment of Cigarette Craving

A three-arm RCT compared the effects of cardiovascular exercise, hatha yoga, or inactive control in 76 smokers following 1 h of nicotine abstinence; participants in both active interventions reported reduced craving to smoke, increased positive affect, and decreased negative affect compared to control (Elibero et al. 2011).

45.2.3.4 Mind-Body Practices with Emphasis on Slow Breathing

A study in 16 healthy subjects demonstrated that slow deep breathing combined with relaxation significantly increased pain thresholds and significantly reduced sympathetic arousal (Busch et al. 2012). A 24-h RCT (n=96) assigned cigarette smokers to two groups. The first group was briefly instructed on yoga breathing exercises and asked to use them when cravings occurred until the next visit (YBG). The control group was shown a video of a breathing exercise and asked to just concentrate on their breathing (VCG). All measures of cigarette craving were significantly reduced in the YBG group compared with the VCG (Shahab et al. 2012).

45.2.3.5 Mind-Body Practices with Slow and Rapid Breathing

Sudarshan Kriya Yoga in the Treatment of Alcohol Detoxification

Following detoxification, 60 hospitalized alcohol-dependent patients were randomly assigned to either Sudarshan Kriya yoga (SKY) breathing or standard

treatment (counseling and benzodiazepine for sleep). The SKY intervention was breath practices for 45 min every other day. In the SKY group mean reductions in BDI scores and cortisol levels were greater than in the standard treatment controls (Vedamurthachar et al. 2006). This study suggests that SKY may reduce anxiety and cortisol levels in recently detoxed alcoholic patients. Methodological issues limit its impact.

Sudarshan Kriya Yoga (SKY) in the Treatment of Opioid Dependence

In a 2-week RCT, community clinic patients with opioid dependence (DSM-IV) on agonist maintenance were given either standard treatment (n=14) or standard treatment plus Nav-Chetna Shivir (n=15), a 5-day course comprised of 2–3 h per day of yoga breathing (SKY), meditation, singing, and discussions about healthy living. After 2 weeks, there was no significant difference between groups on Addiction Severity Index. However, the yoga augmented group showed significant improvements in motivation and on the WHO Quality of Life Brief Scale physical, psychological, and social relationship domains compared to no significant change in the control group (Yadav et al. 2006). The short duration and small sample size limit the conclusions that can be drawn from this study.

Kundalini Yoga in the Treatment of Substance Abusers

The breathing practices emphasized in kundalini yoga include particularly rapid (high frequency) and forceful patterns of breathing. In a psychiatric hospital in Amritsar, India, a 90-day residential treatment program of voluntarily admitted substance abusers (n=10) provided three to four mandatory kundalini yoga sessions per day (yoga postures, breathing, meditation, and mantra); individual, group, and family counseling; vegetarian diets; herbs; vitamins; cleansing spices; music and dance therapies; spiritual studies and Sikh religious practices; energy medicine/spiritual healing (Sat Nam Rasayan); acupuncture; videos; lectures on yoga lifestyle; massage; and psychoeducation. Questionnaires at baseline, mid-treatment, end treatment, and 1-month follow-up showed significant improvements in impulsive and addictive behaviors, daily living, depression, anxiety, and relationship to self and others. The scores on Perceived Stress Scale did not improve significantly (Khalsa et al. 2008). The authors acknowledge the limitations of this study, particularly the small size and the effects of translators on testing. Also, the 1-month follow-up does not provide assessment of the long-term effects of this very intensive, multi-model treatment. However, in areas where populations are interested in extended residential treatments that integrate mind-body, spiritual, physical, lifestyle, and psychotherapeutic modalities, such programs may be desirable.

Religious and spiritual programs have been widely used in the treatment of substance abuse. Yoga programs have been used in substance abuse treatment in India for many years (Nespor 2005). Much of this work is published in Indian language publications or in documents from Indian religious institutions. These studies may not meet modern methodological and reporting standards. Western readers may consider such studies to be biased. While we can continue to wonder to what extent the benefits of such programs are due to their spiritual, emotional,

philosophical, or physical practices, the controlled clinical studies beginning to appear and the neurophysiological studies of yoga practices may lead us to better understand the synergistic interplay of these important components.

45.2.3.6 Meditation, Mindfulness, and Cognitive Behavioral Therapy

In their discussion of Mindfulness-Based Relapse Prevention (MBRP), Witkiewitz and colleagues (Witkiewitz et al. 2012) hypothesize that intentional awareness, nonjudgment, and acceptance of all components of experience enable clients to interrupt the stimulus response cycle of addictive reactivity and to develop alternative responses. They review findings that MBRP reduces the subjective experience of craving, reactivity to cues, and the amount and frequency of substance abuse. In an fMRI study, 47 smokers who were abstinent for 12 h viewed neutral images and images of smoking. They were trained and instructed to view the images passively or with mindful attention. Compared to passive viewing, mindful attention reduced craving in response to smoking images and reduced activity in an area of the subgenual anterior cingulate cortex that is involved in craving (Westbrook et al. 2011).

Transcendental Meditation for Substance Abuse

Most studies of transcendental meditation (TM) for the treatment of substance abuse are of limited quality. In one study college students ($n = 295$) who used cigarettes ($n = 37$), illicit drugs ($n = 60$), or alcohol ($n = 217$) were randomly assigned to 3 months of either TM or a wait list control. No significant effect of TM on abuse of these substances was found. The only effect was a reduction in the drinks per week in men, but not women (Haaga et al. 2011).

45.2.3.7 Guilt, Shame, Anger, Regret, Helplessness, Motivation, and Meaning

Mind-body-spirit programs can improve emotion regulation, reduce physical symptoms of withdrawal, and enhance motivation and compliance. Many patients in recovery report that these programs help them resolve feelings about their past, such as guilt, shame, anger, and regret. They may also discover a new purpose and meaning in life. Having repeatedly experienced overwhelming failures and helplessness, substance abusers lose hope and consequently the motivation needed for recovery. Learning simple natural methods to reduce their feelings of fear and anxiety restores a measure of control, self-efficacy, and hope. Patients with substance abuse problems are usually willing to participate in mind-body-spirit practices when given the opportunity.

45.2.4 Fetal Alcohol Syndrome

Fetal alcohol spectrum disorders (FASD) due to brain damage from prenatal alcohol exposure include children with mental retardation, hyperactivity, behavioral and sexual disorders, and abnormal craniofacial development. Neurotoxicity

from alcohol is multifactorial: oxidative damage, mitochondrial damage, activation of caspase enzymes (leading to apoptosis, cell death), and depletion of ATP and essential fatty acids (Das et al. 2006; Das 2006). Cholinergic neurons in the hippocampus and cerebellum are particularly vulnerable to injury and apoptosis. The rising rate of alcohol abuse including during pregnancy is a major public health concern in many countries.

Studies of neuroprotective compounds in pregnant animals exposed to alcohol have found prevention and reduction in adverse effects on fetal development. Compounds found to be beneficial in treating human brain injury due to stroke, trauma, or substance abuse neurological sequelae may also improve brain function in children with FASD. Choline, vitamins A and D, folate, nicotinamide (an amide of vitamin B3), omega-3 fatty acids, piracetam, Mentat, antioxidants, silymarin bioflavonoid, and the flowers of kudzu (*Pueraria thunbergiana*) administered during pregnancy or in the postnatal period prevented some adverse effects of alcohol on animal neonates (Monk et al. 2012; Ballard et al. 2012; Ieraci and Herrera 2006; Wainwright et al. 1990; Horrocks and Yeo 1999; Bhattacharya 1994; Neese et al. 2004; Thomas et al. 2004). Mentat contains 24 Indian medicinal herbs including brahmi (Bacopa) and ashwagandha. In one study, Puerariaeflos, the flower of *Pueraria thunbergiana*, prevented increased caspase-3 mRNA expression and protected human neuroblastoma cells (SK-NMC) from ethanol-induced apoptosis and (Jang et al. 2001).

The safety and neurodevelopmental benefits of appropriate doses of vitamins A and D, folate, nicotinamide, and omega-3 fatty acids have been demonstrated in humans. In light of the depletion of essential fatty acids, the presence of nutritional deficiencies in many populations, and the devastating life-long consequences of FASD, supplementation with these and additional nutrients is advised. For a review of the benefits of supplementation during pregnancy and lactation, see Morse (2012). Clinical trials of nutritional supplements for the prevention and treatment of FASD during and after pregnancy are needed. Until such studies are completed, it is possible to administer safe treatments that have shown beneficial effects on neonatal brain development and in cases of brain injury, ADHD, learning disabilities, and FASD.

Anecdotally, in a rural mental health clinic, Dr. Richard Brown has use cholinergic agents to treat adolescent and adult FASD patients for cognitive and behavioral symptoms. Damage to the hippocampus and cholinergic function are prominent features of FASD. Donepezil (Aricept) has been shown to improve cholinergic function and hippocampal gating in military veterans with traumatic brain injury (Silver et al. 2005). Disruption of cholinergic function in the hippocampus impairs auditory sensory gating, attention, and memory (Arciniegas 2003). Brown found that administration of donepezil to patients with FASD improved cognitive function and that benefits took at least 3 months as evidenced by reduction in hyperactivity, better attention and impulse control, and greater capacity to engage in vocational rehabilitation. Preadolescent children may become overstimulated by donepezil. However, the use of milder cholinergic enhancers such as centrophenoxine, huperzine A, and CDP-choline for children with FASD warrants research.

45.2.5 Integrative Approaches to the Treatment of Substance Abuse Disorders

Understanding the modes of action, the evidence base, and the high safety profile of the approaches described above will enable clinicians and researchers to judiciously integrate phytomedicines and mind-body practices with standard treatments for optimal patient outcomes. Here is a sample of an integrative plan for treatment of substance abuse.

Integrative Plan for Treatment of Substance Abuse

1. Correct nutritional imbalances: thiamine (B1), folate, B vitamin complex, and an A–Z multivitamin. Brewer's yeast in two rounded tbsps twice a day (Lewis Labs) is an inexpensive source of B vitamins and trace minerals.
2. For neuroprotection: 3,000–6,000 mg/day fish oils (omega-3 fatty acids) (eicosapentaenoic acid + docosahexaenoic), 600–800 mg/day magnesium, 1,800 mg b.i.d. *N*-acetylcysteine (NAC), and 1,000–3,000 mg/day acetyl-L-carnitine.
3. Refer to self-help support groups: Alcoholics Anonymous, Adult Children of Alcoholics, and Al-Anon.
4. Prescription medications as appropriate:
   a. Naltrexone, acamprosate, or both for alcohol dependence
   b. Topiramate 200–400 mg/day or isradipine to reduce craving for alcohol, cocaine, and other drugs
   c. Valproate for bipolar patients who abuse alcohol or marijuana
5. Evaluation for possible ADD/ADHD. In such cases, stimulants may reduce drug dependence.
6. Mind-body-spirit practices such as yoga, qigong, vipassana meditation, MBRP or mindfulness meditation with CBT, MBSR, a DBT.
7. SAMe to improve mood, liver function, immune function, for neuroprotection, and to help reduce alcohol intake. To enhance hepatoprotective effects of SAMe: B6, polyenophosphatidylcholine, betaine, and *Bupleurum*. SAMe is contraindicated in bipolar patients.
8. Formulation of the treatment plan: Discussion with the patient about the treatment options and prioritizing of the target symptoms. Documentation of this discussion in the medical record.
9. Assessment of the feasibility of doing the intervention, taking into account patient motivation, costs, and likelihood of compliance.
10. Time Frame and Treatment Phase
    a. The first 2 weeks: detoxification, physical stabilization, and engagement in treatment. Initiate nutrients, herbs, and slow breathing practices to correct nutritional deficiencies and reduce anxiety, insomnia, withdrawal symptoms, and pain. Cranial electrotherapy stimulation (CES) can help to relieve anxiety, agitation, insomnia, and pain (Kirsch and Nichols 2013).
    b. The first 3 months: relapse prevention and keeping the patient in treatment. Continue nutrients, herbs, and mind-body practices to reduce dysphoria and

craving. Mind-body practices also facilitate progress in individual and group psychotherapy and cognitive behavioral therapy (Brown and Gerbarg 2009, 2012; Gerbarg 2008). Augmentation with CES and neurotherapy improves emotion regulation and cognitive function and accelerates healing of brain injuries (Larsen and Sherlin 2013).

c. During the first year of abstinence, continue nutrients and herbs to support brain recovery and mind-body practices to promote emotion regulation, anxiety and anger management, and physical health. Neurotherapy and cranial electrotherapy stimulation augment neuroplasticity, cognitive function, and emotion regulation (Brown et al. 2009; Larsen and Sherlin 2013; Kirsch and Nichols 2013).

Section IV

Behavioural Approaches

Richard A. Rawson and Marc Galanter

Behavioural Approaches: An Introduction 46

Richard A. Rawson and Marc Galanter

Abstract

Over the past 30 years, numerous empirically tested behavioral approaches to substance use disorders (SUDs) have been adopted by treatment settings. A key focus of many of these approaches is the retention of patients in treatment. This Introduction provides an overview of the chapters in this section on behavioral approaches to SUDs, including psychodynamic psychotherapy, 12-step programs, Motivational Interviewing, Cognitive Behavioral Therapy, Contingency Management, Behavioral Couples Therapy, Multidimensional Family Therapy, Network Therapy, the Community Reinforcement Approach, the Community Reinforcement Approach and Family Training, Mindfulness Meditation, and physical exercise. The final section discusses the dissemination of behavioral approaches to other parts of the world and the importance of adapting approaches in culturally sensitive ways while maintaining fidelity to the original model.

In every society where substance use disorders (SUDs) are treated in some systematic manner, behavioral approaches, including "talk therapies," are at least one element of the treatment approach. In many parts of the world where treatment for SUDs is just emerging, the behavioral treatments consist of advice-giving or commonsense generic counseling. In some areas, including the United States during the 1960s and 1970s, behavioral approaches consisting primarily of confrontational therapies designed to "break through denial" were usually delivered within the context of residential therapeutic communities. These harsh, unpleasant,

and occasionally abusive techniques had no empirical support but were widely adopted, frequently with patient populations that had extensive involvement in the criminal justice system. During the 1980s, when these techniques were applied in outpatient settings with a noncriminal justice population, they proved to be ineffective and, frankly, counterproductive, as they resulted in poor patient compliance and low retention rates, a serious problem in outpatient treatment settings.

Over the past 30 years, a collection of behavioral interventions and approaches that were developed and evaluated in research trials have gradually been adopted into a wide variety of treatment settings. As outpatient settings have increasingly become the location for SUD services, a key guiding principle in the development of these approaches is that they should improve retention in treatment. For this reason, in many of the approaches described in this section, extensive use of positive reinforcement is emphasized to reinforce positive behavioral change, including retention in treatment.

The behavioral approaches and strategies described in the section now represent the foundational treatment paradigm for much of the SUD treatment delivered in the world. For the treatment of SUDs that have effective pharmacotherapies, including the treatment of opioid dependence with methadone and buprenorphine, these behavioral approaches are frequently employed in combination with these medications. For other SUDs, such as stimulant dependence, these approaches represent the only empirically supported techniques currently available. A limiting factor in the rapid dissemination of these approaches is that a significant training effort is needed for the successful transfer of the knowledge and skills needed to deliver these treatments. An ongoing challenge in the international dissemination of these approaches is balancing fidelity to the evidence-based principles and methods of the approach, while allowing for adaptation to the context and values of new cultures. These training and adaptation issues are covered within this section.

Section IV includes a comprehensive set of chapters on the behavioral approaches that have been developed and evaluated for the treatment of SUDs. Psychodynamic psychotherapy has long been used to understand how people use drugs and alcohol to modify hedonic states and self-regulate moods. Khantzian describes how drugs and alcohol are used to cope with suffering and emotional pain. He emphasizes the importance of the therapeutic alliance as an important element in promoting change and describes the key elements of this alliance as kindness, support, empathy, respect, patience, and instruction. Donovan and Daley describe a therapeutic approach developed for the seminal study, Project Match, which promotes the engagement and use of the 12-step program of Alcoholics Anonymous (and other related self-help programs) as a method for achieving and maintaining recovery from drugs and alcohol. The chapter reviews the empirical evidence for the benefits of participation in a 12-step program and provides guidance to physicians and other professionals regarding how they can effectively encourage patients to participate in a 12-step program.

During the past 20 years, three behavioral approaches, Motivational Interviewing, Cognitive Behavioral Therapy, and Contingency Management,

have been the most extensively researched, evaluated, and widely disseminated behavioral approaches. Motivational Interviewing (MI), conceived and presented in a 1991 text authored by Miller and Rollnick, is reviewed in the chapter by Tober (▶ Chap. 47, "Motivational Interviewing and Behaviour Change in Addiction Treatment"). Motivational Interviewing is arguably the most important behavioral strategy ever developed for the treatment of SUDs, as it has been applied in a very extensive array of settings and with a wide variety of patient populations. Tober's chapter reviews the skills that are needed by therapists to effectively employ the MI approach. Clinical examples are given to illustrate the use of key MI concepts, and training and supervision strategies are described to promote the application of MI with fidelity. Lee reviews the learning-theory underpinnings of Cognitive Behavioral Therapy (CBT) and the skills needed by therapists to effectively deliver CBT. She describes the variety of ways that CBT can be applied, with specific guidelines for how sessions can be constructed. She also provides a comprehensive array of CBT models and variations as developed by various authors/researchers, and she reviews the evidence that supports the efficacy of CBT. Roll and Fruci describe the operant-conditioning rationale for Contingency Management (CM) and methods used to apply CM principles in the treatment of addiction. They review the variety of specific modifications that can be used to practically apply CM in clinical settings. Of all the behavioral approaches, CM has the strongest empirical evidence of efficacy. Roll and Fruci organize their review of the research evidence to reflect the key factors that impact the effectiveness of CM interventions. They finish their review by addressing the implementation barriers and limitations of CM.

Three of the chapters in Section IV describe behavioral approaches involving multiple participants. In many parts of the world, group therapy plays a major role in addiction treatment. McHugh, Park, and Weiss review the variety of group therapies used in SUD treatment and the data that supports the value of group therapy. O'Farrell reviews the evidence from studies conducted in the United States and internationally on Behavioral Couples Therapy (BCT). He describes some specific techniques, including couples contracts and communication exercises, as well as some of the possible limitations of BCT resulting from the training and supervision requirements needed to ensure fidelity. Multidimensional Family Therapy (MDFT) is one of the few behavioral approaches that have been evaluated in a large multisite international trial. Rigter and colleagues describe the rationale and elements of MDFT and the methodology and results of that multisite implementation trial. The chapter describes the challenges and limitations of adapting a dissemination model for a complex therapy across different cultures and languages.

Section IV also includes three chapters that describe multielement outpatient approaches. Galanter describes the rationale and elements of Network Therapy and the importance of social support as part of successful treatment. The chapter explains how networks are created and how 12-step program involvement and medication can be valuable as elements of the network. Research evidence for support of Network Therapy is provided. The Community Reinforcement Approach

(CRA) is a multielement intervention that helps patients identify rewarding behaviors in the community that can help them initiate and sustain a nondrug-using lifestyle. Smith and colleagues explain the elements of CRA and the added component of family therapy (CRAFT) that are designed to assist in developing positive relationships with significant others. The evidence to support the efficacy of CRA and CRAFT is also presented. The Matrix Model is a multielement package of CBT, patient education, 12-step involvement, and other elements designed to be used in outpatient settings. Obert, McCann, and Rawson describe the elements of the treatment model and the extensive program of dissemination of the Matrix Model in the United States and internationally.

Two innovative behavioral techniques that are generating considerable interest are Mindfulness Meditation and physical exercise. Mindfulness is a meditation practice rooted in Buddhist tradition, combined with a collection of attentional strategies and skills designed to focus the attention of the individual in the present. Marcus' chapter describes the rationale for mindfulness, the key elements in its use, the health conditions where it has been applied, and modifications that have been added to apply mindfulness to the treatment of addiction (▶ Chap. 50, "Mindfulness as Behavioural Approach in Addiction Treatment"). Mindfulness-based relapse prevention combines mindfulness with cognitive behavioral strategies and is being evaluated in ongoing clinical trials. Mooney and colleagues review the extensive set of research that documents the robust positive health benefits of exercise. Although there is limited research literature on the value of exercise as a component of addiction treatment, the chapter discusses multiple justifications for supporting the promising potential that exercise has in assisting people with addiction.

Castro and Barrera have contributed a unique chapter of exceptional importance to Sect. IV. They discuss the importance of culturally adapting behavioral approaches in a systematic manner that considers the importance of fidelity to the original evidence-based model but allows for adaptation of the model to address specific cultural issues of importance. They describe the challenges of effective language translation as well and caution about misadaptation. They use the example of how the Matrix Model, which was developed in California, was adapted for use in Mexico. And finally, Rawson, Rieckmann, and Capoccia contribute a chapter in which they describe three successful examples of how evidence-based treatments have been implemented in the United Arab Emirates, Vietnam, and Lebanon.

Motivational Interviewing and Behaviour Change in Addiction Treatment

47

Gillian Tober

Contents

Abstract

This chapter explores social and psychological routes into addiction and the naturally occurring and assisted routes to recovery. Evidence for effective mechanisms of change points to specific components of structured treatment and its delivery, practitioner behaviors, and client attributes. The extent to which these specific components are in turn contained in usually delivered treatment methods is explored. Motivational interviewing practice as a style of consultation contains a number of effective practitioner behaviors, while other important mechanisms are found in cognitive behavioral coping skills training and in socially based network treatment approaches. Examples of dialogue and of interactions with clients are given. The specification of treatment protocols in practice manual format provides the basis for training and maintaining practice standards. Supervision and the rating of competence can be based on the use of a validated practice delivery rating method.

47.1 Introduction

For all the evidence for the effectiveness of psychosocial interventions, it is perhaps surprising that a consensus on the optimal or standard treatment, albeit with variants to suit different addiction problems, has yet to be forged. A hundred years of behavioral research has provided both the framework for understanding addictive behavior and the evidence for treating it. There is, however, the perennial challenge of translating research findings into practice, and this is further complicated by the enduring negative attitudes to people with addiction problems, a lack of consensus about the nature of addiction problems, and about who should treat them. Different countries have different expectations of the provision of care and how to intervene, some taking the view that only professionals – medics, psychologists, social workers, and allied professions – are the right people to provide treatment, others taking the view that primarily people who have had the problem themselves are the right treatment providers or that it is the criminal justice system and possibly most commonly a combination of all of these. This makes for a situation in which a shared view of the concept of good practice, let alone the specifics, can be hard to find and effective practice quite difficult to implement.

This raises the question of what is addiction treatment for. Research reports that people seek treatment because they have lost control over an addictive behavior or have a sense that they have lost control over their life. There may be greater or lesser elements of coercion involved in help seeking whether external or somehow self-imposed, and these are combined with the ambition to achieve some sort of change. Thus, there is a need to ensure that treatment seekers have a sense of being helped to reassert control, and so it follows that treatment needs to be an active, task-oriented process. Help seekers will generally have tried to reach their own solutions: they may have appealed to family and friends for help, will intuitively have tried different coping strategies, or tried various kinds of self-help and mutual aid, and turned to other forms of social capital such as religion or spiritual inspiration. The challenge is for the helping professional to build on the individual's own resources, thus harnessing the processes of "natural recovery" into treatment-assisted recovery.

47.2 Understanding the Nature of Addiction

In order to inform effective treatment plans, practitioners need to have an understanding of the way in which the addictive behavior is reinforced; decisions about where to start are based on an accurate assessment of motivation which emanates from understanding what maintains the behavior and what scope there is for change. Addiction can most readily be understood as the manifestation of behavioral phenomena which are learned and can be reversed through the principles of behavioral extinction. Rotgers (2003) and Heather and Robertson (1997) are among numerous authors describing the way that, like all behaviors, addictive behavior is

a set of responses conditioned by internal biological and cognitive cues, external social cues, modified by *reinforcers*, both positive and negative, that are also social, psychological, and biological in nature. Miller and Carroll (2006) illustrate the complexity of addiction behavior in bringing together accounts and evidence from the biological, social, and behavioral sciences. For the practitioner, distilling out those explanations that most readily account for the observed phenomena is necessary to establish a working knowledge base that will inform practice. (Russell 1971, Russell et al. 1974) demonstrated the interaction of cues, or triggers, for a typical path into tobacco-smoking behavior and the development of dependence. This gave a useful prototype for understanding how a "social" behavior becomes an addiction: first, there are social cues and reinforcers, next learning the value of pharmacological reinforcers, and finally, in the establishment of dependence, the importance of physiological sources of reinforcement. Simply put, people usually start smoking because of peer pressure and rewards and continue once they have learned to detect the stimulant effect of the tobacco; it is the neuroadaptive state that results in the perceived inability to abstain and difficulty stopping that reinforces dependent use. Orford (2001) has illustrated the application of these behavioral principles across a range of addictive behaviors. Siegel (1999) adds to this body of knowledge with empirically based explanations of the more complex observed phenomena such as the experience of withdrawal symptoms in the absence of recent drug use, prompted by previously familiar drug using environments.

47.3 What Are the Effective Mechanisms of Change?

If the way into addiction, or dependence, is well understood in terms of social learning theory, what is known about applying this knowledge to the treatment of addictive behavior? Moos (2007) argued that the same processes that protect individuals from developing addiction problems are those that are useful in helping them to recover from these problems. He described four social learning theories that identify these processes and the way they inform psychosocial treatments that have evidence of effectiveness. He identified these as motivational interviewing and motivational enhancement therapy, cognitive behavioral treatment and behaviorally oriented family counselling, contingency management, and community reinforcement. He then presented these essentially cognitive and behaviorally based treatments in sets and identified the common theoretical principles upon which they are based. Thus he argues his case, on the strength of probability, for the theory-based active ingredients of treatments that have evidence of effectiveness. The "probable common active ingredients of effective treatments" which he extracts are (a) support, structure, and goal direction, (b) provision of rewards for abstinence and planning rewarding activities that can replace substance use, (c) abstinence-oriented norms and models, and (d) building self-efficacy and coping skills. The challenge is to ensure that psychosocial interventions contain these active ingredients as the building blocks for structured treatment and for aftercare in order to ensure the maximum benefit from treatment. Moos makes the important

point that harmful side effects of treatment are not confined to pharmaceutical or invasive treatments and he estimates that about 10 % of those receiving psychosocial treatments will be harmed as a consequence of that treatment. Among the possible explanations is a loss of optimism about the possibility of change. Help seeking is always to some extent an expression of optimism about the possibility of change and having a sense of failure following help seeking damages self-efficacy, a belief in one's ability to achieve a particular goal, on which successful change depends. It is not just doing the wrong thing that can cause harm, but doing nothing, it can be argued, is equally likely to result in harm.

Michie and colleagues (2012) have used a different starting point in the search for active ingredients or the effective mechanisms of behavior change treatments, by examining practice manuals and protocols for the treatment of alcohol problems. A list of behavior change techniques was extracted and applied to the findings of the Cochrane Review of brief alcohol interventions, and associations between the effective interventions and the identified behavior change techniques were examined using meta-regression. This method yielded the finding that brief interventions which incorporated 'prompting self monitoring' were associated with larger effect sizes. This is a small finding but one that demonstrates the further potential for identifying those behavior change techniques that are likely to make a difference and should be incorporated in routine addiction treatment.

The effective mechanisms of change reported here are supported by service user accounts of what helps recovery from addiction problems. In their analysis of 1,484 post treatment session questionnaires administered in the UK Alcohol Treatment Trial (UKATT 2005a, b), Orford and colleagues (2009a) found that, regardless of treatment received, service users found talking to the therapist, belief in their progress, and the future focus of treatment to be the most useful elements of the session. In a longer-term follow-up of UKATT service users, face-to-face interviews with 397 participants from several services in different parts of the UK asked questions about the factors to which they attributed change in their drinking. These revealed that they thought social factors, the involvement of others in their treatment, motivational factors resulting from knowing the consequences of their drinking through feedback, personal factors of determination, commitment and decision making, access to detoxification and medication and feeling comfortable talking were key (Orford et al. 2009b).

47.4 In Which Treatments Can These Effective Mechanisms of Change Be Found?

In his first paper on motivational interviewing, Miller (1983) argued that it was the understanding of client motivation, based in perceived reinforcement and shifting consequences of the behavior, which would guide the practitioner in delivering good and useful practice in treating problem drinkers. Ignoring motivation, he claimed, was counterproductive, while identifying current motivation to continue

drinking, mixed feelings about it, and allowing the service user to express their own reservations about their drinking and explore the potential advantages to the service user of change might help to shift the behavioral status quo. It was a simple argument, elegantly stated and enthusiastically received. It unlocked the therapeutic paralysis that characterized attempts to treat people who lacked motivation to change and often resulted in negative attitudes to the treatment of addiction that endure in many settings to this day. Miller went on to describe how this facilitation might be done, with a set of Rogerian (Rogers 1959) principles including listening to the client, not telling the client what to do, asking for the client's perspective, and reflecting their thoughts. Miller however developed the Rogerian principles with a critical new element: he introduced the idea of direction that is of the practitioner having an agenda that focused on change and improvement in the client's health and social well-being through the medium of stopping or changing drinking. In order to pursue this agenda, Miller suggested that reflections should be selective, highlighting negative thoughts about drinking, positive thoughts about the outcomes of change, and about ability to change.

Miller's proposed style of consultation owes its popularity to the context in which it was presented: the equally popular and contemporaneous development by Prochaska and Diclemente (1984) of a model of change that described the fluctuating nature of motivation which determines continuation or modification of addictive disorders (and not just these behaviors) and drew attention to the imperative to address this motivation if change was to be facilitated. Miller operationalized a method of helping people move forward toward making a decision to change, instead of becoming entrenched in arguments for continuing the behavior (manifest as denial, rationalization, or justification).

Thus, motivational interviewing with its support for the client, its structure, and goal directness embodies effective mechanisms of change outlined by Moos. Furthermore, it is designed to increase self-efficacy by exploring the client's beliefs in their ability to change and the resources they need to enhance these beliefs. More recent research on what happens in motivational interviewing by Amrhein and colleagues (2003) deepens our knowledge of how to harness the method to optimize change by ensuring that an expression of commitment to change is the goal of the motivational dialogue. In their analysis of the discourse between practitioners working in a motivational interviewing style and their clients' responses, Amrhein et al. (2003) found that the statement of a commitment to change made by the client predicted that change was more likely to occur than when no such statement of commitment was made. The contribution of this work was to distinguish different kinds of "change talk," where the client expresses the desire to change, the ability to change, the need to change, and reasons for change, and identify "commitment talk," defined as the statement of an intention to change. They found that it was the presence and the strength of this commitment talk or expressed concrete intention to change which predicted that change was more likely to occur. Apodaca and Longabough (2009) reviewed the mechanisms of change in motivational interviewing and their findings support the importance of client change talk that

expresses intention to change. How the practitioner achieves this is less specifically defined; but one thing seems clear. Hours are spent in the average clinic or counselling room talking about the importance of change, that it needs to happen, that it ought to happen, and that life would be so much better if it did happen. Talking about change and its benefits is not enough. Making a commitment to change is the point that needs to be reached in order for change to have a chance of happening, at least in the consultation or counselling setting.

In general terms, the weight of the evidence points to the likelihood that motivational interviewing as a style of consultation enhances treatment engagement and *treatment adherence* (Hettema et al. 2005). People are more likely to come into addiction treatment where they experience being listened to and more likely to stay where they feel that their own thoughts and feelings are being addressed. What the practitioner should be trying to achieve is clear, but how exactly they might achieve this is less clear and the evidence on the specific components of motivational interviewing that make a difference is equivocal. Apodaca and Longabough (2009) claim that practitioner behaviors thought to be inconsistent with motivational interviewing, described as confronting, directing, and warning, were found to be associated with worse outcomes across treatment for problem drinking and illicit substance use, while Miller and colleagues (1993) in comparing motivational interviewing with a confrontational style of treatment as usual found that the latter tended to result in in-session conflict, which in turn predicted worse drinking outcomes up to 2 years after treatment.

Based on these findings, the core skills of motivational interviewing which facilitate the accurate assessment of motivation, enhance motivation to decide upon and pursue a change goal, are thought to be characterized by open questions and selective reinforcement:

If you want to assess the individual's motivation regarding their drinking, ask them, and do it in such a way as to communicate interest in what they have to say; avoid telling them what you think, either verbally, in the tone of your voice, or in your body language. This is open questioning. It makes intuitive sense and it is a learned behavior in itself, one that is difficult for clinicians who are trained to make differential diagnoses by questioning whether a list of things is present or not:

Tell me about your recent drinking
What has recently happened when you have been drinking this amount?
What are your thoughts about this?
What would you like to be different?

This second skill is more difficult for the nondirective counsellor, or the "person-centered" counselling practitioner where the counsellor is required to follow any agenda set by the client; rather it is the skill of contingent or selective reflection. The task is to reflect the things that are relevant to the question of drinking, or drug use, or the health behavior that justifies the conversation. The difference between reflection in this style of motivational dialogue and nondirective reflective listening is that selective reflection facilitates the forward movement of the dialogue in a combination of the directiveness and support to which Moos referred as active mechanisms for change:

You feel ill after drinking that much
You dislike the looks that people give you in the street
You are fed up with being treated as being unreliable
You want to be able to look after the children
You think that your drinking is getting in the way of that

The combination of open questions and selective reflections enables the practitioner to move the dialogue forward through change talk about their desire to change, to reach the point of an expression of optimism about the possibility and outcomes of change, and then a commitment to change. But how does this work? Why do people change their view of their drinking? Some studies have shown that the provision of feedback that is objective and personalized, such as described in the Drinker's Check-up (Miller et al. 1988) which formalized the process of heightening concerns about use, a key component of change talk, is what makes motivational interviewing effective. Thus, neuropsychological tests can be useful, as demonstrated in Miller et al.'s study and liver function tests as demonstrated in the UK Alcohol Treatment Trial (2005a). The distinguishing features of using feedback from test results in a way that is more likely to enhance motivation for change are that the tests themselves are objective and valid, produce results that are measurable against population norms or well-functioning people, are personalized, and are presented in a manner that enables the recipient to understand both their meaning and their potential for change. Importantly, they need to be perceived to be a result of drinking, drug use, or whatever the target behavior is and to be improvable as a result of a change in the target behavior.

Avoiding confrontation and conflict in the consulting room and establishing collaborative working with the client toward a common goal are supported by research on the therapeutic alliance, where collaboration between therapist and client encourages a feeling of mutual respect enabling the therapist to be a helping agent and creating conditions for the client to explore opportunities and enhance self-efficacy for change. Those elements of communicating respect and positive regard, listening to the client, and agreeing the goal of treatment, which are shown to make a difference, highlight the contribution of the motivational interviewing method in the operationalization of this professional conduct or the way to achieve this therapeutic alliance.

The same skills are used throughout the next steps of the process: when motivation to change has been heightened, the decision to make a commitment to change is prompted; thus, if there are, for example, negative thoughts about drinking or drug use and positive thoughts about stopping, a goal can be formulated in a dialogue that follows the open question: *How would you like or prefer things to be*? and then using selective reflections to narrow down the response to a clearly articulated goal. This articulation of the goal may be the result of statements like *I want to stop arguing with my partner*; *I want to stop taking time off work*; *and I want to be someone my children can look up to*, when the practitioner asks the further question about how this can be achieved, eliciting the response *I want to stop drinking*. The requirements of the goal are that it is specific and well defined, measurable, realistic, and achievable and has a time frame attached to it.

This is well-trodden territory, and yet many of these key elements are often missing in addiction treatment. It helps the practitioner as well as the service user to stay focused if the goal is regularly reviewed and restated, enabling repeated assessments of motivation to change: change "but not just yet" is weak commitment, and so are loosely defined goals, unrealistic goals, and goals that cannot be measured. It is not difficult to check that the key criteria are met.

How to implement the behavior change required to achieve the goal takes us into the territory of applying effective behavior change techniques, as the next step involves making short-term behavior change plans. Thinking about the rest of life is too difficult. Listen to the mantras of followers of the 12-step approach. *One day at a time* is popular because it is manageable. In describing the implementation of the active mechanisms of change in behavioral treatments of addiction, Carroll and Rounsaville (2006) point to increasingly robust evidence for key components. Skill rehearsal involves the client trying out the new behavior and rehearsing the thoughts that precede and accompany the behavior. In reviewing these rehearsals, one can decide whether they are realistic approximations of what can happen. Next comes the setting of homework, or skills practice in vivo; the definition of tasks needs to be concrete and specific for time and place; and then monitoring the method. The effectiveness of giving homework is in the monitoring and reporting back of it, without which, the research tells us the setting of homework makes no difference to the learning of new skills.

47.5 The Social Focus of Treatment

People with social networks of family and friends who are supportive of change have a greater chance of changing than those whose social networks support heavy drinking or drug use. Some of the behavioral interventions based on recruiting and mobilizing such a support network are the community reinforcement approach (Meyers and Smith 1995), network therapy (Galanter 1993), and social behavior and network therapy (Copello et al. 2009). While all of these have an evidence base, they are not universally practiced; they do, though, provide a strong argument for moving away from individualized treatment and ensuring that every intervention is delivered to an individual in a social network.

The process of getting other people involved, people who are available, willing, and able to help put the plan into practice, involves a set of skills not always familiar to the addiction practitioner trained in delivering individually based treatments. This approach has been identified repeatedly by clinical researchers: McCrady (2006) emphasizes the importance of the family in each step of the helping-seeking journey. Like Moos, she describes the central role of the family in protecting against or increasing the risk of substance misuse problems, thus highlighting the opportunity for harnessing their support in recovery. The wider search for sources of support beyond the family was at the heart of the development of social behavior and network therapy (Copello 2007) in which "think network" is a key practitioner skill. Good network plans are made by people who want to work together, who want

to give and get support from each other, and who want the same outcome. The pharmacological components of treatment and compliance with them can be incorporated into the network plan, and the behavioral principles of rehearsal and reporting back and modifying behaviors in the light of feedback can be pursued.

The importance of positive role models is addressed in the network approach. A well-functioning network will include modelling of behaviors and positive experiences of rewarding activities not associated with drinking or drug use. If such role models are to be found outside the network, for example, in a local Alcoholics Anonymous meeting, or other mutual help fellowship, the network can provide the support to make the initial contact which people can find so difficult. Treatment staff have variable attitudes to encouraging attendance at and affiliation with mutual aid when the evidence for their effectiveness is gathering momentum.

In each of the sets of skills described, the active mechanisms identified by Moos and others are included. Thus, the network-based support, change plan, and relapse prevention plan enhance self-efficacy (there are always people there to help) and coping (everyone learns new coping skills in the network); it is focused on the goal and support is explicit; its direction is enshrined in its future focus (how are things going to be different from now on?). This set of skills, a combination of motivational enhancement for change and behavior change skills delivered in a network supportive of change, can be adopted in a variety of addictive behavior change settings, whether there is an addiction problem in isolation or in combination with other disorders, at each stage of behavior change, decision making, planning, and maintenance of change, in the context of pharmacological, psychological, and social interventions, and whether the treatment goal is abstinence, control, or harm reduction.

47.6 Treatment Protocols and Their Inclusion in Manuals to Guide Practice

Effective methods for helping the client to change their addictive behavior have been incorporated into treatment manuals, self-help materials, training guides, and numerous forms of brief interventions. Let us get the problems with treatment manuals out of the way. The first is that they are not often published and so are difficult to find. Where they have been developed as part of clinical trials, they are likely to be placed in the public domain. The three treatment manuals which were used in Project MATCH: Motivational Enhancement Therapy (Miller et al. 1992) which gives useful examples of worksheets for delivering feedback from tests and monitoring behavior; Cognitive Behavioral Coping Skills Training (Kadden et al. 1992) combines the core and elective sessions of behavior change treatments with adaptable worksheets; and Twelve Step Facilitation (Nowinski et al. 1995) focuses on an introduction to the 12-step philosophy and practice and encouragement to embark on that recovery journey, all available from NIAAA. Treatment manuals used in subsequent US trials for different substance dependencies such as cocaine, heroin, and cannabis are published by the US Clinical Trials Network via Internet media.

Monti et al. (2002) have developed their manual for the treatment of alcohol dependence and incorporated developments in clinical research. Manuals may also be published as books giving extensive examples of practice (e.g., Copello et al. 2009; Tober and Raistrick 2007).

Rigid adherence to manual-based protocols is counterproductive. Indeed in their meta-analysis, Hettema et al. (2005) found that motivational interviewing was more effective when practiced without a manual. The strongest message to come from the use of manuals in guiding treatment is that they are useful for ensuring practitioners adhere to a structure, the prescribed content and style of treatment delivery, but they are not useful when practitioners follow them "blindly." Manuals do not compensate for lack of knowledge and experience, and the best use of them is by more experienced practitioners. Every treatment session needs to be adapted to the individual client, their motivation, social circumstances, and the severity of their condition, and a good manual will be designed to be used in this way.

Manuals can provide the basis for detailed scrutiny of practice where video or audio recordings of practice form the basis for detection and analysis of the components of treatment and the quality of their delivery. There are validated methods to rate competence and practitioner adherence to practice protocols. These can be used for the dual purpose of independent rating of treatment delivery and for supervision to improve and maintain good practice. Such ratings ensure that the active mechanisms of change are present and make it possible to identify differences in practice and explore whether and perhaps why practitioners successfully engage service users in treatment and change (see, e.g., Tober et al. 2008). Practitioner competence is the key to effective treatment; time and money can be saved by focusing on just doing those things that make a difference.

47.7 Who Treats Addiction Problems?

Everybody who works in health and social care can contribute to addictive behavior change. Successful outcomes are not just the result of formal treatment but also the accumulated effect of small but positive "nudges" toward motivation to change. There is no sense in thinking that busy staff with other responsibilities on their minds can screen or deliver brief treatments to people with drinking or drug problems: the liver transplant surgeon, the nurse looking after the patient with pancreatitis, the emergency room doctor dealing with trauma, and the social worker handling a child protection case can all see where drinking or drugs are causal agents. What these staff need to be able to do is help to build motivation; in part, this is by working in a motivational style, that is, being empathic, using open-ended questions where possible, and reinforcing change talk, and it is also by simple motivational enhancement techniques like asking a question such as "what difference do you think your drinking is making?". Making the specialist addiction services as available as is possible is going to be more fruitful than trying to get staff with other jobs to do to screen and treat people with addiction problems. Promoting optimism for and confidence in the outcomes of specialist treatment may

be the one ingredient necessary to encourage generalists to refer to specialists in addiction. It is up to the specialists to help others to have a positive experience of helping people with addiction problems and also to understand that these individuals can be very challenging when they present in health and social care settings that are not geared up to deal with them.

47.8 Implementing Effective Treatment: Getting Competent Practitioners

What are the necessary conditions for being a competent specialist addiction practitioner? Knowledge of the nature of addictive disorders, as well as understanding of the experience of having an addiction disorder, gained from listening to people who have them, and of the illnesses and other consequences that result from them are the foundations for accurately assessing the problem and its various consequences and making the right treatment decisions. Understanding the behavioral principles that drive the addiction itself and the evidence-based effective mechanisms of change provides the building blocks for the specific intervention. Utilizing a manual that incorporates these and gives guidance for practice that is context specific and culturally relevant gives the prototype against which to measure competence and will enable practitioners to maintain treatment protocol adherence, once this has been established through training followed by supervised practice and the rating of competence (Tober et al. 2005).

Those practitioners who are perceived to be authoritative in their knowledge of the problem and their knowledge of effective treatment and who are perceived by the client to be competent in effective treatments will be likely to deliver better outcomes, so the research has shown. Knowledge and then practice of behavior change techniques, moving from the key components to the complex business of practicing in addiction treatment settings, are not as simple as the description of skills suggests. Addiction problems are by definition complex, and people present with multiple complexities such as dual diagnosis with mental illness, physical illness, pregnancy and child care concerns, and criminal and other antisocial behavior. Competence will be achieved through continually supervised practice in a supportive environment where there is an ambition to implement the evolving science as a matter of routine.

Cognitive Behavioural Therapies for Substance Use Problems

Contents

Abstract

Cognitive behavior therapy (CBT) is an umbrella term that describes a group of therapies, that although many in number and broad in their approach, have in common a focus on thoughts and beliefs (cognitions) as the central driver of, and the solution to, effective emotion regulation. The early CBT models (sometimes referred to as the "first wave") focused primarily on response to stimuli and included the theories of B.F. Skinner and Joseph Wolpe. The "second wave" introduced the concept of cognition into the behavioral models; the most well known of these models were developed by Aaron Beck (Cognitive Therapy) and Albert Ellis (Rational Emotive Behavior Therapy). The "third wave" models are primarily the mindfulness-based cognitive therapies, although a range of other integrative therapies, such as Schema Focused Therapy and Emotion Focused Therapy, are sometimes included in the group of newer CBT models.

This chapter describes how these models work and how they have been adapted to substance use treatment, ranging from intensive to brief and low-intensity interventions. The evidence shows that CBT is one of the most effective interventions for substance use issues, as well as for co-occurring substance use and mental health problems. Traditional (second wave) CBT has the most evidence for its effectiveness, and the mindfulness therapies have a growing body of evidence that shows that they potentially have similar outcomes for substance use disorders. CBT has been adapted and applied across a range of cultures and countries.

"We are what we think. All that we are arises with our thoughts. With our thoughts we make the world."
Shakyamuni Buddha

48.1 Introduction

Cognitive behavioral therapy (CBT) is an umbrella term that encompasses a large number of therapies. Although many in number and broad in their approach, they have in common a focus on thoughts and beliefs (i.e., cognitions) at their theoretical center.

These therapies are not just a collection of random strategies but are based on a coherent theory that drives the techniques that now form the collection of CBT approaches. Due to its important role in treatment, CBT has become a core competency for alcohol and other drug workers.

This chapter introduces the range of therapies that come under the CBT banner, briefly describes their underlying theoretical structures, and summarizes the evidence for their effectiveness.

48.1.1 A Brief History of CBT

The history of CBT is important to an understanding of its current form and application, since it encompasses a very broad range of therapies that have in common a focus on cognitions and their influence on behavior.

From the late 1800s to the 1940s, psychotherapy was dominated by the theories and therapy of Sigmund Freud – referred to as psychoanalytic psychotherapy or psychoanalysis – and a number of other therapies that grew out of, and diverged from, psychoanalytic psychotherapy, such as dynamic psychotherapy and Gestalt therapy. These therapies have a focus on unconscious conflicts and processes and on the dynamics between the therapist and client. Therapy by these methods is usually offered several times a week or even daily and is expected to take several years to be effective. Over time, other briefer versions of these therapies have developed, based on similar theoretical hypotheses.

In the 1950s, something of a revolution took place in psychotherapy. Psychology more broadly had begun to develop itself into a scientific discipline with a focus on the scientific method, and psychoanalytic therapy came under public criticism from people like Noam Chomsky for its lack of scientific rigor. Psychoanalytic therapy adapted and changed in response, but at the same time another branch of psychology began to form, driven by scientific enquiry: the behavioral therapies.

Although the term "behavior modification" was used much earlier by Thorndike and "behaviorism" was described by John B Watson in the early stages of the twentieth century, the real development of behavioral theories as applied to modern practice began in the 1950s, drawing on earlier theories of classical conditioning (Pavlov 1927).

By the 1950s, B.F. Skinner in the USA and Jack Rachman and Hans Eysenck in the UK began looking at environmental factors that could shape behavior and developed treatments based on operant conditioning, such as contingency management (a structured system of rewards for achieving treatment goals). Around the same time, Joseph Wolpe began experiments looking at changing behavior through reinforcement using rewards and punishments, the results of which led to the development of Behavior Therapy (Wolpe 1973).

These therapies were all based on the theory that a response (behavior) was triggered by stimuli (learned external triggers). This group of early behavioral therapies is often referred to as "first wave" behavioral therapies.

The "second wave" came in the 1960s via two psychoanalytically trained therapists. Aaron Beck ("Cognitive Therapy"), a psychiatrist, and Albert Ellis ("Rational Emotive Behavior Therapy"), a psychologist, both came to believe that something other than psychoanalytic ideas of unconscious conflict was the cause of their patients' problems and theorized that there was also something deeper than just the "stimulus" and "response" of the behaviorists.

Second wave models described a process, often not in complete awareness, by which an individual interprets a stimulus and then uses that interpretation to mediate a response – that is, thoughts and beliefs. The intervention, therefore, is focused on assisting a person to become more aware of, understand, and analyze his or her thoughts and beliefs that drive a response in a given situation and then to consider whether the thoughts are (a) true or irrational and (b) helpful or unhelpful.

As the second wave theories developed, they drew ideas from cognitive psychology (Neisser 1967), which described how sensory input is received, transformed, and interpreted by an individual, and from social learning theory (Bandura 1977), the latter of which puts additional importance on the context of learning, particularly through concepts like modeling and observational learning.

The "third wave" of CBT has most recently developed with the mindfulness-based therapies such as Dialectical Behavior Therapy (DBT) (Linehan 1993), Mindfulness-Based Relapse Prevention (MBRP) (Bowen et al. 2010), Mindfulness-Based Cognitive Therapy (MBCT) (Segal et al. 2002), and Acceptance and Commitment Therapy (ACT) (Hayes and Strosahl 2011). These therapies are based on a similar theoretical understanding of the function of thoughts and beliefs, and while they focus on increasing awareness of thoughts, they differ from

traditional CBT approaches in that, rather than analyzing or controlling them, the aim of therapy is accepting the thoughts and letting them pass.

This chapter focuses on the second and third waves of cognitive behavioral therapies.

48.2 The Cognitive Behavioral Approach

48.2.1 Description of the General CBT Approach

Like any other therapy, CBT is not merely a manualized set of techniques but is based on well-researched theoretical models that share the underlying assumption that our thoughts, behaviors, and emotional reactions are learned and that the path to well-being is through managing thoughts and beliefs in some way. The fact that CBT is often manualized is an artifact of its structured and scientific approach rather than a fundamental part of the approach. There is some evidence that a single-focused approach is more effective than an eclectic one (e.g., Moos et al. 1999), suggesting that a sound basis in a single therapy is most effective. Therefore, it is important to understand the underlying theoretical structure of CBT, not merely the strategies or techniques, to apply the interventions effectively.

Strategies to manage thoughts and beliefs may differ between different styles of CBT. For example, in Cognitive Therapy, change is facilitated through strategies to analyze and change thoughts, while in mindfulness approaches the focus is on becoming aware of, and accepting, thoughts.

In general, cognitive and behavioral therapies are relatively brief (usually 10–20 sessions), and even briefer therapy versions have been developed that are designed for delivery in between 1 and 6 sessions.

48.2.1.1 General Assumptions of CBT Approaches

A number of assumptions are specific to CBT (Mitcheson et al. 2010), including:

- Substance use and dependence is a learned behavior, emerging over time, and can therefore be "unlearned."
- Substance use and dependence is seen within a context of environmental influences, including the influence of family and friends, availability of substances, and sociodemographic circumstances.
- Substance use and dependence is developed and maintained by particular thought patterns and processes.

Although CBT models understand that substance use and dependence is complicated by genetic, biological, and temperamental factors, these are considered risk factors rather than determinants. Much in the same way, certain people may have a biological or genetic history of heart disease that puts them at higher risk of heart problems, but environmental and learned factors such as eating habits, ability to control stressors, and exercise can prevent or lead to the development of a heart condition.

Beck (2011) outlined ten principles that underlie CBT:

1. CBT requires a sound therapeutic alliance.
2. Collaboration and active participation by clients in their own treatment is essential and is an important vehicle to developing a positive therapeutic alliance.
3. CBT is goal oriented and problem focused. While building the whole person is important, addressing the client's immediate goals through developing problem-solving skills is the initial focus of treatment.
4. CBT emphasizes the present, at least initially. This is especially important because, for many substance using clients, focusing on resolving past difficulties, especially those associated with the development of substance use, may be of little benefit unless the day-to-day issues of drug use are addressed (Mitcheson et al. 2010). For example, it is difficult to address childhood trauma, which may have contributed to the development of a drug problem, if the client is attending sessions intoxicated.
5. CBT teaches the client to be their own therapist and emphasizes relapse prevention. CBT helps clients to develop skills in self reflection and self-management during sessions, but the emphasis of therapy is what happens outside therapy; hence, "homework" is important.
6. CBT is relatively brief and time limited.
7. CBT sessions are structured but not inflexible. Structure helps the process of therapy and also models a structured way of thinking and being for the client. Clients with substance use issues sometimes have chaotic and disorganized lifestyles that enable and maintain further substance use.
8. The focus is on thoughts and beliefs, linked to the idea of developing the client as their own therapist through learning to manage their thoughts.
9. A variety of strategies are employed to address thinking, mood, and behavior management skills. All these strategies are drawn from a clear theoretical base.
10. CBT is based on a constantly evolving formulation, based on the scientist-practitioner approach.

48.2.1.2 The Scientist-Practitioner Approach

CBT is driven by the scientist-practitioner approach. That is, the practitioner applies the scientific method to understanding and addressing client issues. Therefore, in-session CBT is based on a constantly evolving cognitive behavioral case formulation that develops hypotheses that are collaboratively tested. This is referred to as "collaborative empiricism."

The case formulation is a way to put relevant information from an assessment into a guide for treatment. It looks at all factors that contribute to the client's presentation and how these might be addressed to meet the client's goals.

The "7Ps" is one method to understand the client's issues and develop a case formulation:

1. Presenting problem(s): What is the problem the client presents with? Are there issues that have been identified through the assessment? Is the client prepared to work on their presenting problem, or is it better to focus on a less salient problem initially?

2. Pattern and onset: What is the current pattern of substance use, how did it start, and how do the pattern and history of use impact on current strengths and vulnerabilities?
3. Predisposing factors: What are the client's vulnerability and risk factors (e.g., family history of drinking or drug use; trauma; or neglect in childhood)? Understanding these risk factors can help tailor treatment and indicate the need for referral. For example, if a client has a history of trauma, ensuring that treatment is "trauma informed" and does not inadvertently re-traumatize the client is not only client sensitive but can also assist in reducing the client's risk of relapse.
4. Precipitating factors: What are the client's immediate triggers to substance use (e.g., anxiety or stress, external cues)? Identifying immediate- and longer-term triggers for use can focus treatment substantially.
5. Perpetuating factors: What variables maintain substance use (e.g., homelessness, friendship circles, dependence)?
6. Protective factors: What protective factors does the client currently have at their disposal (e.g., friendship circle, attendance at meetings, clear insight)? These protective factors can be used to support treatment and can also be further developed in treatment.
7. Prognosis: What is the likely outcome of treatment for this client? Prognosis helps practitioners understand how to modify treatment options to realistically address client's needs. For example, if the client is highly likely to relapse given the current circumstances, harm reduction strategies may be most helpful at this stage, while trying to engage the client in 12-step groups may be setting them up for failure.

48.2.1.3 A Typical Session

Typically, CBT uses a structured session plan, and the session can be considered in three or four sections. Within those sections, the work is tailored to the client's needs, so the session format is both structured and flexible.

Carroll (1998) recommends the 20-20-20 rule: 20 min on review of the week, homework tasks, and issues arising during the week; 20 min on discussion and practice of a particular skill or topic linked to an issue from initial assessment or something that has arisen during the week (e.g., "since you've had a couple of close shaves this week, I thought we'd talk about high-risk situations today"); and then 20 min on recapping the session, agreeing on homework tasks, and planning for the next week. In reality, sometimes the middle 20 min takes up slightly more time than the first and third 20 min, and it may become a 15-30-15 rule.

Mitcheson et al. (2010) use a 4-part structure: (1) setting the agenda and recap of previous session, (2) dealing with the specific agenda items (i.e., the focus of the session), (3) planning for the next session, and (4) session review.

Structure is necessary because often clients do not have well-developed skills in structuring their own lives and this serves as a model to assist them to learn these skills. Therefore, generally in CBT, the structure is outlined to, and agreed with, the client at the beginning of each session. This practice is referred to as "setting an agenda".

It is important to note that "structured" does not necessarily mean "inflexible," and if issues arise, they should be incorporated into the agenda as appropriate. The purpose of the structure is to help the client learn how to structure activities themselves and so that it is clear to both the client and the practitioner what the focus is for the session. The structure is not rigid, and practitioners still need to use their clinical judgment and skills to determine what happens within the structure and when it may need to adapt to the immediate circumstances.

48.2.2 Application of CBT to Alcohol and Other Drug Treatment

48.2.2.1 Relapse Prevention

The original focus of Relapse Prevention (RP) (Marlatt and Gordon 1985) was to address the important issue of relapse after cessation of substance use (Marlatt and Donovan 2005), although it is now used in cases of controlled use and among alcohol and other drug users who are not yet abstinent.

The primary focus of RP is to identify and understand "high-risk situations" (which may be locations, people, or emotions) and for the client to develop behavioral coping strategies for those situations. RP distinguishes between a "lapse" (initial use after abstinence) and a "relapse" (continued use after abstinence). The main goals of RP are to (a) prevent relapse from occurring and (b) if a "slip up" does occur, to prevent the lapse from becoming a long-term relapse. Salient beliefs about the effects of using alcohol and other drugs, such as "I can only relax if I have a drink," can increase the risk of lapse and relapse in specific situations, for example, during periods of high stress (Mitcheson et al. 2010).

The cognitions and emotions underlying a lapse, such as perceived loss of control, guilt, and self-blame, may lead to an "abstinence violation effect" (AVE) (i.e., yielding fully to using substances – "I've blown it so I might as well use whatever I want. . ."). Several early studies have shown a link between the AVE and relapse. If the person attributes the lapse to a moral or personal failure, AVE may be activated and relapse is more likely, but if the person sees the lapse as external and controllable, relapse is less likely. Therefore, self-efficacy (one's belief in one's ability to achieve a goal – in this case abstinence or controlled use) and expectancies (beliefs about the effects of alcohol and other drug use) become very important and are one of the main targets of treatment.

In the RP model, negative emotional states are considered to be one of the main predictors of relapse. Therefore, developing emotional regulation skills is an important component of preventing relapse (Witkiewitz and Marlatt 2004).

48.2.2.2 Cognitive Therapy

Cognitive therapy of substance abuse was first developed by Aaron Beck et al. (1993); based on his general Cognitive Therapy (CT) model, CT is now the psychological treatment of choice for a wide range of psychological and psychiatric problems. Cognitive Therapy is often used interchangeably with the term cognitive behavior therapy, but the latter refers to the collection of CBT interventions,

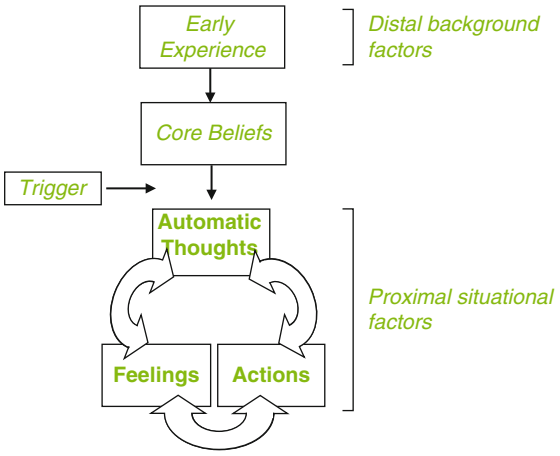

Fig. 48.1 General Cognitive model

including CT; Cognitive Therapy is a type of CBT. Typically, in the literature an intervention described as "cognitive behavior therapy" is a pure or modified form of CT or sometimes a pure or modified form of RP.

Not dissimilar to RP, the theory of CT focuses on "proximal situational factors," such as cognitive, behavioral, emotional, and physiological variables that are immediate triggers for substance use, and "distal background factors," such as personal history, long-standing cognitive and behavioral variables, and personality traits that provide a context or set of vulnerabilities for substance use and may act as maintaining factors (Wenzel et al. 2012).

A general Cognitive model is outlined in Fig. 48.1. In this model, early experience develops our fundamental beliefs about ourselves and the world (distal background factors). These beliefs are referred to as "core beliefs" or "schemas" and can be positive or negative. At various times, our core beliefs may be triggered by people, places, or events (proximal situational factors) that lead to "automatic thoughts" or the day-to-day thoughts that drive our feelings and behaviors. Everybody's early experiences are different, even those from the same family, and their core beliefs will therefore be highly individualized.

48.2.2.3 Coping Skills Therapy

Coping skills therapy (CST) was developed by Monti and Rohsenow (1999), initially in conjunction with cue exposure therapy, and has many similarities to relapse prevention. Like RP, CST is based on social learning theory but focuses more heavily on learning behavioral coping skills and less on cognitive skills, in high-risk situations. It also teaches specific social skills both to improve relationships that have been damaged through alcohol or other drug use and to help develop healthy, nonusing social networks.

Monti also used cue exposure therapy to extinguish alcohol-related cues and to enable an environment to test out coping skills (Monti and Rohsenow 1999). Although there are several positive studies linking cues to relapse, cue exposure

has not shown the same effectiveness in substance use treatment as it has in other mental health areas, such as post-traumatic stress and obsessive-compulsive and panic disorders (e.g., Kavanagh et al. 2006), and CST is more commonly practiced as a stand-alone treatment.

The four main components of stand-alone CST are relapse prevention training, social and communication skills training, training in coping with urges and cravings, and mood management. Project MATCH, the largest alcohol treatment outcome study, used a modified CST as the cognitive behavioral arm of the study (Kadden et al. 2003) and found modified CST equally as effective as motivational enhancement and 12-step facilitation.

48.2.2.4 Brief CBT

A number of brief CBT interventions have been developed, primarily based on relapse prevention or coping skills therapy. In general, brief CBT interventions are best utilized for moderate- to high-risk use and with people who are dependent but are not ready to engage in intensive treatment. They have been found to be effective for a range of substance users, including those who are dependent.

In Australia, Baker et al. (2003) developed a two or four session intervention for amphetamine users that combined Motivational Interviewing with brief RP, including coping with cravings and lapses, controlling thoughts about using (triggers, seemingly irrelevant decisions, and pleasant activity scheduling), and preventing relapse (refusal skills and relapse planning). Methamphetamine users can be difficult to engage and retain in treatment, and a briefer intervention may be more desirable for this group.

A six-session intervention for cannabis dependence (Copeland et al. 2001; Rees et al. 1998) has also been developed in Australia, using a combination of Motivational Interviewing and CBT. Sessions include goal setting, planning to quit, dealing with lapses and relapses, refusal skills, managing withdrawal, and cognitive and coping skills.

In addition, a range of brief therapies (one to two sessions) and brief interventions (5–20 min) for moderate- to high-risk drinking have been developed, based on social learning and CBT principles, including coping skills training and relapse prevention (see Substance Abuse and Mental Health Services Administration 2012).

48.2.2.5 Low-Intensity CBT

"Low-intensity" mental health interventions are those that are less intensive for the practitioner or service and sometimes, but not necessarily, less intensive for the client. They can be delivered face-to-face, usually by nonspecialists in drug treatment, for example, by medical practitioners delivering screening, brief intervention, and referral into treatment (SBIRT), and through psychoeducational groups and "advice clinics." They may also be delivered using a range of remote and self-directed technologies, such as books and paper-based materials, CD-ROMS and computers, and online media such as the Internet (NICE 2011).

Low-intensity interventions have the advantage of increasing reach, access, flexibility and responsiveness, patient choice, and cost-effectiveness

(Bennett-Levy et al. 2010) and can be used to address a range of substance use problems from prevention to tertiary treatment. Cognitive behavioral therapies are ideally suited to the low-intensity environment because they are typically brief, structured, and easily manualized.

There have been a number of different types of low-intensity interventions developed in recent years. Advice clinics, for example, operate in mental health services in the UK (White 2010) as a one-off 30-min appointment with a clinician.

Guided self-help CBT (Kenwright 2010) involves either paper-based or Internet-based self-directed learning materials that are supplemented by lower-intensity guidance from a practitioner as required. The practitioner is available to answer questions about the material, but otherwise the client works through a brief program essentially on their own.

While brief telephone counseling has been accessible for decades in some countries, more recently there has been development of a number of similar services using email and online media. An online service in Australia (counsellingonline.com.au), for example, uses live online chat-style environment to provide brief interventions for people with substance use problems. An early review of the service showed that the types of clients and the types of presenting issues are markedly different from telephone counseling, with younger people and methamphetamine users making up a greater proportion of online clients (Swan and Tyssen 2009), suggesting that these types of interventions do indeed increase reach and access to hard-to-reach populations.

In addition, interventions have been developed for SMS (mobile phone text messaging) (Shapiro and Bauer 2010), mail (Kavanagh et al. 2010), and online-facilitated peer support (Griffiths and Reynolds 2010) (see www.theshedonline.org.au for an example).

48.2.2.6 "Third Wave" Therapies

Broadly, third wave therapies integrate mindfulness theory and practice with CBT, although Schema-Focused Therapy (SFT) (Young et al. 2003), originally developed for personality disorders, is also sometimes considered in the third wave. SFT is an integration of CBT, gestalt, psychoanalysis, and psychodrama theories and strategies. There has been some attempt to use SFT for co-occurring personality and substance use disorders (Ball and Young 2000), but it is not widely used in substance use treatment.

Mindfulness approaches focus on the cultivation of acceptance of negative thoughts and feelings and strategies to regulate affect. Some have suggested that there is a substantial difference between mindfulness-based and traditional CBT, enough to consider them as a new therapy, but Hoffman et al. (2010) have noted that the (limited) evidence available suggests that the mechanisms of action between new and traditional CBT approaches are more similar than different.

Among the range of mindfulness-based cognitive therapies, only one has been developed specifically for substance use disorders. Mindfulness-based relapse prevention (MBRP) is an 8-week outpatient program that incorporates traditional relapse prevention strategies with mindfulness practice such as acceptance and meditation (Bowen et al. 2009).

Other mindfulness-based interventions that have been trialed with substance users include dialectical behavior therapy (DBT), acceptance and commitment therapy (ACT), and mindfulness-based cognitive therapy (MBCT).

DBT was originally developed for borderline personality disorder (BPD) and is a combination of standard CBT strategies for emotion regulation and four mindfulness-oriented modules of mindfulness, distress tolerance, emotion regulation, and interpersonal effectiveness (Linehan 1993). It has been recommended by its developers as most suitable for very complex substance use disorder presentations, including people with co-occurring substance use and BPD, substance use disorder and chronic suicidality, and substance use disorder that has not responded to traditional CBT over time, especially if emotion regulation is a key factor in relapse. It is not considered a first-line treatment for uncomplicated substance use disorder.

ACT is a form of applied behavior analysis (ABA) and grew from the same radical behaviorist perspective as ABA (Hayes 2004). The central components are cognitive diffusion (i.e., learning not to place a high importance on thoughts), acceptance of thoughts without judgment, and commitment to action based on one's core values.

Similarly, MBCT is a cognitive therapy that uses traditional cognitive therapy combined with mindfulness strategies. It has been primarily developed for the treatment of depression but has been used to address other mental health issues, including substance use disorder (Hoppes 2006).

48.2.2.7 CBT to Address Co-occurring Problems in AOD Treatment

Alcohol and other drug clients rarely present to treatment with *only* substance use disorders. Up to 80 % of clients seen in substance use treatment have co-occurring mental health issues (Mills et al. 2009), up to 80 % have been exposed to at least one traumatic event in their life with nearly half screening positive for some post-trauma symptoms (Dore et al. 2012), and an estimated 50–80 % have some level of functional cognitive impairment (Bates et al. 2002).

CBT is ideally suited to substance use treatment populations with comorbid disorders because it is highly structured, enabling those with cognitive deficits to gain benefit from the treatment, and has been well researched both in populations where these disorders are primary and in populations where these disorders co-occur with substance use problems.

48.2.3 Evidence to Support CBT

48.2.3.1 Traditional CBT Approaches

There is extensive evidence for the effectiveness of CBT for a range of mental health problems, including substance use disorders. McHugh et al. (2010) showed moderate effect sizes (on average $d = 0.45$) with the largest treatment effects found for cannabis use disorders, followed by cocaine, opioids, and then polysubstance dependence. Magill and Ray (2009) showed similar results.

The inconsistent use of the term "cognitive behavior therapy" to describe both interventions based on common general principles and specific treatments makes it difficult to distinguish outcomes between the different styles. However, overall, CBT appears to be both effective and long lasting when compared with general drug counseling, treatment as usual, and no treatment controls and is effective in both individual and group formats (McHugh et al. 2010).

A number of studies have examined specific relapse prevention treatments, including a systematic review of psychosocial interventions for substance use disorders (Dutra et al. 2008), which included five studies of RP that showed positive but modest outcomes on retention in treatment and substance use. Compared to other types of behavioral therapies, RP was most effective in maintaining abstinence post treatment (39 % abstinent post treatment), suggesting that if abstinence is the treatment goal, RP may be the treatment of choice.

Other treatments that draw heavily from the RP model have also been found to be effective. The matrix model (Rawson et al. 1995), for example, is a 16-week manualized group-focused outpatient intervention that includes many components of RP, plus a range of other behavioral interventions such as contingency management and 12-step participation. It has been found to be effective for a range of drug users, including amphetamine and cocaine users (Shoptaw et al. 2009).

In a review of CBT, RP, and contingency management, Dutra et al. (2008) found that the group referred to as "CBT therapies" (which included cognitive therapy and therapies drawn from CT such as dialectical behavior therapy) had lower dropout rates (35 %) than RP (57 %), equivalent effect sizes, but lower abstinence rates post treatment.

CBT appears to be more effective with the addition of contingency management, although the evidence is mixed and limited (McHugh et al. 2010). Project COMBINE (Anton et al. 2006) showed that in combination with medical management, "combined behavioral intervention" (including CBT) was as effective as naltrexone, and both were more effective than placebo for alcohol dependence.

48.2.3.2 Brief Therapy and Low-Intensity Interventions

A range of brief therapies have been developed and tested for a range of substance use disorders. Baker et al. (2005) trialed a brief two- and four-session treatment for methamphetamine users, drawn substantially from RP, and was found to be effective in increasing abstinence among severely dependent injecting methamphetamine users.

A five-session brief cognitive behavioral intervention improved confidence to resist urges in high-risk situations among heroin and methamphetamine users and a six-session brief intervention increased abstinence Yen et al. (2004); and sense of control over drug use and reduced drug-related problems among cannabis users (Copeland et al. 2001). Brief CBT interventions have also been shown to assist with cocaine, alcohol, and polydrug dependence (see Magill and Ray 2009 for a review) and with drug-related problems such as insomnia (Currie et al. 2004) and drug-related harms (Marlatt et al. 2012).

Low-intensity interventions have also been shown to be effective. A large international World Health Organization (WHO) study looked at screening

(using the AUDIT) and 5-min brief intervention in primary care (McAvoy et al. 2001). Computer-assisted CBT has been found to improve abstinence and treatment engagement compared to standard outpatient treatment for substance dependence (Kay-Lambkin et al. 2009) and for co-occurring mental health and substance use problems with some studies showing equivalent or better outcomes than treatment with a psychologist face-to-face.

48.2.3.3 Third Wave CBT Therapies

There is a more limited, but growing, research base for third wave, mindfulness-based therapies than other CBT interventions. Studies have shown reductions in substance use and craving and increases in acting with awareness and acceptance using mindfulness strategies (Bowen et al. 2009; Luoma et al. 2008).

Öst (2008) notes that the trial methods used in mindfulness-based studies have not been as stringent as that of traditional CBT so caution is required when comparing the two. A recent review of mindfulness-based therapies concluded that the data do not favor mindfulness-based interventions over traditional CBT interventions (Hofmann et al. 2010), with both showing similar effectiveness.

48.2.4 International Considerations

Cognitive behavior therapy has its origins in the developed world and is heavily based on Western concepts and models of illness (Rathod and Kingdon 2009). However, it is a broad and flexible model of care based on a well-grounded treatment formulation that can accommodate cultural and other influences and as a result has been adapted and successfully used across a number of cultures.

For example, in some cultures, such as many Indigenous groups, collective history is an important component of their world view (Rathod and Kingdon 2009) or, in CBT terms, their core beliefs. Although CBT does not tend to delve deeply into the past to routinely reappraise it, past issues are not precluded when they are driving or maintaining current problems, and CBT can easily accommodate these types of cultural differences.

Similarly, Hodges and Oei (2007) have examined the compatibility of CBT with Chinese values and have identified a number of potential issues for CBT, including the value Chinese and other Asian cultures place on conformity, certainty and discipline, persistence and a strong work ethic, and respect for authoritarian systems. In Asia more broadly, there is also a high level of stigma around mental health issues and a tendency for somatization (i.e., expressing mental health issues as physical symptoms).

Hodges and Oei (2007) argue that because CBT is structured and can be adapted to a more instructive rather than collaborative style, it may suit cultural contexts needing a directive and structured therapy style. This adaptation may suit the need for certainty and authority in these cultures and can also reduce the stigma of mental health treatment by using a more "coaching" style of therapy. Finally, they note that with the expansion of CBT using Eastern and Buddhist mindfulness strategies, CBT is well suited to Asian cultures.

CBT for mental health problems has been applied successfully in a range of diverse cultures and countries including, but not limited to, Pakistan (Rahman et al. 2008), Japan (Chen et al. 2007), and China (Williams et al. 2006) and among Latina women in the USA (Amaro et al. 2010), Muslims (Williams et al. 2006), and Aboriginal Australians (Laliberté et al. 2010), using a more narrative style of delivery sometimes referred to as "bush CBT" (Rickwood 2006). Although many of these studies are not specifically related to substance use disorders, the cross-cultural applications still apply.

48.3 Conclusion

CBT is an umbrella term that describes a wide range of therapies that have in common a focus on thoughts and beliefs as the central driver of, and the solution to, effective emotion regulation.

It tends to be relatively brief and highly collaborative. It is collaboration that is considered to be key in the development of the therapeutic alliance, an essential component of the application of CBT. It comes in a wide range of formats, including group and individual therapy, longer-term and brief therapy, and low-intensity interventions such as computerized CBT.

It is one of the most researched treatments in the world; both traditional (e.g., cognitive therapy) and newer (e.g., dialectical behavior therapy) models have shown effectiveness for treating substance use disorders.

Its structured and theoretical base makes it ideally suited to issues that co-occur with substance use problems, including common mental health problems, cognitive impairment, and trauma.

It has been adapted and applied across a range of cultures and countries. CBT is ideal for adaptation to non-Western cultures because of its flexible collaborative style and its reliance on effective case formulation.

Psychodynamic Psychotherapy for the Treatment of Substance Use Disorders

49

Edward J. Khantzian

Contents

Abstract

An understanding of addiction to drugs and alcohol and their treatment is reviewed from a modern-day psychodynamic perspective drawing on ego/self-psychology and object relations and attachment theory. The author places emphasis on addictions as a self-regulation disorder. Deficits in regulating emotions, self-esteem, relationship, and self-care interact variably and cause individuals so affected to relieve their pain and suffering associated with these deficits with addictive substances and to become addicted to them. The author considers addictive drugs to be appealing not so much as pleasure producing but rather as agents that create and foster comfort and contact for individuals who are discomforted and disconnected. Alcohol and drugs relieve and/or change states of anhedonia, dysphoria, and unbearable painful emotional states. Individuals so affected discover that depending on the particular emotional pain with which they suffer, they discover a preference for a particular class of drugs. The action of each class of drugs is linked to how individuals discover these specific effects in relation to the suffering associated with their self-regulation problems.

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment: International Perspectives*, DOI 10.1007/978-88-470-5322-9_38,

Appreciating these vulnerabilities and in contrast to outmoded psychoanalytic modes of detachment, passivity, and more strictly interpretive approaches, the author considers, from a contemporary perspective, important therapeutic elements and attitudes necessary to address the vulnerabilities such as being more interactive and to incorporate attitudes of kindness, support, empathy, respect, patience, and instruction in order to build and maintain a strong therapeutic alliance.

49.1 Introduction

Psychodynamic psychotherapy rests on the principle that important psychological factors are at the root of addictive behaviors and that these factors can be identified, targeted, and modified in the treatment relationship and thus eliminate or make less likely a reliance on addictive substances. We have reviewed elsewhere (Dodes and Khantzian 2005) early psychoanalytic formulations that, with a few exceptions, emphasized the use of addictive drugs as a regressive, pleasurable adaptation, whereas more contemporary formulations have placed emphasis on a progressive adaptation where addictive substances serve to cope with painful internal states and conditions and overwhelming external realities. Contemporary psychodynamic psychiatrists dating back to the 1960s and 1970s have reported on the nature of addictive vulnerability based on an appreciation of factors from structural, ego/self, and object relations perspectives. These perspectives underscore how disturbances and vulnerabilities in experiencing and processing emotions, sense of self/self-esteem, interpersonal relations, and behaviors are important if not essential factors for the development and maintenance of addiction to substance of abuse. Although there is empirical data supporting the efficacy of psychodynamic psychotherapy for a range of psychiatric disorders, including treatment of addictive disorders (Khantzian 2012; Dodes and Khantzian, in press; Shedler 2010), there is a rich clinical literature describing how an appreciation of the underlying dynamics of addictive behavior can be fathomed and targeted in individual and group therapy to help addicted individuals understand and modify these dynamics and overcome their addictive attachments and behaviors (Dodes and Khantzian, in press). Although individual psychotherapy is the primary focus here, this treatment modality should not or need not compete with complimentary or alternative treatments when psychodynamic findings indicate the need for additional or alternative treatment as will be discussed subsequently.

What is reviewed in this chapter derives mainly from clinical work with drug-dependent individuals. The chapter rests on the assumption that the case method and the treatment relationship (practice-based evidence) yields rich data that illuminates the nature of addictive disorders and provides keys to understand and treat patients who suffer with addictive illness. We will emphasize the more contemporary formulations that provide a basis to appreciate the vulnerabilities that underlie reliance on addictive substances and behaviors and how individual and group psychotherapy can ameliorate addictive suffering and modify addictive behavior.

49.2 Addiction as a Self-regulation Disorder

Addictive disorders are rooted in suffering – not pleasure-seeking or self-destructive motives as early psychodynamic formulations suggested. The suffering is mainly a consequence of addicted individual's inability to regulate their emotions, self-esteem, relationships, and behavior, especially their self-care (Khantzian 2012). From the earliest phases of infancy through early adult development, environmental influences around parenting, safety, comfort, traumatic abuse/neglect, and peer relationships are crucial in influencing self-regulation capacities, and significantly, experiences from earliest phases of development, for which there are no memories or symbolic representations, have some of the most profound influences (Gedo 1986; Khantzian 2003; Krystal 1988; Lichtenberg 1983). In this respect, these developmental factors weave their way through addictively prone individuals' ways of experiencing their emotions, sense of self, relationships, and behaviors to make addictions more likely. In what follows, I will elaborate on these self-regulation problems and how appreciation of the dynamics involved can guide effective individual and group therapeutic responses.

49.2.1 Disordered Emotions

Contemporary psychodynamic views have placed heavy emphasis on how addictively prone individuals suffer in the extreme with their emotions. Affect life at one extreme is perplexing, elusive, cut off, or absent, and at the other extreme feelings are overwhelming and unbearable. Terms such as alexithymia, disaffected, anhedonia, non-feeling states, etc., have been adopted to capture how feelings are not available, elusive, and disconnected, thus causing individuals so effected to feel empty, cut off, and unable to use their emotions to guide their reactions and behavior (Krystal 1988; McDougall 1984; Krystal and Raskin 1970). Krystal and Raskin (1970) appreciated some of the bases of these deficits when they described how feeling life has a normal developmental line (and potential for arrest or regression secondary to trauma or neglect) and how at the outset of life feelings are undifferentiated (i.e., anxiety cannot be distinguished from depression), that feelings are somatized, and without words (alexithymic). Addictively prone individuals at the other extreme suffer because feelings are intense, overwhelming, and unbearable. In this respect, more recent psychoanalytic investigators stressed defects in affect and drive defense and deficits in psychological structure to explain how substance-dependent individuals adopt addictive drugs to make intolerable feelings more bearable, especially those involving rage and aggression (Khantzian 1978; Weider and Kaplan 1969; Wurmser 1974).

These same investigators have elaborated on how addictive drugs can stimulate and enliven individuals who are cut off or feel vacuous or help to contain disorganizing and intense emotions when such affect is threatening or overwhelming. In these reports, the activating properties of stimulants and the releasing effects of low to moderate doses of depressants are described as correctives for individuals

experiencing their feelings as cut off or vacuous (Khantzian 1975, 1985, 1997). Weider and Kaplan (1969) coined the term "drug of choice," elaborating on how individuals self-select addictive drugs as a "prosthetic" to cope with overwhelming adolescent anxiety. The works of Wurmser (1974) and Khantzian (1985) emphasized the calming or muting action of opiates or obliterating doses of alcohol, especially for feelings of rage and aggression. What should be emphasized here is that these reports better focused on and appreciated how addictive drugs were used not for pleasure or self-destructive motives as early psychoanalytic studies stressed, but more precisely to selectively alleviate or make more tolerable affects that were confusing, unbearable, or intolerable.

More recently, Khantzian (2012) has considered some of the more subtle psychodynamics of addictive behavior that are insufficiently considered, namely, why so much of addictive behavior unfortunately continues to be linked to pleasure seeking (especially by neuroscientists) and how and why seeking relief from addictive drugs most usually produces more suffering than it relieves, and yet addicted individuals persist in the use of their drugs. In the former instance, especially those who are alexithymic and confused about their feelings, addicted individuals wittingly and unwittingly substitute the suffering which they perpetuate and control with use for the suffering they do not understand or control. The operative changes from simply relieving suffering, for one of control where they better understand and control it. In the second case, Khantzian (2012) has speculated, based on clinical observations, that addicted individuals often suffer with pervasive anhedonia and that the often magical relief they first experience with their drug of choice is experienced as euphoric, which is interpreted as pleasure, when in fact it is the result of relief of the anhedonia.

49.2.2 Disordered Relations with Self and Others

Dating back to the seminal contributions of self-psychologist Heinz Kohut (1971, 1977), recent formulations have underscored the faulty and troubled ways addictively inclined individuals suffer with troubled inner states of discomfort about self. Inner states of cohesion and well-being are lacking and lead to periodic and/or chronic feelings of helplessness, fragmentation, impoverishment, shame, and a low sense of self-worth; as a consequence, feelings of rage and defensive postures of omnipotence and bravado often result to mask underlying feelings of emptiness and inadequacy (Khantzian 2012). Dodes (1996, 2002) has emphasized how feelings of helplessness and compensatory narcissistic rage are major factors leading to drug use and relapse. On this basis, he formulated that addictions are a compulsive disorder and thus subject to traditional psychodynamic psychotherapy. Along similar lines, Director (2005) focused on feelings of powerlessness, unimportance, and compensatory reactions of omnipotence to explain recurrent relapse to addictive drugs in her work with two addicted women.

The importance of these perspectives is that clinicians must be sensitive and fine-tune to the troubled sense of self and painful lack of self-regard drug-dependent

individuals struggle with and to be appreciative of how the off-putting defensive characteristics can be understood as necessary postures to avoid narcissistic collapse. Furthermore, these findings indicate the significance of appreciating how such dynamics basically interweave with the compulsion to self-medicate the emotional pain such dynamics engender.

Troubled sense of self and self-esteem issues powerfully interact with relational difficulties for substance-dependent individuals. The early psychoanalytic literature linked addictions to pathological or problematic dependency. In contrast, contemporary psychodynamic views underscore problems of interpersonal isolation and counterdependence (Khantzian 2012). Although drug-dependent individuals suffer from enduring troubled, disrupted, and often traumatizing histories, experiencing or expressing their needs for connection and comfort with others that they so desperately need cannot be dared or accepted. As a consequence, feeling lonely, cut off, and alienated becomes a tragic way of life. Psychodynamic explorations of these attachment problems, more often infantile in origin, reveal how such adaptation is powerfully connected to addictive use of substance to deal with the associated distress and the pain perpetuating defenses of self-sufficiency, disavowal of need, and counterdependence (Flores 2004; Khantzian 2012; Walant 2002; Weegmann 2004).

Considering how these problems with sense of self, self-worth, and relational difficulties cause drug-dependent individuals so much pain and difficulty in tolerating distress and interactions with others, it should not be surprising the action of addictive drugs provide temporary relief and "solutions" to their intrapsychic and interpersonal pain and difficulties. Stimulants can counter states of helplessness, enfeeblement, and deflation in narcissistically injured individuals as well as provide a psychic boost for deflated self-esteem, or opiates can contain or offset the dysphoria that comes with disorganizing rage and make connections to others less threatening (Dodes 1996; Khantzian 1997, 2012). Low to moderate doses of alcohol can help shamefully restricted individuals, briefly, and therefore tolerably, to breakthrough and connect with others (Krystal and Raskin 1970).

These examples offer support for the recurrent clinical observation of why and how addictive substances become so compelling in individuals who suffer with an injured sense of self, poor self-esteem, and problematic interpersonal relations.

49.2.3 Disordered Self-care

Khantzian (2012) and Khantzian and Mack (1983) have described a fundamental ego function involved in life and in addictive vulnerability, namely, a capacity for self-care.[1] Self-care functions ensure safety, well-being, and survivability. They are underdeveloped or deficient in substance-dependent individuals. Early in his career, Khantzian (2012) cites his experience working with intravenous heroin users in

[1]The following sections on self-care and treatment are based in part on a recent report by Khantzian (2012).

a methadone program wherein he describes his powerful subjective reaction to the idea of injecting oneself with illicit drugs; he realized that his reaction of repugnance to that idea was one of countertransference (modern theorists would call it an "intersubjective" response, namely, patients getting the therapist to feel something that the patient is unaware or incapable of). Tactfully sharing his recoil and discomfort with the many patients he was evaluating consistently and monotonously elicited reactions of little or no emotions or concerns of alarm about crossing the so-called needle barrier. Subsequently, working with abstinent drug- or alcohol-dependent patients in psychotherapy, Khantzian was struck by how such lack of worry or thought persisted when no longer addicted. He observed these deficiencies to be involved in interpersonal and physical mishaps, slipups around management of important matters of unpaid premiums, lapsed licenses, and preventable medical and dental problems. It is in this context that he began to conclude that a major contributing factor to the development of addictions involved deficits in a capacity for self-care. Namely, addictively prone individuals think and feel differently about potential and real situations of harm and danger. Anxiety, fear, worry, and apprehension are deficient or absent and fail to guide such individuals in risky or self-harmful situations. There is a failure to draw cause/consequence relationship in the face of risk. Where anticipatory shame and guilt might guide when self-care capacities are better developed, in addictively prone people shame and guilt come after the fact (e.g., "I felt stupid and bad when I did that" [rather than] "I will feel stupid and bad if I do that"). It is the combination of self-care deficits interacting with the pain and suffering involved in self-regulation difficulties that makes vulnerable individuals more likely to develop addictive disorders.

49.3 Implications for Psychodynamic Psychotherapy

Treating clinicians need to constantly appreciate the underlying dynamics and vulnerabilities that govern addictive behavior. Considering the difficulties addicted individuals have with regulating their emotions, sense of self/self-esteem, relationships, and self-care, therapists need to think about therapeutic elements and attitudes that would best attune and respond to the suffering and dysfunction with which patients struggle. Old psychoanalytic approaches of passivity, therapeutic detachment, and strictly interpretive methods, therefore, would not be the order of the day. In fact, such approaches could perpetuate the confusion, shame, alienation, and disconnect with which addicted patients suffer. Thus, a contemporary psychotherapist needs to be more interactive (balance talking and listening) and incorporate attitudes of kindness, support, empathy, respect, patience, and instruction in the service of building and maintaining a strong treatment alliance. These elements are essential in order to deal with and overcome the problems with inaccessible or intense emotions, shame, broken self-esteem/relationships, and poor self-care (Khantzian 2012). Confrontation should be avoided and used only rarely such as concerns about safety but done in a way that preserves self-esteem.

The psychodynamic findings that have been outlined previously are considered in what follows, not only in reference to individual psychotherapy but also as they apply to considering other treatments, especially psychodynamic group therapy, as they can enhance individual therapy or be considered as alternatives when there are psychodynamic indications to do so.

Remembering how cut off addicted patients can be with their thoughts and feelings, therapists can help significantly with these dysfunctions by actively drawing out, identifying, and labeling feelings that begin to surface or seem evident to the therapist. When patients protest they do not know what they are feeling, treating clinicians should avoid concluding it is resistance or denial but rather use such interactions to invite and support the patient to consider the challenge of exploring, discovering, and understanding their feelings and emotions. Allen, Fonagy and Bateman (2008) have coined the term *mentalization* to emphasize one of the most basic aspects of psychotherapeutic work in general, but the concept preeminently applies to work with addicted patients, namely, to persistently focus on helping patients to access feelings, put them into words, and sustain them. Beyond individual therapy, the narrative and storytelling traditions that occur in group therapy and 12-step meetings are often very beneficial in helping patients to develop a capacity to recognize, express, and practice their own thoughts and feelings.

For those patients who struggle with and self-medicate intense and threatening emotions, particularly anger and rage, considerations and efforts should be made to help them contain and moderate the feelings that can feel so dangerous to self and others. It is worth noting how the positive treatment relationship and the therapist's concern for the safety of the patient is in and of itself a containing influence. For those whose rage and violent feeling derive from trauma and neglect, it is crucial to acknowledge and validate the legitimacy of such reactions and help them to understand how and why they have resorted to addictive drugs to contend with such intense emotions. Carefully timed and gentle explorations of the experiences that engender such emotions can gradually diminish or resolve such intense affect. In this context, judicious use of legitimate psychotropic medications targeting these affects can significantly attenuate the intensity to make the working through of these affects in psychotherapy more doable.

The support and empathy exhibited by the therapist in response to drug patients' pervasive sense of shame and broken self-esteem (predisposing and consequential) are a vital element in engaging and retaining such patients in psychotherapy. Such an approach helps in gaining inroads on the confusing and elusive ways in which the sense of self and others is experienced by substance users. Openings are created to focus on and help identify and resolve feelings of powerlessness, defensive rage, and reactions of omnipotence that are experienced and often surface in treatment. Patience, support, and kindness remain of paramount importance and allow for opportunities to therapeutically address and help the patient and the therapist, understand, and better work out problems with off-putting characteristics. These characteristics are more often reactive and defensive secondary to feelings of helplessness as well as feelings of unimportance (Dodes 1996; Director 2005).

And for those who are seemingly void of emotions and disengaged, the therapist may draw on their own energy and liveliness to help activate and enliven patients who are so affected. Again, group therapy experiences often can be invaluable in this respect in instilling and validating a better sense of self/self-esteem.

The issue of low self-esteem of substance abusers is related to their tendency to be avoidant of relationships and interpersonally isolated. They feel undeserving of the care and connection to others. Remaining interactive, engaging, and empathic are important elements in responding to patients' fear of and ambivalence about relationship. Impassivity and detached interpretations can be counter-therapeutic and devastating. Tactful focus on the ambivalence can materially stimulate possibilities of beneficial connections to others. It is in this respect that the connections stimulated by individual and group therapy are extraordinarily helpful in addressing and ameliorating the attachment difficulties and sense of alienation with which substance-dependent individuals struggle.

The thoughtless and unfeeling behaviors of substance-dependent patients that are characteristic of self-care deficits become manifest in the treatment relationship by the alarm stirred in the therapist by patients' risky or dangerous behaviors. Such reactions and interactions can alert the therapist and patient to how such deficits are major factors for patients to use and relapse to additive behaviors. The therapist should be unhesitant in using their reactions of alarm and concern that patients stir to identify the lack of such reaction in the patient. Constant attention to patients' poor self-care can help to instill a growing awareness of how their self-care deficits continuously leave those so affected continuously in harm's way, especially those involved with the harm and dangers associated with addictive substances. Long-term therapy often helps in getting at and understanding the developmental and environmental roots of these deficits, but a here-and-now, active, instructive approach is essential in order to stimulate and better develop a better capacity to recognize, anticipate, and avoid self-harm, particularly related to addictive substances. Finally, "We need to help patients use self-respect, feelings of apprehension/worry, relationships with others, and thoughtfulness as a guide for safe behavior and self-preservation" (Khantzian 2012, p. 278).

49.4 Conclusion

Contemporary psychoanalytic understanding of addictive disorders has generated and documented observable, developmental, structural, ego/self, and object relations disturbances that predispose to and maintain addictive behaviors and attachments. These findings provide a basis to identify the ways in which these disturbances affect feelings, self-esteem, relationships, and self-care. They provide a basis to guide therapists in targeting these problems psychotherapeutically. Impassive and strictly interpretive approaches are contraindicated if not damaging. Modern psychotherapeutic treatments employ more interactive, supportive, and empathic attitudes and techniques to help patients and therapist to focus on vulnerabilities and dysfunction that perpetuate addictive suffering and pain. This contemporary

perspective provides understanding, hope, and more effective means to overcome the compelling, self-defeating, and tragic causes and consequences of addictive disorders.

Mindfulness as Behavioural Approach in Addiction Treatment

Marianne T. Marcus

Contents

Abstract

This chapter discusses the concept of mindfulness and reviews the theoretical and empirical evidence for the use of mindfulness-based strategies as behavioral approaches to addiction treatment. Mindfulness is defined as bringing nonjudgmental, intentional awareness to present-moment experiences. Mindfulness encourages the individual to acknowledge and accept thoughts, feelings, and bodily sensations as they arise, recognizing their impermanence. Mindfulness training as a component of addiction treatment is particularly compelling because it fosters acceptance of one's moment-to-moment thoughts and experiences rather than engaging in substance use to avoid or suppress distressing thoughts and emotions. Various psychological constructs associated with substance abuse, including experiential avoidance, stress, thought suppression, craving, self-compassion, and coping,

have been studied in relation to mindfulness-based interventions for addictive disorders. Mindfulness-based behavioral interventions targeting these constructs, and addressing specific recovery populations, are explored. Those interventions include mindfulness-based stress reduction, mindfulness-based cognitive therapy, dialectical behavior therapy, acceptance and commitment therapy, mindfulness-based relapse prevention, mindfulness-based therapeutic community treatment, and mindfulness-oriented recovery enhancement. The intervention protocol, relevant mindfulness practices, and outcome measures studied for each of these treatment strategies are presented. The chapter concludes with a review of empirical evidence for mindfulness-based interventions for treatment of addictions and suggestions for future research.

Alcoholism is the disease of living elsewhere.
William Alexander (1997)

50.1 Introduction

Substance use disorders (SUDs) continue to be a public health problem across the globe. An estimated 230 million individuals, or 5 % of the adults across the world, had used an illicit drug in 2010. Twenty-seven million adults worldwide are estimated to be problem drug users (World Drug Report 2012). The World Health Organization reports that 2.5 million deaths result from harmful alcohol use each year, 320,000 of which are young people between the ages of 15 and 29 (WHO 2012). In the United States 58.3 million people aged 12 or older reported heavy drinking, 20.6 million were classified with substance dependence, and 68.2 million were current users of a tobacco product in 2011 (SAMSHA 2012). Substance use disorders are a major cause of disability and death worldwide. While the scope of SUD and the impact of the problem on health are incontrovertible, effective treatment and prevention of relapse pose challenges to researchers and clinicians. Addiction is defined as a chronic relapsing brain disease involving reward, motivation, memory, and related circuitry which leads to biological, psychological, social, and spiritual manifestations (ASAM 2012). Much has been learned about addiction and its underlying neurobiology over the past few decades. Addiction changes the brain causing characteristic behavior changes associated with enhanced motivational drive for the substance and weakening of control over this drive (Volkow et al. 2011). There has been increasing interest in the utility of mindfulness-based strategies in addressing the cognitive and emotional processes and behavioral urges underlying addiction (Dakwar and Levin 2009). The purpose of this chapter is to discuss mindfulness and review the theoretical and empirical evidence for use of mindfulness as a behavioral approach to addiction treatment.

50.1.1 Mindfulness

Mindfulness is defined as "paying attention in a particular way: on purpose, in the present moment, and nonjudgmentally" (Kabat-Zinn 1994). Mindfulness encourages awareness and acceptance of thoughts, feelings, and bodily sensations as they arise, recognizing their impermanence. Mindfulness teaches the individual to acknowledge and accept their experiences rather than to modify or suppress them. Mindfulness changes in one's relationship to present-moment experience have been described as "reperceiving" (Shapiro et al. 2006) or "attentional control," which may facilitate more mindful behavioral responses. The three axioms of mindfulness are posited to be *intention*, or the deliberate aspect of mindfulness; *attention*, or focus on the present moment; and *attitude*, or nonjudgmental acceptance (Shapiro et al. 2006). Mindfulness practice originated in the Buddhist tradition, but the associated set of skills can be taught independent of religious and cultural associations and in a variety of interventions (Baer and Krietemeyer 2006). Mindfulness-based approaches have been applied to a number of individuals and groups from those with physical or mental disorders to those who seek to reduce stress to improve general well-being (Baer and Krietemeyer 2006). Common elements in these approaches include focusing on whatever activity is at hand, whether it is breathing, walking, or eating, and observing the activity carefully. When the mind wanders the mindfulness practitioner is taught to bring the focus back to the target activity, observing and accepting the cognitions, sensations, or emotions that arise without judging or attempting to change them.

50.1.2 Mindfulness-Based Approaches to Substance Use Disorders

The utility of mindfulness training as a component of treatment for individuals in recovery from addictive disorders is particularly compelling. Mindfulness fosters an accepting attitude of one's moment-to-moment thoughts and experiences and might be expected to reduce the tendency to engage in substance use to avoid or suppress distressing thoughts and emotions. Various psychological constructs associated with substance abuse, including experiential avoidance, stress, thought suppression, craving, self-compassion, and coping, have been targeted in studies of mindfulness-based interventions for addictive disorders. Studies of mindfulness approaches as adjunct for particular treatment modalities such as therapeutic communities or relapse prevention programs are also increasing. Behavioral interventions which incorporate varying degrees of mindfulness training have been integrated into addiction treatment. Those interventions include mindfulness-based stress reduction (MBSR) (Kabat-Zinn 1990), mindfulness-based cognitive therapy (MBCT) (Segal et al. 2002), dialectical behavior therapy (DBT) (Linehan 1993), and acceptance and commitment therapy (ACT) (Hayes et al. 1999). Three recent modifications of these approaches were developed

specifically for substance-abusing populations, mindfulness-based relapse prevention (MBRP) (Witkiewitz et al. 2005), mindfulness-based therapeutic community treatment (MBTC) (Marcus et al. 2009), and mindfulness-oriented recovery enhancement (Garland et al. 2010). Descriptions of these approaches with examples of how they have been applied in the research literature are explored as follows.

50.1.3 Mindfulness-Based Stress Reduction

Mindfulness meditation is the foundation of the mindfulness-based stress reduction (MBSR) program developed by Kabat-Zinn in 1979 to teach patients with chronic physical and mental health problems how to improve their lives with a focus on reducing stress. Mindfulness meditation, derived from Buddhist *Vipassana* or insight meditation, is distinguished from *Samatha* or concentrative meditation techniques by its attentional style. Mindfulness meditation is a diffuse technique, allowing thoughts, feelings, and sensations to arise and experiencing them in a nonjudgmental, detached, and accepting manner. In contrast, concentrative meditation focuses on a single stimulus such as the breath or a mantra, excluding anything else (Dakwar and Levin 2009). MBSR was originally used as an adjunct to treatment in a wide range of chronic illnesses and as a psychosocial treatment approach to mental illnesses (Kabat-Zinn 1990, 2003; Reibel et al. 2001; Kabat-Zinn et al. 1992). Early studies indicate that MBSR was used to assist patients with psychosocial adaptation to chronic pain (Kabat-Zinn et al. 1986), depression (Teasdale et al. 2000); fibromyalgia (Kaplan et al. 1993), anxiety (Miller et al. 1995), and binge eating disorder (Kristeller and Halleh 1999). MBSR was also found to be a highly effective psychosocial approach for managing stress and mood disorder in cancer patients (Speca et al. 2000; Carlson et al. 2003). There is also evidence that MBSR is an effective stress reduction technique in nonclinical populations (Shapiro et al. 1998). MBSR is now being used as an adjunctive treatment for an increasing number of disorders (Ludwig and Kabat-Zinn 2008) including addiction. As originally developed, MBSR involves 8 weekly class sessions of 2 and a half to 3 h each. The teaching of MBSR is guided by a manual and includes a variety of mindfulness meditative exercises including breathing, sitting, walking, and eating. Hatha yoga postures are included as a way to cultivate awareness rather than as exercise. The body scan, or sequential focus on sensations in parts of the body, is also taught in MBSR. Classes are highly experiential with discussions of the various exercises as they occur. MBSR also includes homework. Participants are given audiotapes and encouraged to practice 45 min of formal, and 5–15 min of informal, mindfulness daily. Didactic information on stress is provided as well as a workbook to record weekly events associated with stress and mindfulness practice. The sixth class is an all-day experience of mindfulness, usually experienced in silence. Recommended guidelines for MBSR teachers are provided by the Center for Mindfulness at the University of Massachusetts Medical School where MBSR originated. Minimum qualifications include a master's degree in a mental health field, personal experience of daily meditation practice, attendance

at 2-week-long silent meditation retreats, 3 years' experience with hatha yoga, 2 years' experience teaching stress reduction, and attendance at a 5- or 7-day residential professional training program in MBSR (Baer and Krietemeyer 2006). Teacher certification is available through the Center for Mindfulness (Center for Mindfulness).

50.1.3.1 MBSR in Addiction Treatment

MBSR as described, with and without adaptation, has been studied in several addiction treatment approaches. Alterman et al. (2004) conducted a pilot study comparing outcomes of 18 randomized substance-dependent residents of a recovery house who received mindfulness meditation and standard treatment to 13 patients who received standard treatment alone. The only significant findings in this small study were changes in problem levels over time reported on the Addiction Severity Index (ASI) (McLellan et al. 1985). The ASI decreased in the mindfulness group, whereas it increased in the standard treatment alone group. The authors found that half of the MBSR group reported continued practice of mindfulness meditation 5 months after the baseline assessment which may indicate additional benefits from the intervention that were not captured by measures used in the study. Vidrine et al. (2009) conducted a randomized control pilot study to evaluate a mindfulness-based group therapy for nicotine dependence. Participants ($n = 158$) were randomly assigned to the mindfulness intervention or "standard of care." The 8 weekly MBSR sessions were integrated with a cognitive behavioral relapse prevention-based intervention consistent with a standard coping skills training approach (Fiore et al. 2000). This study found that mindfulness was negatively associated with the level of nicotine dependence and withdrawal severity and positively associated with a sense of agency related to cession, factors that have been found to be critical in assessing vulnerability to relapse.

50.1.4 Mindfulness-Based Cognitive Therapy (MBCT)

Mindfulness-based cognitive therapy (MBCT), which combines many of the components of MBSR with cognitive behavioral therapy (CBT), was designed to focus on depression and depressive relapses (Segal et al. 2002). The MBCT intervention is also taught in 2-h weekly class sessions for eight weeks in group format. Homework and group discussion are included but not a full day mindfulness session. MBCT differs from MBSR in the inclusion of a 3-min mini-meditation, or breathing space, which encourages focus on awareness of experiences for brief periods during the day to discourage automatic reactive behavior. During sitting meditation, MBCT practitioners are encouraged to think deliberately of difficult sensations or troubling problems, to face them, and work with them, rather than trying to avoid them. While MBCT does not include exercises to change thoughts traditionally taught in cognitive behavioral therapy, it does incorporate cognitive exercises related to thoughts, moods, and feelings. Participants are encouraged to develop relapse prevention action plans to implement when they experience

a negative mood. MBCT sessions are outlined in Segal et al. (2002). No formal set of qualifications have been proposed for MBCT therapists, but training in counseling, psychotherapy, or cognitive therapy is considered important (Baer and Krietemeyer 2006). MBCT has been found to decrease relapse of depressive disorders in several studies (Teasdale et al. 2000; Ma and Teasdale 2004; Teasdale and Ma 2004; Teasdale and Williams 2000).

50.1.4.1 MBCT in Addiction Treatment

Hides et al. (2010) conducted a systematic literature search to identify studies using CBT for the treatment of co-occurring depression and substance use. They found limited evidence for the effectiveness of CBT alone or in combination with antidepressant medication for the treatment of these comorbidities. They also concluded that while CBT was more efficacious than no treatment, there was little evidence that it is more efficacious than other psychotherapies for depression and substance abuse. They indicate that CBT may be enhanced for these disorders by combining it with other approaches such as mindfulness to induce a mediating or interacting effect on outcomes. Dakwar and Levin (2009) indicate that MBCT has not been evaluated for the treatment of substance abuse disorders alone, but there is interest in the theory, clinical application, and research of MBCT for mental health and SUD.

50.1.5 Dialectical Behavioral Therapy

Dialectical behavioral therapy (DBT) was originally developed for borderline personality disorder (BPD) (Linehan 1993), but it has been adapted for other conditions and comorbidities such as eating disorders, depression, and BPD with substance abuse (Dakwar and Levin 2009). The central dialectic in DBT is between acceptance and change, accepting the self while working toward change through skills training. The DBT treatment program incorporates an initial commitment to participate for a year, individual and group psychotherapy, shorter less formal exercises, and a cognitive behavioral component which includes four skill modules: core mindfulness, interpersonal effectiveness, emotion regulation, and distress tolerance. A manual is available to guide therapists of DBT (Linehan 1993). Therapist training for teaching DBT does not stipulate that the therapist have an ongoing formal mindfulness practice, but they must understand and be familiar with mindfulness and plan and practice the exercises in advance. Sharing and discussion of experiences is important in DBT as in MBSR and MBCT. A major point of discussion is the continued practice of mindfulness to confront the dialectical worldview emphasizing balance and synthesis of opposing ideas. DBT has been evaluated and found to be efficacious in reducing suicidal behavior and emotional problems in individuals with BPD (Neacsiu et al. 2010). A number of successful randomized control trials (RCTs) provide substantial supporting evidence for DBT as an efficacious treatment for BPD (Linehan et al. 2006; DeVylder 2010).

50.1.5.1 DBT in Addiction Treatment

For substance-dependent individuals DBT specifically targets behaviors that decrease abuse of substances, alleviate physical discomfort such as withdrawal, diminish urges and cravings, avoid cues to abuse, and increase reinforcement of healthy behaviors (Dimeff and Linehan 2008). The dialectic for the substance-dependent individual is to push for cessation of drug abuse (i.e., change) while accepting the possibility of relapse (i.e., acceptance) (Dimeff and Linehan 2008). Two RCTs have evaluated the efficacy of DBT for individuals with BPD and substance dependence. Linehan (1999) compared DBT with community treatment as usual among polysubstance-dependent women with BPD. Findings of the study indicate that individuals in the DBT group were significantly more likely to remain in treatment, achieved greater reductions in drug abuse, attended more individual therapy sessions, and sustained these outcomes at the 16-month follow-up assessment. In a second RCT with 23 opiate-dependent individuals, Linehan et al. (2002) compared DBT with comprehensive validation therapy plus 12 Steps (CVT + 12S), a manual-guided strategy that combines the major acceptance-based approaches in DBT with 12-Step participation. Both treatment conditions were associated with reductions in opiate abuse, but only the DBT participants retained those reductions during the last 4 months of treatment. The CVT + 12S intervention was more effective in retaining subjects to treatment. Subjects in both treatment conditions showed overall reductions in psychopathology levels from baseline and posttreatment and 16-month follow-up assessments.

50.1.6 Acceptance and Commitment Therapy

Acceptance and commitment therapy (ACT) is a behavioral and cognitive intervention which combines mindfulness and acceptance processes with commitment and behavioral change processes to induce psychological flexibility or the willingness to experience the present moment as it occurs (Hayes et al. 2011). A goal of ACT is to decrease experiential avoidance or the unwillingness to experience negative feelings, sensations, or urges and take action to eliminate those experiences. ACT strategies link behavior change to the individual's values, encouraging redirection and commitment to actions that are in line with those values (Hayes, et al. 2012). There is empirical evidence for the efficacy of ACT across a broad range of problems. A recent review by Ruiz (2010) reported 25 outcome studies (18 randomized trials) in clinical psychology, 27 (16 randomized trials) in health psychology, and 14 randomized studies in other areas including sports, stigma, organization, and learning. ACT is suggested as a unified model of behavior change applicable for major psychological problems as well as routine counseling to empower individuals to deal with social contexts (Hayes et al. 2012).

50.1.6.1 ACT in Addiction Treatment

Several studies illustrate application of ACT to addiction treatment. Smout et al. (2010) compared ACT with CBT in a randomized control trial for

methamphetamine use disorders ($N = 104$). Study participants were randomly assigned to 12 weekly 60-min individual sessions of CBT or ACT. Both interventions were guided by manuals adapted for the study. Doctoral- and master's-level therapists with experiential training in each intervention conducted the sessions. Therapy sessions were audiotaped and reviewed for adherence. The study found no significant differences between the groups in treatment attendance and methamphetamine-related outcomes. Both groups significantly improved over time on use, negative consequences, and dependence severity. The study authors suggest that ACT may be a promising alternative for treatment for methamphetamine use disorders. Vieten et al. (2010) developed and tested an acceptance-based coping intervention for alcohol dependence relapse prevention (ABCRP). The intervention combined elements from MBSR, MBCT, MBRP, and ACT. The first 3 months of the study were devoted to the development of a manual for the 8 weekly 2-h group-based sessions and a follow-up booster session to be administered 4 weeks later. The therapists were experienced in addiction treatment and the delivery of mindfulness-based interventions. The ABCRP intervention was administered to two consecutive cohorts of 22 participants in a local substance abuse treatment program, and participant feedback used to refine the manual. Adults over the age of 18 who were in their first 6 months of having quit drinking were then recruited to test the intervention. Pre- and post-data were collected on study completers ($N = 23$). Positive chances were reported in craving (decrease of 32 %; $P = .06$), positive affect (increase of 20 %; $P = .004$), negative affect (decrease of 32 %; $P = .0001$), emotional reactivity (decrease of 17 %; $P = .0001$), psychological well-being (increase of 15 %; $P = .004$), perceived stress (decrease of 23 %; $P = .002$), and mindfulness (increase of 21 %; $P = .002$). Mean percent days abstinent were 97.6 post intervention and 87.5 after 6 months, a change that was not statistically significant. These findings provide preliminary support for the clinical promise of ABCRP and the feasibility of adding acceptance-based coping in a mixed treatment for recovering alcoholics. Stotts et al. (2012) conducted a Stage I behavioral therapy trial of ACT for methadone detoxification. The goals of the study were to (1) decrease experiential avoidance and (2) make commitments to engage in value-based goals rather than allowing negative feelings and thoughts or withdrawal symptoms to influence behavior. Participants were opioid-dependent individuals currently taking methadone treatment at a licensed facility ($N = 56$). The study was a 24-week, randomized controlled parallel group pilot trial of two treatment conditions, an ACT-based opioid detoxification treatment or drug counseling. Both treatments were delivered in twenty-four 50-min weekly sessions. Both were guided by established protocols and audiotaped to assure adherence. No difference was found in opioid use during treatment, but 37 % of participants in the ACT group were successfully detoxified at the end of treatment compared to 19 % in the drug counseling protocol. Fear of withdrawal during detoxification was differentially reduced in the ACT group suggesting that ACT-based treatment has promise as an adjunct to detoxification in this population.

50.1.7 Addiction-Specific Mindfulness Treatment Approaches

50.1.7.1 Mindfulness-Based Relapse Prevention (MBRP)

Craving and negative affect are commonly endorsed risk factors for relapse, or the return to addictive behaviors after treatment (Witkiewitz et al. 2012; McMahon 2001). Marlatt and Gordon (1985) developed a cognitive behavioral relapse prevention program to teach skills such as identifying and coping with high-risk situations, triggers that threaten abstinence. MBPR combines mindfulness meditation practices with relapse prevention skills (Witkiewitz et al. 2012). Cognitive behavioral skills situations are taught with mindfulness practices to increase the participant's awareness and acceptance of challenging cognitive, emotional, and physical states. Unlike ACT and DBT in which mindfulness is one element of multicomponent therapies, mindfulness is the foundation of MBRP (Witkiewitz et al. 2012). MBRP, based on a manual, is taught in group format in weekly 2-h sessions. Each session includes formal guided meditation practice of 20–30 min. Participants are also introduced to experiential exercises which encourage nonjudgmental acceptance of negative thoughts and feelings rather than suppression of those potential cues to relapse. As an example, they are taught the SOBER space exercise as an alternative response to negative cues. The exercise teaches the participant to "stop," "observe," "breathe," "expand awareness," and "respond mindfully" to negative affective states rather than attempting to avoid them or change them (Witkiewitz et al. 2012). MBRP participants also receive meditation audiotapes and are assigned to practice daily (Chawla et al. 2010). Therapists who deliver MBSR in clinical trials typically hold master's degrees in psychology or social work and have a background in cognitive behavioral therapy and mindfulness meditation practice (Witkiewitz et al. 2013). Several studies have examined the effect of MBPR on client outcomes post treatment. Bowen et al. (2009) evaluated substance use outcomes in a randomly assigned group of inpatients and outpatients following an intensive stabilization period of treatment. Study participants ($N = 168$) were randomly assigned to an 8-week outpatient MBRP program or to treatment as usual (TAU), a 12-Step model with psychoeducational content. Findings indicate that consistent homework compliance, attendance, and client satisfaction support the feasibility of delivering MBRP in this setting. Significantly lower rates of substance use were reported in the MBRP group as compared to the TAU participants in the 4-month posttreatment period. MBRP participants also experienced greater decreases in craving and increases in acceptance and acting with awareness when compared to TAU participants. In a follow-up study Witkiewitz and Bowen (2010) examined the relation between depressive symptoms, craving, and substance use among the participants in the previous study. They found that craving mediated the relation between depressive symptoms and substance use among the TAU group but not the MBRP group. MBSR also attenuated the relation between posttreatment depressive symptoms and craving for 2 months following the intervention, a moderation effect which predicted substance use 4 months following the intervention. Witkiewitz et al. (2013) highlight the differing

perspectives on craving, biological, cognitive, and affective and suggest that a focus on all three may be important in understanding the impact of MBRP on craving. The authors stress that research which integrates information from brain to behavior is necessary to determine the various mechanisms of behavior change following mindfulness-based treatments such as MBRP (Witkiewitz et al. 2012).

50.1.7.2 Mindfulness-Based Therapeutic Community Treatment (MBTC)

Mindfulness-based therapeutic community treatment (MBTC) is an intervention designed to capture the congruence between the tenets of the therapeutic community (TC) method and the teachings of MBSR and to affect progress and retention in TC treatment through lowered stress. MBTC combines MBSR with the recovery curriculum offered in TCs, the "rules and tools of right living" (DeLeon 2000). Therapeutic communities (TCs) play an important role in the treatment of substance use disorders. TCs offer a unique approach to treatment, a highly structured social learning environment in which the community itself is the key element of behavior change. The major goal of the TC is to encourage and support social learning, which fosters changes in behavior and attitudes and the more elusive phenomenon of change in world view and self-image (DeLeon 2000). TCs hold that SUDs are disorders of the whole person which contribute to problems with socialization, cognitive and emotional skills, and psychological development. TCs stress living in the personal present and developing a positive work ethic, personal accountability, economic self-reliance, acceptance of family responsibility, community involvement, and concern for others (DeLeon 2000). Studies have shown that individuals who complete TC treatment have lower levels of substance use, criminal behavior, unemployment, and depression than they had prior to treatment (Simpson et al. 1997; Wexler et al. 1999) For individuals whose lives were characterized by impulsiveness and lack of self-control, the TC environment is restrictive and intrinsically stressful (Marcus 1998). TC dropout rate is significant, often as high as 50 %, with the highest attrition occurring the first 30–60 days after admission. A considerable body of research has shown that stress is associated with the initial acquisition of SUD behaviors in vulnerable individuals as well as with relapse or return to use following abstinence (Brown et al. 1995; Kreek and Koob 1998; Adinoff et al. 1998; Gordon 2002; Sinha 2001). MBTC includes the content and exercises taught in MBSR delivered in six longer sessions to coincide with the orientation phase of the TC. The didactic content is aligned with the TC teachings presented in orientation. Each session is illustrated with a corresponding principle of TC treatment. As an example, in Session l the MBSR protocol theme addresses reducing the tendency to operate on automatic pilot and stresses becoming awake. Session l of MBTC adds the TC principle that *right living* is being in the personal present, the here and now, and stresses that "to be awake is to be alive." The protocol and method are described in Marcus et al. (2007). Meditation practices include formal sitting, walking, the body scan, and mindful movement. Therapists are master's prepared in psychology or counseling, have a long-standing personal practice of mindfulness, and have completed the 7-day intensive training program

for health professionals offered by the Center for Mindfulness, University of Massachusetts Medical School. Further teacher preparation included 6 h of training on the TC method, a thorough orientation to the use of the manual, and a 6-week internship during which teachers observed and participated while an experienced, certified MBSR teacher taught initial sessions. A Stage 1 behavioral therapy trial of MBTC, using historical control methodology ($N = 459$), compared TAU ($N = 164$) with MBTC ($N = 295$) on measures of stress, the Symptoms of Stress Inventory (SOSI), and salivary cortisol in an 18-month residential TC. A survival analysis of time to dropout did not show a significant difference between the groups; however, the level of participation in MBTC was associated with decreased likelihood of dropout, and higher SOSI scores at baseline were associated with increased likelihood of dropout (Marcus et al. 2009). A linguistic analysis of written stories of stress from the historical control group ($N = 140$) and 253 MBTC participants was conducted to assess self-change. Data were collected five times over a 9-month period. Linguistic analysis showed no difference between the groups over time; however, over all time points, the MBTC group used fewer negative emotion words than the TAU group (Liehr et al. 2010). Three themes emerged from the content analysis of 38 written stories of stress conducted to formulate focus group questions to give voice to participants in the MBTC arm of the study. Participants identified three qualities of the experience: *utility*, or the usefulness of MBTC for calming the self; *portability*, or the potential for transferring MBTC lessons out of the classroom to real-life experiences; and *sustainability*, or the potential of MBTC to contribute to future goal attainment (Carroll et al. 2008). These studies provide support for further research on MBTC.

50.1.7.3 Mindfulness-Oriented Recovery Enhancement (MORE)

Mindfulness-oriented recovery enhancement (MORE) is a ten-session intervention for alcohol dependence which was adapted from mindfulness-based cognitive therapy, the mindfulness treatment developed to prevent depression relapse. MORE combines mindfulness meditation practices such as breathing and walking with addiction-specific experiential exercises to encourage participants to apply mindfulness principles to relapse triggers, craving, thought suppression, stress, and unconscious substance use behaviors (Garland et al. 2010). The MORE intervention, guided by a manual, was taught by a master's-prepared social worker who was trained in cognitive behavioral therapies and had mindfulness experience. Garland et al. (2010) compared MORE to an alcohol dependence support group (ASG) in a randomized controlled pilot study. The ASG intervention also included ten therapist-facilitated sessions in which participants were encouraged to discuss feelings and provide peer support but were not given prescriptive information for change. MORE participants were asked to practice mindfulness exercises for 15 min a day, while ASG participants were asked to journal on support group topics for 15 min per day. Study participants were 37 alcohol-dependent residents of an 18-month TC. Study outcomes revealed that MORE participants had significantly larger decreases in stress over the 10-week intervention period when compared to the ASG. The MORE participants also had significant decreases in

thought suppression, while the ASG participants increased thought suppression during the intervention period. Mindfulness training also increased physiological recovery from alcohol cues and modulated alcohol attentional bias, factors considered to be related to alcohol misuse (Garland et al. 2010). Eighteen members of the MORE group were interviewed in a subsequent qualitative to increase understanding of mindfulness-related treatment effects (Garland et al. 2012). Individual interviews of 15–30 min were conducted to ask open-ended questions about the MORE intervention, what participants liked, what could be improved, and how the experience benefitted the participant. A grounded theory approach and constant comparative methods were used in analyzing the interview data. Three general categories emerged: effects of the intervention on participant awareness, effects on coping, and participant perceptions of the most beneficial aspects of MORE. These findings provide further support for the therapeutic benefits of mindfulness training for individuals in recovery from alcohol dependence by eliciting their first-person experience which, in turn, informs and guides clinicians in providing the training.

Table 50.1 summarizes the major intervention models used in the studies of mindfulness-based approaches for SUD treatment. Most of the studies report adaptations of the original MBSR program developed by Kabat-Zinn (1990). The manner and degree to which mindfulness was integrated into the intervention was specified. Mindfulness content is foundational to MBSR, MBCT, MBRP, MBTC, and MORE, while ACT and DBT include only informal or brief mindfulness practices. Outcome measures relevant to initial recovery from substance abuse and prevention of relapse were collected across the studies.

50.2 Conclusion

While meditation practices were added to addiction treatment well over four decades ago, it was only in early 2000 that empirical reports of *mindfulness* meditation began to appear in the literature (Black 2012). Since that time there have been an increasing number of studies, and two systematic reviews, indicating the potential benefit of mindfulness approaches to the treatment of SUDs (Zgierska et al. 2009; Chiesa and Serretti 2013). Chiesa and Serretti (2014) note that the reasons why mindfulness may be of benefit to SUD treatment are related to the potential of mindfulness training to develop a nonjudgmental attitude toward distressing thoughts and feelings, adapt to one's own thought patterns, and accept present-moment experiences without attempting to suppress unpleasant experiences by using substances of abuse. These authors reviewed 24 quantitative, controlled studies of mindfulness-based or associated treatments for SUDs. The study interventions included MBSR, MBCT, MBRP, DBT, and ACT. Control conditions involved nonspecific educational support groups and wait-list controls. All four of the studies of smoking cessation reviewed showed significant benefits for the mindfulness condition over controls. While there was limited evidence that mindfulness interventions can reduce substance use over controls in studies of other substances such as alcohol, opiates, cannabis, methamphetamines, and

Table 50.1 Mindfulness approaches in addiction treatment

Intervention	Protocol	Mindfulness content	Outcome measures
Mindfulness-based stress reduction (MBSR)	8 weekly 2-h. classes, didactic information on stress, workbook	Variety of mindfulness meditative exercises, experiential discussion	Stress, addiction severity, level of dependence, withdrawal severity
	Therapist qualifications: master's degree, mindfulness experience, retreat attendance	Homework: 45 min. of formal and 15 min. of informal mindfulness practice daily guided by audiotape	
	Manual		
Mindfulness-based cognitive therapy (MBCT)	8 weekly 2-h. classes, didactic – cognitive therapy concepts without change concepts, relapse prevention action plans	Variety of meditative practices, 3-min mini-meditation	Co-occurring depression and substance use
	Therapist qualifications: training in counseling and cognitive therapy considered important		
	Manual		
Dialectical behavior therapy (DBT)	Individual and group psychotherapy	Core mindfulness module	Treatment retention, reduction in drug use
	Four skill modules: core mindfulness, interpersonal effectiveness, emotion regulation, distress tolerance central dialectic: acceptance and change		
	Therapist qualifications: must understand mindfulness and plan and practice exercises		
	Manual		
Acceptance and commitment therapy (ACT)	Behavioral and cognitive content to increase psychological flexibility, behaviors linked to values, varying length of sessions across studies	Mindfulness content directed at reducing experiential avoidance	Craving, negative affect, emotional reactivity, stress, positive affect, psychological well-being, mindfulness, successful detoxification
	Therapist qualifications: experience in addiction treatment and mindfulness-based interventions		
	Manual		

(*continued*)

Table 50.1 (continued)

Intervention	Protocol	Mindfulness content	Outcome measures
Mindfulness-based relapse prevention (MBRP)	8 weekly 2-h. sessions, guided mindfulness meditation with established cognitive behavioral program to teach skills to cope with relapse triggers, audiotapes, daily homework	Mindfulness is foundation, SOBER exercise (stop, observe, breathe, expand awareness, respond mindfully)	Substance use, craving, acceptance, acting with awareness
	Therapist qualifications: master's in psychology or social work, mindfulness practice, cognitive behavioral therapy training		
	Manual		
Mindfulness-based therapeutic community (MBTC)	6 weekly 3-h. group sessions, MBSR with social learning environment and therapeutic community curriculum, mindfulness homework	MBSR content aligned with therapeutic community curriculum, mediation practice room with audiotapes	Stress (salivary cortisol, psychometric measures, stress narratives), progress in therapeutic community, retention
	Therapist qualifications: master's preparation in psychology or counseling, long-standing personal practice of mindfulness, 6-h. training in therapeutic community method, 7-day mindfulness retreat		
	Manual		
Mindfulness-oriented recovery enhancement (MORE)	10 weekly group sessions combined MBCT with variety of mindfulness exercises, experiential discussion of application of mindfulness to relapse triggers, therapeutic community setting	Variety of mindfulness meditative exercises, 15 min of daily mindfulness practice	Thought suppression, stress, physiological recovery from alcohol cues, alcohol attention bias
	Therapist qualifications: master's-prepared social worker with mindfulness experience, trained in cognitive behavioral therapy		
	Manual		

polysubstances, methodological limitations were of concern. Those limitations included small sample size, lack of randomization, relative paucity of objective measures of drug use, and insufficient information on treatment adherence and follow-up. Zgierska et al. (2009) reviewed 22 studies, 13 of which were controlled, and concluded that while there is preliminary evidence of the efficacy of mindfulness interventions, significant methodological limitations exist in most of the studies. Despite study limitations noted in both systematic reviews, there is sufficient evidence to support future research in this promising area. In addition to larger trials and randomization, future studies should include refinements and more rigorous methodology. Recommendations include standardization of treatment manuals to facilitate data pooling and replication, assessment of participants' mindfulness practice or "dose," and appropriate controls including biomarkers (Zgierska et al. 2009). Neuroimaging offers another important avenue for exploring the effect of mindfulness-based interventions on addiction treatment. Neural correlates have been found on fMRI for individuals who have had as little as an 8-week course of mindfulness meditation (Farb et al. 2007) as well as for long-term practitioners (Short et al. 2010). Westbrook et al. (2013) examined the neural pathways linking a mindful attention exercise to reduced craving for cigarettes. Imaging results suggest that mindful attention decreases craving-related activity in the brain. Considering the promising early results of mindfulness-based interventions for treatment of addictions and recent advances in neuroimaging to investigate brain changes in addiction, it should now be possible to apply these techniques to fully understand how mindfulness practice may contribute to better outcomes for those who experience the devastating effects of addictions (Brewer et al. 2012).

Contingency Management as Behavioural Approach in Addiction Treatment

51

John M. Roll and Bethany Fruci

Contents

Abstract

This chapter describes the underpinnings of the contingency management interventions for treating substance use disorders. It presents historical data establishing the efficacy of the procedures. Sections addressing key factors for the use of these protocols and current limitations are also included. In no way is the chapter meant to be an exhaustive review of the contingency management literature. Nor is the chapter intended to provide the necessary level of detail needed to implement these procedures. Instead, this chapter is a brief introduction to contingency management. Resources for implementation are included in the suggested reading section of this chapter. Contingency management interventions have shown remarkable promise for promoting the initiation of abstinence. The use of these protocols may increase overall treatment efficacy. The chapter is intended to introduce the reader to this class of interventions with the hope that they will be motivated to dig deeper into the extensive literature surrounding contingency management-based treatment of substance use disorders and associated comorbidities.

51.1 Introduction

At its heart drug abuse – addiction – is an easy concept to understand. People misuse drugs because the drugs make them feel good. This occurs either by inducing euphoria or by eliminating an unpleasant state, for example, pain or withdrawal. The effects of drugs are usually short lived. That is to say that the euphoria or relief usually lasts for hours, not days. In order to regain the sought-after effect (feeling good), the drug must be taken again and again and again. This repeated consumption quickly turns into addiction. Addiction is a vicious cycle in which the original efficacy of the drug is diminished and must be taken more frequently and at higher doses to obtain similar efficacy (i.e., tolerance and habituation occur).

Addiction is often further characterized by damage to the physiology of the person consuming the drug as a result of the drug's pharmacologic action. The lifestyle associated with compulsive drug seeking also damages the person – they do not take care of their personal health, and their relationships with others deteriorate and often are terminated. Compulsive users often engage in dangerous behaviors to acquire drugs such as engaging in sex trade work or engaging in violent criminal activity. Unchecked, the person in the grasp of this vicious cycle of addiction will most often die or at best adopt what is essentially a palliative existence. This tragic outcome is the result of a person simply wanting to feel euphoric or seek relief from a negative state, something every human alive can relate to.

Characterizing this downward spiral that starts with the universal quest to feel good in terms of a scientific framework is important if we are to fully understand, effectively treat, and eventually prevent the condition. One of the best frameworks for characterizing addiction comes from the field of the experimental analysis of behavior. While this field has its genesis in the distinguished work of scholars such as the British philosophers Lloyd Morgan, Edward Thorndike, and others (e.g., Boakes 1984), it was essentially popularized and is most closely associated with the operant psychology of B. F. Skinner (e.g., Skinner 1938; See Roll 2014 for discussion of the history and evolution of operant psychology's influence on behavioral pharmacology).

One of the seminal events in the growth of operant psychology was the development of laboratory preparations (operant chamber, eponymously known as a Skinner box) for the convenient study of operant behavior. Briefly (see McSweeney and Murphy 2014 for a detailed discussion of operant psychology) organisms could be put into the operant chamber, and under tightly controlled conditions their behavior could be studied. A common example would be to place a hungry rat in the operant chamber and allow it to press a lever for food. Rate of responding for food will increase as the rat acquires the lever-pressing repertoire and then plateau as the rat masters the behavior. This change in rate across experimental sessions demonstrates learning. The food, which maintains the responding in the foregoing example, would be considered a reinforcer. A reinforcer can be defined as a stimulus that increases the behavior it follows.

In this case food reinforces lever pressing and the lever pressing increases until the behavior has been mastered. Most would consider the food to be an example of positive reinforcement. That is to say the behavior produces a stimulus (food) which increases the homeostatic "good" of the rat. Another type of reinforcement that can be demonstrated in a laboratory preparation is negative reinforcement. An example of this would be a rat placed in an operant chamber that receives a shock every 2 min regardless of what the rat did, in other words, the shock is inescapable. However, if a lever is placed in the box and the rat presses the lever, the next scheduled shock can be avoided. As in the positive reinforcement example, the rat will acquire the lever-pressing behavior over time until it has mastered the behavior and maintains it at a level that avoids shocks. Negative reinforcement, which is reinforcement that removes an aversive state, like this occurs when a behavior eliminates a noxious stimulus.

The forgoing is not merely a historical footnote. The use of the operant chamber opened many avenues for the study of how drugs influence behavior. Early examples of this work were conducted by Skinner and Heron (Skinner and Heron 1937) who examined how caffeine and amphetamine (Benzedrine) impacted food-reinforced behavior and the extinction of that behavior.

However, the aspect of operant psychology that is of the most relevance to this chapter was the demonstration that naïve animals would self-administer most of the same drugs abused by humans. In an early study, Thomson and Schuster demonstrated that drug-naïve monkeys would self-administer morphine (Thompson and Schuster 1964). This was a seminal demonstration that drugs of abuse could serve as positive reinforcers analogous to other positive reinforcers like food and water. Since this demonstration, thousands of studies in which drugs are provided to organisms (human and nonhuman) contingent on an operant response have demonstrated the robustness of this phenomenon (e.g., Roll 2014). It is one of the more unambiguous and well-accepted *facts* that drugs of abuse act as sources of positive reinforcement. Similarly, it has been demonstrated in laboratory paradigms that drugs of abuse can also serve as powerful sources of negative reinforcement (e.g., Holz and Gill 1975; Kandel and Schuster 1977; Thompson and Schuster 1968; Negus 2006; Negus and Banks 2013). In brief, drug-dependent organisms will increase their responding for a drug when they are in a state of withdrawal (see especially the body of work of Negus for discussion of this). That is, the animal, or person, will increase their consumption of a drug to escape from a negative state. In situations such as this, the drug may function as a negative reinforcer.

This observation that drugs of abuse serve as sources of reinforcement, both positive and negative, has been an important observation in our quest to understand, treat, and prevent addiction. Many would argue that the goal of treatment (and prevention) efforts should be the diminution of the reinforcing efficacy of the drug of abuse.

To relate this operant framework back to the opening discussion about a drug user's quest to feel good, we can refine that description so that instead of describing a quest to feel good, we can describe a quest for reinforcement. This could be

positive reinforcement, which some might equate with euphoria or negative reinforcement, for example, the diminution of withdrawal symptoms. This conceptualization now allows us to place drug addiction and its associated sequela into the operant psychology framework.

To appreciate the utility of this operant framework for addressing addiction, one more point needs consideration, that is, that primary, or naturalistic, reinforcers are biologically important for the survival of the organism and hence the species. Food, water, and sex are crucial to survival and these are powerful sources of natural reinforcement. Human biology has evolved to be maximally sensitive to sources of reinforcement such as these. A detailed discussion of the neurobiology underpinning reinforcement is well beyond the scope of this chapter. Suffice it to say that an impressive array of neurobiological systems are in play. When a thirsty person takes a drink of water, it is a powerful source of reinforcement, and our neurobiology guarantees that in a similar state of thirst, we will again seek a drink of water. Unfortunately, most drugs of abuse interact with the same neurobiological system that governs our reinforcing relationship to primary sources of reinforcement. As popularized by a past director of the National Institute on Drug Abuse, Dr. Alan Leshner, drugs of abuse hijack this neurobiological system and insidiously shift a user's motivation toward a compulsive focus on drug-derived reinforcement. The result is that an addicted person develops a compulsive motivation to seek drug-based reinforcement and that that reinforcement is of exceptional strength.

While daunting, this conceptualization does point toward an effective treatment mechanism. In order to help an individual enter into recovery from drug addiction, it is necessary to reduce the reinforcing efficacy of the drug. We would argue that this is the goal of all drug abuse treatment efforts at some level. The cognitive behavior treatments seek to restructure thoughts about drugs or to reorganize a user's cognitions so that they conceptualize the negative aspects of drug use as being more salient than the positive aspects. Motivational therapies seek to alter the user's motivation to seek the drug reinforcement; pharmacologic and immunotherapeutic approaches seek to block the drug from ever interacting with the user's reward-related neurobiology. While some will surely disagree, we postulate that all successful treatment approaches can be couched in terms of lowering the abused drug's reinforcing efficacy. One approach that takes this as its stated goal is contingency management (CM). The remainder of this chapter will focus on this approach. We will briefly describe the basic science supporting the approach and discuss prototypic examples of how to use the approach, key factors to consider when using the approach, populations for which the approach has been used, barriers to implementation, and finally potential limitations to the use of the approach. A series of meta-analyses supports the use of CM (Dutra et al. 2008; Lussier et al. 2006; Prendergast et al. 2006). The interested reader is encouraged to consult these publications as they are much more detailed than this chapter. There also exist a number of books on the topic of CM. We especially encourage the interested reader to consult those listed in Table 51.1. This brief chapter can provide only a glimpse of the wealth of research on CM. Consulting these other texts is crucial prior to actual implementation of the procedure.

51.2 Contingency Management

51.2.1 Underlying Logic of CM Approaches

One of the clearest demonstrations of the underlying principle of CM-based interventions is found in a study by Nader and Woolverton (1991). In this study they allowed rhesus monkeys to make choices between intravenously delivered cocaine and food (Nader and Woolverton 1991). When the choice was between cocaine and a small amount of food, the monkeys showed a strong preference for self-administering the cocaine. However, when the dose of cocaine was held constant and the magnitude of the alternative source of reinforcement (food) was increased, the monkeys chose to self-administer cocaine on only about half of the choice opportunities. Finally, when the magnitude of the alternative reinforcer was increased even further, the monkeys selected the alternative reinforcer, food, almost exclusively. As discussed in Roll (2014), this well-designed experiment demonstrates the powerful impact of arranging an environment so that the organism needs to make choices between a drug and a salient, high-magnitude, alternative source of reinforcement. This finding has been demonstrated by many investigators working with different drugs, different alternative reinforcers, and different animal species (e.g., Carroll et al. 1989). When the magnitude of the alternative source of reinforcement is low, the drug has a powerful reinforcing efficacy. However, simply by elevating the magnitude of the available alternative sources of reinforcement, the reinforcing efficacy of the drug can be reduced to such a low level that it is not self-administered. That is to say, it is no longer an effective reinforcer.

It is reasonable to question how applicable these findings are to humans. In order to address this question, Higgins and colleagues conducted a similar study with human volunteers in which they investigated the impact of manipulating the magnitude of alternative reinforcers on cocaine self-administration (Higgins et al. 1994a). In this study, recreational cocaine users were recruited to participate in an outpatient study. Participants came to the laboratory where they made ten repeated choices between cocaine and money on a given day. Cocaine dose was 10 mg per choice and was held constant throughout the study. Money was used as an alternative source of reinforcement and was provided at three different levels: low, medium and high. During a given session monetary value was always held

constant. In each experimental session a participant made ten exclusive choices between cocaine and money. When the money value was low, participants elected to self-administer cocaine exclusively. As the value of the alternative source of reinforcement increased to a medium level, participants elected to receive about half of the available cocaine doses, and when the magnitude of the alternative was increased to a high level, participants switched their preference – relative to that demonstrated with the low magnitudes of alternative reinforcement – and elected to decline cocaine and receive only money. This procedure has been replicated with other types of drugs besides cocaine (e.g., Roll and Newton 2008; Roll et al. 2000). Exactly as in the Nader and Woolverton study with monkeys, the penchant for humans to self-administer drugs typically decreases in an orderly and predictable fashion as the amount of the alternative source of reinforcement increases. These data demonstrate that providing a salient alternative source of reinforcement of sufficient magnitude reduces a drug's reinforcing efficacy. As noted, we consider this to be the hallmark of the successful treatment of drug addiction. Contingency management approaches take advantage of this observation and seek to arrange a drug user's environment so that they can garner salient alternative sources of reinforcement when abstaining from drugs and forfeit that reinforcement when consuming drugs (note this section has been adapted from Roll 2014; also see Andrade and Petry 2014).

51.2.2 Prototypic Examples

Contingency management can take many forms, but in all cases it is a technique that clinicians use to *engineer* a drug user's environment so that the drug user must choose between drug use (maintained by the drug's reinforcing efficacy) and other nondrug reinforcers. The salient nondrug reinforcers that have often been employed included access to housing (Milby et al. 1996), access to employment (Silverman et al. 2012), provision of vouchers which can be exchanged for monetarily based goods and services (Higgins et al. 1994b), access to prizes which are valued by the user (e.g., Petry and Martin 2002), escape from judicial sanctions (Prendergast et al. 2008), and access to one's monetary resources (Ries et al. 2004). Several research groups have developed potential lists of other types of reinforcers that can be employed, and these include such things as reduced clinic fees, access to clinic-sponsored social events, fee rebates, and donated goods and services (e.g., Amass and Kamien 2008; Roll et al. 2005).

While the CM class of interventions have been used for most types of drug abuse treatment (Higgins et al. 2008), they have, in our opinion, been most successful for those types of addictions for which no viable pharmacotherapy exists. This largely excludes opioid addiction and nicotine addiction as both of these disorders can be controlled with pharmacotherapy (e.g., opioids: Bart 2012; nicotine: Aubin et al. 2013). That is not to say that CM cannot be a useful adjunct for the management of opiate addiction. For example, take-home doses of methadone that are delivered contingent on compliance with clinic regulations and the continued provision of

drug-free urine tests is a relatively common practice (e.g., Stitzer et al. 1992). Contingency management may also have utility in treating nicotine addiction (Ledgerwood 2008), but in our experience CM is usually a secondary focus to the pharmacotherapy, which is the first-line treatment of these disorders. Please note that even when good pharmacotherapy is available, some populations (such as pregnant women) may not be able to use the pharmacotherapy. In cases such as this, CM may become a very important treatment modality (e.g., Higgins et al. 2012. However, we still do not have accepted pharmacotherapies for psychostimulant addiction (excluding nicotine addiction), especially cocaine and methamphetamine. It is for these disorders that we believe CM is a useful first-line approach. There are two types of CM that are most commonly employed in the treatment of psychostimulant addiction. The first, popularized by Higgins (e.g., Higgins et al. 1994b), is perhaps best described as voucher-based reinforcement therapy (VBRT) and the second popularized by Petry (e.g., Petry and Martin 2002) is variously referred to as the fishbowl technique and prize-based CM, but is more accurately known as variable magnitude of reinforcement CM (e.g., Silverman et al. 2008). Examples of each are provided below, and in the following section the key factors related to the efficacy of the procedures are discussed.

Steve Higgins at the University of Vermont first demonstrated the efficacy of VBRT in a relatively large randomized clinical trial designed to assess the intervention's impact on cocaine-using individuals (Higgins et al. 1991). The basic procedures for this type of intervention are as follows: patients receive vouchers for the provision of biological samples (urine or breath) that indicate no recent drug use. Participants receive a voucher each time they test negative for the target drug. These vouchers can then be exchanged for goods or services. The initial voucher value is set at a low value (e.g., $2.50). Each consecutive instance of abstinence increases the magnitude of the voucher by a small amount (e.g., $1.50). Three consecutive abstinences result in the delivery of an additional bonus (e.g., $10.00). A drug-positive urine sample, or failure to test, results in a reset of the voucher magnitude back to its original level (i.e., $2.50), from which the escalation can begin again.

Nancy Petry at the University of Connecticut popularized the variable magnitude of reinforcement procedure (Petry et al. 2005). This procedure involves making "draws" from a bowl of chips representing different prize/reinforcer magnitudes. These chips can be exchanged for goods that are available on-site. Typically about half of the chips say "good job" and do not result in the delivery of any tangible reinforcement. 41.8 % of the chips result in a small reinforcer (worth about $1.00), 8 % result in a large reinforcer (worth about $20.00), and 0.2 % result in a jumbo reinforcer (worth about $80.00). Participants earn at least one draw for each urine sample submitted that is drug negative. The number of draws awarded at each urine collection escalates by with consecutive instances of drug-negative urine tests. Missing or drug-positive urine samples result in a reset to one draw available when the next negative sample is submitted.

Both of these (VBRT and variable magnitude of reinforcement) procedures are quite effective at treating psychostimulant addiction. In fact, the United States

Veterans' Administration has recently adopted CM as a treatment modality for psychostimulant addiction (Rash et al. 2013b). Often people wonder about the relative efficacy of the two procedures. It is important to note that there is substantial evidence suggesting that they both work. We are aware of no evidence demonstrating the superiority of one over the other. It is often erroneously claimed that the variable magnitude of reinforcement procedure is more cost-effective than the VBRT procedure. This is simply not true as the magnitude of the prizes or vouchers employed is scalable. That is, neither procedure has a universal inherent cost; the clinician can decide what the value of the prizes and the voucher will be (see below for a discussion of the importance of using relatively high-value reinforcement to insure efficacy in all CM procedures). Both procedures have the advantage that they allow clinicians and consumers of their services to celebrate success (e.g., drug abstinence) in a clinical session as opposed to focusing on failure (drug use). The variable magnitude of reinforcement procedure has a potential advantage in that the prize drawing phase has an inherent excitement built into and an element of chance which many may find exciting. This may confer additional reinforcing efficacy to the prizes above and beyond that which can be accounted for via their monetary value via a process of conditioning (e.g., Alessi et al. 2002). However, this suggestion is in need of empirical assessment. Some have suggested that on the face of it, this may resemble gambling and be a risk for pushing individuals who are seeking treatment for addiction to develop or exacerbate a pathological gambling problem. It is important to note that the variable magnitude of reinforcement procedure is not gambling. The participant does not put up any of their own resources and does not have an opportunity for personal financial loss as is the case in gambling. In addition, we have studied those going through this type of CM procedure and found no evidence that they transition to or develop a gambling disorder (Petry et al. 2006).

A potential advantage of the VBRT procedure relative to the variable magnitude of reinforcement procedure is that it allows a skillful clinician to engineer the voucher exchanges so that the consumer/patient comes into contact with powerful sources of nondrug reinforcement that exist in the consumer's natural environment. The hope being that these sources of naturally occurring reinforcement will come to exert control over the consumer's behavior as they initiate and maintain their recovery from their addiction, for example, exchanging vouchers for goods or services that allow the consumer to increase the reinforcement they get: from family interactions (e.g., exchanging a voucher so a mother can go roller skating with her daughter), from employment (e.g., exchanging a voucher for a set of clothes to wear at a job interview), or from engaging in a hobby (e.g., exchanging a voucher for a fishing license so that the consumer can engage in a hobby), all serve to increase the consumers contact with potentially powerful sources of nondrug reinforcement. In other words, the vouchers can act as behavioral vectors to draw the consumer's behavior into contact with nondrug reinforcers. It should be noted that in the variable magnitude of reinforcement procedure, this can also be accomplished by tailoring the prizes that are available to consumers.

In summary, both of these procedures work well and have improved the lives of many individuals who have benefited from treatment that utilized these approaches. There is no immediate reason to prefer one approach over the other. Both are effective if delivered with high degrees of fidelity. There is good evidence that the procedures work for most types of addiction (Dutra et al. 2008; Hartzler et al. 2012; Higgins and Silverman 1999; Lussier et al. 2006; Prendergast et al. 2006) and for many populations including adolescents (Branson et al. 2012), polysubstance abusers (Downey et al. 2000), pregnant women (Higgins et al. 2012), and those afflicted with both substance use disorders and serious and persistent mental health issues (McDonell et al. 2013). There is also evidence that the procedures work best for those who rapidly initiate abstinence during treatment (Yoon et al. 2009) and for those who begin treatment in a drug-free state (Stitzer et al. 2007). The utility of the CM procedures for treatment in the criminal justice system is less compelling (e.g., Hall et al. 2009; although see De Fulio et al. 2013). This is perhaps not surprising as most criminal justice systems are punishment based. While punishment is usually to be avoided in therapeutic contexts because of the proclivity of the person being punished to escape the punisher (e.g., terminate the treatment interaction), that is not an option in a criminal justice setting in which the person is compelled to engage in treatment. Given these circumstances contingent punishment should be quite effective in controlling behavior. For example, if a cocaine user is clearly informed that if they use cocaine they will be incarcerated, it is a powerful contingency management protocol based on punishment. This is the norm in many criminal justice systems (punishers range from mild sanction in some countries to death in others!). In such a milieu it is unlikely that a reinforcement-based CM procedure will garner much additional control over a user's behavior unless very high-magnitude reinforcers are employed. In criminal justice systems where behavior is less controlled, however, CM interventions should be effective.

51.2.3 Key Factors

In this section we briefly describe what we believe are four key factors for the successful implementation of any variety of CM. For a detailed discussion of these factors and others, please consult Petry (2012) and Tuten et al. (2012).

The first factor to consider is the procedure by which vouchers or prizes (henceforth both referred to as reinforcers) are disbursed. This is known in parlance of operant psychology as the schedule of reinforcement. Schedules of reinforcement have been extensively studied and it has been repeatedly demonstrated that schedule changes can have profound impacts on behavior (Ferster et al. 1957). Higgins developed the basic schedule that is routinely employed in CM procedures. This has two key components. First, as outlined in the examples in the previous section, there is an escalation in reinforcement magnitude for consecutive instances of abstinence. Secondly, as described above, there is a reset in reinforcer magnitude (voucher value or number of prize draws) following a failure to abstain. The combination of these components seems to provide the greatest likelihood for

achieving a successful treatment outcome (Roll et al. 1996; Roll and Higgins 2000). While we do not precisely know why these components are operative, it is likely that they function to integrate individual instances of abstinence into a consecutive period of abstinence. If each abstinence were reinforced independently of those that preceded or followed it, the behavioral target would be individual instances of abstinence. By linking consecutive instances of abstinence via the escalation and reset procedure, the target becomes consecutive instances of abstinence, which should be the goal of all treatment efforts. Whenever it is possible, CM procedures should try to incorporate both of these schedule components to have the greatest likelihood of success.

The second factor to consider is the magnitude, or value, of the reinforcers used. There exists an extensive body of literature from both laboratory and clinical trials and with different species, including humans, that unambiguously demonstrates that higher magnitudes of reinforcement are better at controlling behavior (Nader and Woolverton 1991; Packer et al. 2012; Wong et al. 2003). Clinically, this means that the higher the value of the reinforcer employed, the more effective it is likely to be. Use of reinforcer magnitudes that are too low to control behavior (e.g., Packer et al. 2012) will result in failure of the intervention. Unfortunately, this could be interpreted as a failure of the CM protocol, when in fact it is a lack of fidelity to the protocol that is responsible for the failure. One should not expect a low-magnitude reinforcer procedure to be very effective. This often poses a significant challenge to the implementation of CM (Roll et al. 2009). Treatment centers are often underresourced and do not have the means to employ high-magnitude monetary reinforcers such as vouchers and prizes. In this case, other noncash-based reinforcers can be used (as described above), or community donations can be sought (e.g., Amass and Kamien 2004). It is our belief that funders are beginning to embrace CM interventions as many insurance companies employ CM-based efforts to control health behaviors and as the United States Veterans' Administration adopts CM as a primary treatment strategy (Rash et al. 2013b). Hopefully, this will reduce the difficulty surrounding the provision of reinforcement of sufficient magnitude.

It should be noted that what is reinforcing for one person may not be reinforcing for another. Thus, when using noncash-based reinforcers, it is incumbent on the clinician to find reinforcers that are salient to individual consumers. This can be done by identifying a functional relationship between behavior and reinforcers as described in Johnston and Pennypacker (1993). Also of note is that reinforcement magnitude can be changed during treatment, if necessary, to garner more control over a user's behavior. In a study by Robles and colleagues (2000), it was demonstrated that even treatment-resistant cocaine users would abstain if relatively high-magnitude vouchers were used.

The third factor to consider when developing, or delivering, a CM protocol is delay (Petry 2000; Roll et al. 2000; Packer et al. 2012). There are two types of delay that are common in CM protocols. The first is the delay between earning a reinforcer (e.g., providing biological evidence of drug abstinence) and receiving the reinforcer, that is, how long after someone provides a drug-negative urine

sample until they receive their prize or voucher. In order to be maximally effective, this delay should be minimized. Another type of delay encountered when using vouchers is an exchange delay, that is, the delay between telling the counselor what you want to exchange your voucher for and the actual receipt of the item. Again, in order to maximize protocol efficacy, this delay should be minimized.

The fourth and final factor we wish to mention is intervention duration. While it is quite understandable that clinicians, consumers and their families, and funders want short, effective treatment, it is important to remember that addicts spend a lifetime developing an addiction; it may not be reasonable to think that the behavioral patterns established in order to support compulsive drug taking behavior can be terminated quickly. For this reason, we recommend that the longest possible duration of treatment be employed. There is evidence to suggest that longer treatments are more effective than shorter ones (Roll et al. 2013) and that long-term treatment is acceptable to consumers (Silverman et al. 2004).

51.2.4 Barriers

Given the widely accepted efficacy and relative ease of implementation, one could reasonably ask why CM is not more widely employed. To begin with, it is often employed although perhaps not as frequently as one would expect. In our experience, three common barriers are raised that hinder effective implementation of the procedure. These barriers have been discussed in detail and interested readers should consult the literature for a thorough vetting (e.g., Rash et al. 2012; Roll et al. 2009).

Primary among the barriers is the perceived cost of the CM interventions. We have touched on this in several of the above sections. Cost is an issue, but nonmonetary reinforcers can be employed. Some work has even demonstrated unanticipated benefits such as decreased hospitalizations and improved comorbid psychiatric functioning which result in significant cost savings (McDonell et al. 2013).

It has also been argued that CM protocols are too complex. Proponents of this argument claim that busy, poorly resourced clinicians do not have the time needed to calculate reinforcer value and carry out prize draws or voucher exchanges. While we certainly agree that clinicians are overworked and underpaid, we find this class of argument to be repugnant. It is akin to a surgeon declining to operate on someone because the surgical procedure was too complex and they were too busy with other procedures. Moreover, the advent of computerized programs to aid clinicians with the delivery of CM (www.bettertxoutcomes.org) and the ability to conduct online voucher exchanges (Meredith and Dallery 2013) obviate most of these concerns.

The final perception we wish to discuss is one of consumer resources. It has been suggested that CM-based interventions will only work for those who have limited financial resources. While it is undeniable that drug addiction eats away at a person's resources until they are depleted and that most abusers are financially

deprived, we are aware of no data to suggest that CM efficacy is influenced by income level. In fact, research has shown the income level (both legal and illegal) does not impact CM efficacy (Rash et al. 2013a). That said, most treatment efforts and especially those involving clinical research protocols for substance abuse are populated by individuals of limited financial means. Further work is needed to assess the efficacy of the monetarily based procedures in those of relative wealth. There is evidence that the use of nonmonetary CM is effective in those who have sufficient financial resource, however. Crowley and colleagues (Crowley 1984) demonstrated that attorneys and physicians who were abusing drugs could be treated by contingently arranging punishment. Crowley had the treatment seeking professionals write letters to their licensing boards which reported their substance addiction and requested that their license be revoked. Crowley kept the letters and did not mail them unless the professional tested positive for the prohibited drug in which case the letter was mailed. Evidence suggests that the procedure was effective.

51.2.4.1 Limitations

While we are strong proponents for the use of CM-based interventions, we are also realistic. As of yet there is no silver bullet for the treatment of psychostimulant addiction, including CM. In our experience, however, CM is a great treatment modality for initiating abstinence. While some have demonstrated encouraging long-term maintenance of abstinence post-CM-based treatment (e.g., Higgins et al. 2000), a perception lingers that long-term effects are difficult to demonstrate. As discussed above, we believe that VBRT provides a mechanism for bringing consumers in contact with nondrug sources of reinforcement than can serve to maintain abstinence, but in our experience this is not an automatic occurrence. Once individuals are treated for their addiction, they often find themselves right back in the same environment that occasioned their drug use in the first place. In this environment, the same pressures began to re-exert their influence and a risk of relapse is high. This brings us to our second limitation. We do not believe that CM should be a stand-alone intervention in most instances. Instead, we recommend pairing it with other evidence-based treatment. Drug abusers have complicated chaotic lives. They need help navigating affective, legal, and cognitive aspects of their addiction. While CM initiates abstinence and provides a sober client for the clinician to work with, it does nothing to inherently address these other concerns. These need to be addressed in the therapeutic relationship in order to maximize the likelihood of maintaining the abstinence which CM is so effective at initiating. One of the clearly most effective treatment strategies, the MATRIX model, does combine CM with other psychosocial modalities (Rawson et al. 2002).

51.3 Conclusion

An impressive array of basic science research supports the notion that drugs of abuse serve as potent reinforcers. Further, the hallmark of successful drug abuse

treatment is the diminution of the drug's reinforcing efficacy. CM is a very effective means for accomplishing this, especially in the treatment of psychostimulant addictions. Different types of CM appear to be generally effective and when delivered with high fidelity offer the clinician and the consumer perhaps their best chance for breaking the pernicious cycle of addiction.

Acknowledgment The authors would like to extend their appreciation to Arlana Buyers and Dr. Donelle Howell. The authors were funded by the WA State Life Sciences Discovery Fund during the time when this chapter was produced.

Contents

Abstract

Hazardous and harmful alcohol use, illicit drug use, and the misuse of prescription medications represent major public health concerns that affect a large segment of the population. These highly prevalent conditions are associated with medical, social, and psychiatric comorbidities that bring them to the attention of practitioners in a variety of health-care and social service settings. While many such individuals will benefit from brief interventions or more formal specialty substance abuse treatment, many also might choose to engage in a mutual support program to seek assistance or gain additional support in their communities to help

them achieve and maintain their goal of reducing or discontinuing their substance use. The present chapter reviews 12-step mutual support programs that serve as widely available, no-cost resources in substance abuse recovery. It reviews evidence about the effectiveness of such support groups and of specific interventions designed to facilitate engagement in them. It also describes the physician's role in educating patients and families in promoting 12-step programs. Important steps for physicians include understanding 12-step mutual support programs, preparing patients or family members to engage in a mutual support program, monitoring attendance and engagement, exploring patient resistances to mutual support programs, knowing the components and "tools" of the program, and being aware of alternatives for patients who will not use 12-step programs.

52.1 Introduction

Hazardous and harmful alcohol use, illicit drug use, and the misuse of prescription medications represent major public health concerns that affect a large segment of the population. These highly prevalent conditions are associated with medical, social, and psychiatric comorbidities that bring them to the attention of practitioners in a variety of health-care and social service settings (Kelly and McCrady 2008; Schulden et al. 2012). With an increased emphasis on conducting screening, brief intervention, and referral to treatment in primary care, emergency medicine, HIV and STI, and psychiatric clinics, the likelihood is high that medical and psychiatric practitioners will encounter individuals with substance use disorders (SUDs). While brief interventions in such settings may be sufficient to lead to behavior change for many, with a move toward either abstinence or reduced use and harm reduction, many other individuals will be referred for more intensive specialty substance use disorder treatment. Individuals might also choose to engage in a mutual support program to seek assistance or gain additional support in their communities to help them achieve and maintain their goal of reducing or discontinuing their substance use.

One such source of support is the large number mutual support programs based on the 12-step philosophy and principles, which originated with Alcoholics Anonymous (AA), but now includes Narcotics Anonymous (NA), Cocaine Anonymous (CA), and a number of others (Laudet 2008). These programs involve no cost and only require a desire to stop drinking or using drugs as a condition of membership, making them highly accessible and readily available, thus serving as important resources in substance abuse recovery. It is estimated that there are nearly 64,000 AA groups with 1.4 million members in the United States and Canada and over 114,000 groups and 2.1 million members worldwide (Alcoholics Anonymous 2012b). Similarly, NA and CA have meetings available throughout many countries internationally. All of these mutual support programs have also expanded their services through the availability of Internet-based meetings and "chat rooms" that provide an additional, supplemental source of support.

Given that many individuals who are in need of treatment never seek specialty SUD care, 12-step programs have served as the primary, if not only, source of

behavior change for many individuals dependent on alcohol or drugs. They have also been incorporated into specialty SUD treatment programs, either as a component of or as an adjunct to formal treatment, and have served as continuing care and community support following treatment. Of the over five million adolescents and adults in the United States that attended substance-focused mutual support groups during 2006 and 2007, approximately two-thirds were not involved in formal treatment during this period, while the remaining one-third were also involved in some type of specialty SUD treatment over that same period (Substance Abuse and Mental Health Services Administration 2008).

52.2 12-Step Approaches: An Overview

52.2.1 What Are 12-Step Programs?

Alcoholics Anonymous and other mutual support programs that are based on AA have their foundation in 12 steps, which represent a general philosophy, principles, beliefs, and behavioral guidelines for individuals seeking to discontinue their alcohol or drug use. The AA 12 steps are found in Table 52.1. The underlying philosophy reflected by these steps emphasizes a particular view of the recovery process. Acceptance of addiction as a disease that can be arrested but never eliminated, enhancing individual maturity and spiritual growth, minimizing self-centeredness, and providing help to other addicted individuals are all viewed as essential components (Humphreys et al. 2004). The 12 steps represent a series of self-reflective and behavioral activities that substance abusers engage in during their recovery. As noted in Table 52.1, individuals seeking to overcome their SUD should admit their powerlessness over alcohol and drugs, take a moral inventory of themselves, admit the nature of their wrongs, make a list of individuals whom they

Table 52.1 The 12 steps of Alcoholics Anonymous

1. We admitted we were powerless over alcohol – that our lives had become unmanageable
2. Came to believe that a power greater than ourselves could restore us to sanity
3. Made a decision to turn our will and our lives over to the care of God as we understood Him
4. Made a searching and fearless moral inventory of ourselves
5. Admitted to God, to ourselves, and to another human being the exact nature of our wrongs
6. Were entirely ready to have God remove all these defects of character
7. Humbly asked Him to remove our shortcomings
8. Made a list of all persons we had harmed, and became willing to make amends to them all
9. Made direct amends to such people wherever possible, except when to do so would injure them or others
10. Continued to take personal inventory and when we were wrong promptly admitted it
11. Sought through prayer and meditations to improve our conscious contact with God as we understood Him, praying only for knowledge of His will for us and the power to carry that out
12. Having had a spiritual awakening as the result of these steps, we tried to carry this message to alcoholics and to practice these principles in all our affairs

have harmed, and make amends to those people. The essence of recovery activities and guiding principles has been described as the 12-step "six pack": don't drink or use drugs, go to meetings, ask for help, get a sponsor, join a group, and get active (Caldwell and Cutter 1998).

In addition to the general philosophy and behavioral guidelines, 12-step approaches place a considerable emphasis on "fellowship" or the social network that is associated with 12-step group membership (Kaskutas et al. 2002). One of the characteristic features of a substance dependence syndrome is a narrowing of the drinking repertoire, which most often includes a narrowing of the friends and associates the individual has to those who are drinking/drug-using friends and acquaintances who tend to reinforce continued use. By joining a 12-step program, the individual begins to shift one's social network away from those who support drinking/drug use to an expanding network of those who support abstinence and promote recovery (Bond et al. 2003; Groh et al. 2008; Kelly et al. 2012, 2011; Longabaugh et al. 1998). There is an increased sense of bonding with other members in the fellowship who are also working toward a common goal of abstinence. This new social network provides a set of behavioral norms and role models for how to work toward abstinence and follow a personal recovery plan, the development and engagement in non-substance-related activities that are rewarding and can take the place of substance-related activities, a decreased exposure to drinking/drug-related activities and cues that induce craving, and rewarding social relationships (Kelly et al. 2011, 2012). Consistent with this, greater attendance at AA meetings was associated with decreases in social ties with individuals who supported the individuals' drinking and in drinking-related activities while also increasing social ties with those supporting abstinence and engaging in nondrinking activities, all of which contributed to better outcomes with respect to abstinence (Kelly et al. 2011). These social aspects of 12-step programs may be as important, if not more so, as 12-step specific factors or spiritual mechanisms in the positive benefits of 12-step mutual support groups (Groh et al. 2008; Kelly et al. 2012).

52.2.2 Effectiveness of 12-Step Programs

There is an increasing body of literature that indicates that involvement in 12-step programs is associated with both short-term and long-term benefits with respect to reduced alcohol or drug use and increased rates of abstinence, quality of life, and psychosocial function. In addition, engagement in 12-step programs is associated with reduced health-care, substance abuse, and mental health service utilization and costs (Humphreys and Moos 2001, 2007; Mundt et al. 2012).

The data supporting 12-step effectiveness comes from membership surveys, observational studies, and cross-lagged analyses of longitudinal studies. Surveys of AA and NA members indicate that the median length of abstinence among members is over 5 years, with approximately a third of each group having between 1 and 5 years of abstinence. Observational studies have demonstrated, for both alcohol- and drug-dependent individuals involved in and those not involved in

formal treatment, that increased attendance at 12-step meetings and involvement in 12-step activities and service have better outcomes across substance-related and psychosocial dimensions (Gossop et al. 2008; Humphreys 2003; Humphreys et al. 2004; Kaskutas 2009; Krentzman et al. 2010; Moos and Moos 2006; Pagano et al. 2013; Weiss et al. 2005; Zemore et al. 2013). It appears that both meeting attendance and engagement in recovery activities contribute to the observed benefit, with earlier, more frequent, and more regular attendance typically being associated with higher rates of abstinence (Zemore et al. 2013). This is consistent with 12-step programs' recommendation of attending 90 meetings in 90 days. While attendance trajectories that show low levels of attendance or an initial high level that subsequently drops off substantially most often are associated with poorer outcomes than patterns of high and consistent attendance or initially low but increasing attendance over time, many individuals who have limited attendance may also show benefit (Kaskutas et al. 2005, 2009a; Witbrodt et al. 2012). While even small amounts of participation may be helpful in increasing abstinence, higher "doses" (e.g., three or more meetings per week) may be needed to reduce the likelihood of relapse.

While attendance at meetings may decrease across time, the level of involvement in 12-step recovery and helping activities (e.g., doing service at meetings, reading 12-step literature, doing "step work," getting a sponsor, or calling other 12-step group members or one's sponsor, serving as a sponsor) may increase and that this engagement in such activities may be more important than meeting attendance (Owen et al. 2003; Pagano et al. 2013; Weiss et al. 2005). The results of longitudinal studies involving cross-lagged analyses or structural equation modeling have demonstrated that there is a causal pathway, rather than merely a correlational relationship, in which increased meeting attendance and/or engagement in 12-step activities leads to subsequent decreases in alcohol and drug use (Connors et al. 2001; Magura et al. 2013; McKellar et al. 2003; Weiss et al. 2005).

There have been questions raised about the applicability of these findings of benefit from 12-step involvement to particular subgroups of individuals such as women, minority groups, youth, and individuals with co-occurring substance use and psychiatric disorders. Although the literature has been somewhat mixed, it appears that these groups, despite potential barriers, do engage and can benefit equally from meeting attendance and engagement in 12-step activities (Donovan et al. 2013). In addition, many 12-step organizations have groups for special populations such as women, youth, and sexual minorities, and there are alternative groups available, such as Women For Sobriety, Double Trouble in Recovery, or Dual Recovery Anonymous, that may meet the specific needs of subgroups involved in the recovery process (Daley and McDonald 2013).

52.2.3 Interventions to Facilitate 12-Step Involvement in Specialty Treatment Programs

A number of interventions have been developed for use in substance abuse treatment programs to facilitate 12-step meeting attendance and engagement in 12-step

activities (Cloud and Kingree 2008; Donovan and Floyd 2008; Donovan et al. 2013). These differ with respect to their primary focus but share the common goal of getting individuals actively involved in 12-step groups. Twelve-Step Facilitation (TSF) therapy, developed in Project MATCH with alcohol-dependent individuals (Nowinski et al. 1992) and subsequently adapted for use with drug-dependent patients (Baker 1998; Carroll et al. 1998), focuses on helping individuals better understand and appreciate 12-step philosophy and the first three of the 12 steps, which focus on acceptance and surrender. The underlying assumption of TSF, which can be delivered in either individual or group formats, is that this increased appreciation will lead to subsequent engagement. Making AA Easier (MAAEZ) (Kaskutas et al. 2009b), a six-session group intervention, does not focus explicitly on 12-step philosophy and concepts. Rather, it attempts to facilitate 12-step engagement by familiarizing individuals with the "culture" of 12-step meetings, helping them identify potential barriers to engagement, and minimizing their resistance by helping them anticipate and learn ways to deal with issues in 12-step meetings and programs that often lead them to reject future participation. The intensive referral intervention (Timko and DeBenedetti 2007; Timko et al. 2006) focuses on a much more active and direct process of engaging individuals in meeting attendance. In a three-session, individually delivered intervention, an attempt is made to link the alcohol- or drug-dependent individual with a member of a community-based 12-step program who will accompany the individual to a 12-step meeting, thus helping reduce the potential fear of not knowing anyone at a meeting that can serve as a barrier to attendance. The volunteer helps prepare and "socialize" the patient, answering questions, introducing them to other group members, and serving as a transitional support. As with MAAEZ, the assumption of the intensive referral is that getting the individual to a meeting is paramount and that understanding of 12-step concepts and principles will follow. The STAGE-12 intervention (Stimulant Abuser Groups to Engage in 12 Step) (Daley et al. 2011; Donovan et al. 2012), consisting of three individual sessions and five group sessions, attempts to combine the active engagement process based on the intensive referral linkage with 12-step volunteers with TSF therapy content focused on better understanding 12-step concepts. The underlying assumption of STAGE-12 is that, given the high rates of early attrition, getting people to meetings may be insufficient to maintain involvement without an understanding of the philosophy and steps of the program; thus, a combined approach that focuses both on meeting attendance and active participation and on 12-step practices and principles may be needed. Each of these four interventions has demonstrated an ability to increase attendance and/or engagement in 12-step activities with a resultant decrease in alcohol or drug use.

52.2.4 The Physician's Role in Educating Patients and Families in Promoting 12-Step Programs

While such 12-step facilitative interventions in specialty treatment programs are effective, the majority of individuals with substance use disorders do not enter

specialty care. Approximately two-thirds of those who attended a mutual support program group meeting in the past year were not involved in some type of formal treatment over that same period (Substance Abuse and Mental Health Services Administration 2008). Many individuals with SUDs are seen in settings such as primary care, family practice, emergency medicine, or mental health settings, where there has been increased emphasis on screening, brief interventions, and referral to treatment. Many health professionals working in such non-specialty settings may be relatively unfamiliar with the general philosophy (e.g., the 12 steps and traditions) of 12-step-based mutual support groups in general, about the different types of meetings and the way in which they are conducted, about the benefits associated with participation in 12-step programs, and about recovery-oriented resources in their communities (Donovan et al. 2013; Kelly and McCrady 2008). Based on the evidence of the positive benefits associated with 12-step program involvement, the World Health Organization, in its advice concerning the management of alcohol use disorders, has recommended that nonspecialist health-care workers should routinely familiarize themselves with locally available mutual help groups and should encourage the alcohol-dependent patient to engage with such a group, should monitor the impact of attending the group on the patient, and should encourage family members of patients with alcohol dependence to engage with an appropriate mutual help group for families (World Health Organization 2012). The 2011 survey of AA members indicated that 40 % of members said they were referred to AA by a health-care professional and 75 % of members' doctors know they were in AA (Alcoholics Anonymous 2012a).

Physicians can assume many helpful roles with patients and their families vis-à-vis 12-step recovery programs. They can provide education, identify common resistances and help patients and families overcome these, facilitate their engagement in these programs, and monitor their attendance and involvement. Physicians who supervise, teach, or mentor medical students, residents, or other medical professionals can also prepare them for doing the same with patients in a broad range of settings from the emergency room to primary care practices to specialty practices (e.g., pain clinics, OB/GYN clinics, psychiatric clinics, etc.).

52.2.4.1 Understanding 12-Step Mutual Support Programs

The initial component of the World Health Organization's recommendation is to become familiar with local mutual support programs. A helpful strategy to learn about these programs is to attend meetings to "see" and "feel" the program in action. This makes it easier to explain the program to patients and family members. Attending "open" discussion and speaker meetings provides an experience that is valuable in knowing what occurs at meetings and how members help each other. We suggest attending meetings for patients with substance problems (Alcoholics Anonymous, Narcotics Anonymous, Cocaine Anonymous, or other 12-step programs) and for families affected by these problems (Al-Anon, Nar-Anon).

The physician can also encourage medical students, residents, and others involved in patient care to attend meetings and read literature (online or in written publications) describing these programs. Reading program literature can help the physician and medical staff understand these programs as well as serve as resources to recommend to patients interested in learning about and engaging in these programs (Alcoholics Anonymous 2001, 2009; Narcotics Anonymous 1993, 2008). Alcoholics Anonymous has developed a special brochure and video to help familiarize physicians and health-care providers about the program and ways to facilitate referrals to it (Alcoholics Anonymous 1992).

Following are some key issues in understanding 12-step programs and facilitating their use by patients or their family members:

- These programs consist of many components: meetings, the 12 steps of recovery, sponsorship, recovery slogans, recovery literature, supportive activities (e.g., holiday events, conventions, sober social events), and service.
- Meetings are free and accessible in many countries and communities and follow a similar format, depending on the type of meeting (open or closed; speaker or discussion meeting). Attending different meetings can help the patient find ones that fit his or her recovery needs.
- No one is in charge of the 12-step fellowship and all members are equal. Discussion meetings have chairpersons to lead discussions, but these are members of the program. Meetings are "anonymous" and no records are kept.
- People from all walks of life can attend, even if they are not yet abstinent from alcohol or drugs. The only requirement is a "desire to stop" using alcohol or drugs.
- Members become educated about addiction, recovery, and other topics/issues. Some may even learn social and/or recovery skills such as how to self-disclose (cravings, problems, feelings, and thoughts) and to accept or give support.
- The emphasis of 12-step programs is one alcoholic or drug-addicted individual helping another. Newcomers are welcomed and accepted, which helps reduce their shame. Program members help them learn to work a "we" versus an "I" program.
- Members help each other by sharing their experience with addiction and recovery, thereby sharing hope and strength. This is done at the meetings, at "meetings after the meeting" (e.g., members go out for tea or coffee after a meeting to support each other in recovery), and via sponsorship.
- Members who connect with others can reduce their isolation. They can receive social support and help from other members "who have been there" and are managing the common challenges faced in recovery from alcoholism or drug addiction.
- Groups and other program activities are a positive replacement for drinking or drug use. In early recovery, addicted patients often struggle with boredom and not knowing what to do with their time. Some lack non-substance leisure interests.
- Group members can give participants (especially newcomers) a "dose" of reality to reduce their distorted or "stinking" thinking as well as recovery sabotaging

behaviors such as missing meetings, not showing a commitment to the program, or failure to get "active" in using the tools of the program.
- Members also help each other get back on track if one has a lapse or relapse. Members are encouraged to use these experiences to change their recovery program.
- These programs are spiritually based, not religious. Many members find it helpful to identify a power greater than oneself. For those who do not believe in God or a supreme being, the 12-step fellowship can serve this role of something "greater than the self."

52.2.4.2 Preparing Patients or Family Members to Engage in a Mutual Support Program

Physicians and medical staff can educate patients or family members about these programs and discuss their resistances, concerns or questions, and prior experiences. The care provider can recommend specific types of programs or meetings. This can be done in brief face-to-face interactions during the medical visit as well as by providing written literature or giving information about how and where to get literature about these programs. For example, in response to a patient's comment "I don't like to share my personal business with strangers," the physician can respond "I can understand why you think that way Mrs. Brown. You are not required to share anything you do not want to talk about at meetings. One option would be to attend a speaker's meeting at first where you hear others in recovery share their stories. Later, you can consider discussion meetings where you can talk about your drinking, too."

Or, in response to a family member who says "my husband is addicted to cocaine and ruining our family," the physician may respond "Mrs. Johnson, I can hear your distress about your husband's cocaine use. I recommend counseling to help you deal with this. We will provide you with names of counselors or clinics. I also want to tell you about a support program called Nar-Anon that helps family members cope with the distress caused by a loved one's drug addiction. Some of my other patients have told me how Nar-Anon has helped them learn to deal with their family member's drug problem. They also say this helps them focus on their own needs as well and not put all their energy on the addicted family member."

Physicians and medical practices can provide information on bulletin boards in the waiting or examination rooms and give patients or family members local meeting lists, brochures (e.g., "*This is AA*; *Frequently Asked Questions about AA*; and *Is AA for You*?"), or handouts with telephone numbers they can call to get this information from local AA, NA, Al-Anon, or Nar-Anon offices. Having names and phone numbers of volunteers active in mutual support programs to offer to patients or family members can also facilitate a patient's transition to meeting attendance. This, however, requires relationships with individuals in recovery who are trustworthy and have a natural desire to help patients or families deal with substance-related problems. Programs using such peer volunteers have been particularly successful (Blondell et al. 2001a, b), often even more so than direct physician encouragement and referral (Manning et al. 2012). The *Bridging the Gap* program

of Alcoholics Anonymous, which uses volunteers in recovery to help facilitate the transition of alcohol-dependent individuals from treatment programs into community-based 12-step programs, may be a resource (Alcoholics Anonymous 1991) and could be contacted through the local AA office. However, due to HIPPA regulations, physicians would have to get patients to agree to initiate the contact with a community volunteer rather than provide a patient name to a volunteer.

52.2.4.3 Monitoring Attendance and Engagement

Another strategy is briefly inquiring about the patient's current involvement in mutual support programs. This can help the care provider get a sense of what the patient is learning and gaining from the program. Or, it can help to identify problems that interfere with their ongoing attendance or participation. For example, Dr. George said to one of her patients who she referred to AA "to give me a brief update on how your AA program is coming along." When the patient responded "well Doc, I found the meetings helpful, but I've been busy and have been missing them lately," her physician explored the details of this and found that "lately" was the past 3 months. Dr. George was then able to help the patient recognize stopping meetings as a potential relapse risk factor. She also got this patient to commit to resume regular AA attendance. This process worked out well as the patient did not relapse and returned to regular AA involvement.

In another case, a patient complained about some of the people he described as "shady" at a NA speaker meeting that attracted a large number of people. The patient believed some of these people were not serious in the program and had questionable intentions, which made him uncomfortable. After a brief discussion, his physician got the patient to agree to connect with others at this meeting who he believed were serious or to attend other NA meetings. The patient learned from this experience that he had to decide who to connect with at the meetings and how to deal with unpleasant issues that may arise such as members with questionable motivation.

52.2.4.4 Exploring Patient Resistances to Mutual Support Programs

Resistances are common among individuals new to 12-step programs as well as among some regular attendees. Some common resistances stated by patients include "I don't like to open up with strangers, the program is too religious for me, some people who go are hypocrites because they go out after the meeting and drink (or use drugs), I don't like being told what to do by someone else, or I'm different that 'those' people." A good strategy is to do what proponents of Motivational Interviewing refer to as "roll with the resistance." Let the patient share his or her concern and then reflect this back in an empathic, nonjudgmental manner in which the patient is not told what to do. "Mr. Kelly, I appreciate you telling me that you worry about sharing personal information with strangers. That's understandable since you are a private person. Some of my other patients who expressed this concern tell me that starting out with speaker meetings instead of discussion meetings helped ease them into the program because they did not have to share any details of their past. Later, when they felt more

comfortable to attend discussion meetings, sharing was easier for them. What do you think about this idea?"

52.2.4.5 Knowing the Components and "Tools" of the Program

Health-care providers can use their knowledge to educate patients and deal with their concerns and questions about mutual support programs. They can also help patients find "specialty programs or meetings" to help meet their needs related to a personal characteristic or situation (e.g., a physician; a young person; a gay, lesbian, bisexual, or transgender patient; or one with an addiction and a psychiatric illness). A brief summary of components and program tools is given as follows (Daley and Donovan 2007):

- **Meetings**, which usually last 1 h, are either "open" or "closed." Open meetings are for anyone who is interested in the particular 12-step program and can be attended by students, professionals, and other nonmembers interested in learning more about the recovery programs. This is the type of meeting that physicians and other health-care providers can attend to familiarize themselves with the programs. Closed meetings are limited to members and prospective members only. There are two primary types of closed meetings: (a) a speaker meeting in which a member shares a personal story of addiction and recovery, which is known as a lead or a qualification, and (b) a discussion meeting in which members share ideas and experiences related to a specific topic (e.g., gratitude, relapse, acceptance) or one of the 12 steps or 12 traditions. The provider can recommend a patient new to the program to try a dozen meetings before judging their helpfulness. Also, have meeting lists available for patients and families or know where they can obtain these.
- **Chat rooms or online resources**, many of which are available 24 h a day. These include chat rooms for those with addiction as well as family members or significant others, including adult children of alcoholics (ACOA) or drug-dependent parents. See AA, NA, Al-Anon, or Nar-Anon websites to access their chat rooms, or go to other websites such as www.aalivechat.com or www.nachatroom.org or use an Internet search engine and enter "AA, Al-Anon, NA, Nar-Anon, ACOA chat rooms or online meetings." These online resources are viewed as ways to supplement, not replace, attending meetings in person.
- **Sponsorship** refers to a member in the program with substantial recovery who mentors new members in a variety of ways (attending meetings together, talking by phone, meeting outside of meetings, working the 12 steps, providing support and feedback, and facilitating the use of the tools of the program). Sponsors have been found to serve three broadly defined functions in their relationship to the individual: (1) encouraging the new member to become actively involved in 12-step activities, (2) providing ongoing emotional, social, and personal support, and (3) sharing their own personal experience of recovery through which they serve as role models (Whelan et al. 2009). Not only does sponsorship benefit the new 12-step member, it also helps to solidify the sponsor's own recovery through the principles of "giving back" (Pagano et al. 2004, 2010).

- **Higher Power** refers to "something greater than oneself" to help in the recovery journey. Many of the 12 steps (steps 2, 3, 5, 6, 7, 12) focus on spirituality and how to use a Higher Power to deal with the challenges of recovery. However, for those who do not believe in God as a Higher Power, the fellowship of AA or NA can be the suggested source of an "outside" support to the patient.
- **12 steps of AA, NA, or other programs** provide a way to actively engage in the recovery journey by understanding the spiritual principles of the program. The 12 steps focus on the following: (a) acceptance of addiction and negative effects on life (e.g., powerlessness and unmanageability), (b) spirituality (e.g., relying on a "Higher Power"), (c) self-assessment (e.g., looking at one's character defects and strengths via a personal inventory), (d) making amends to loved ones and others hurt by one's addiction, and (e) service by carrying the message of the program to others with alcoholism or drug addiction.
- **Slogans** refer to sayings or ways of thinking to help the member think more like a person in recovery and less like an addicted person. These can be used to coach oneself through stressful times such as when the member has a strong craving for alcohol or drugs or is obsessed about using. Some of the more common sayings include "One day at a time," "easy does it," "this too [craving/desire] shall pass," "let go and let God," and "put off the first drink (or drug)," to name a few.
- **Providing or recommending literature** about these programs or common issues faced by members is a helpful intervention. AA has the "Big Book" and NA has the "Basic Text," as well as many other books and information pamphlets or tapes on addiction or recovery. AA, NA, Al-Anon, Nar-Anon, and other 12-step programs all have a rich selection of recovery literature for all phases of recovery. Many members continue to use this literature on a daily basis years (or even decades) into their recovery.
- **Events** sponsored by these programs include those that take place during the holidays to provide extra support during high-risk times for some members (e.g., Christmas and New Year), as well as social events such as picnics or attending some activity of mutual interest (e.g., bowling or a sports event). In addition, there are a number of Alano Clubs and Recovery Cafes found in many cities. These venues, in addition to hosting recovery group meetings, provide alcohol- and drug-free environments in which recovering individuals and their families can engage in social and recreational activities. These activities reinforce the belief that is possible to have fun without being under the influence of alcohol or drugs.

52.2.4.6 Alternatives for Patients Who Will Not Use 12-Step Programs

It is not unusual for some patients to state that they have tried 12-step programs to no avail, they are simply not interested, or they have difficulties accepting the basic philosophy and spirituality of the programs. If, after exploring the resistances to find out what did not help or any other experiences that impacted on not wanting to use program, the physician believes an alternative mutual support approach could help, then options for non-12-step programs can be provided. These include, but are not limited to, the following: Women for Sobriety, Men for Recovery, Rational Recovery, SMART Recovery, Secular Organizations for Sobriety/Save Our Selves

or SOS, and others. One potential limitation is that these groups are less readily available than are 12-step groups, with many towns or cities having few or none of these programs available.

52.3 Conclusion

Mutual support programs (12-step and others) are an excellent resource for individuals with alcohol or drug addictions as well as loved ones or significant others adversely affected by an addiction. These programs are available at no cost, and each provides a framework for recovery, based on the philosophy of the program. The most widely used and available programs are AA, NA, An-Anon, and Nar-Anon. Becoming familiar with these programs, educating patients about them, providing literature or meeting lists, facilitating attendance, and monitoring involvement are some of the helpful strategies for physicians and their medical staffs to help patients with alcohol and drug problems and affected family members.

Acknowledgment This chapter was supported by a series of grants from the United States National Institutes of Health/National Institute on Drug Abuse (NIDA) as part of the Cooperative Agreement on National Drug Abuse Treatment Clinical Trials Network: Pacific Northwest Node (U10DA13714) and Appalachian/Tri-States Node (U10DA20036). Its contents are solely the responsibility of the authors and do not necessarily represent the official views of NIDA.

Group Therapy for Substance Use Disorders

53

R. Kathryn McHugh, Sara Park, and Roger D. Weiss

Contents

Abstract

Group therapy is the predominant type of behavioral therapy offered in substance use disorder treatment settings. This chapter provides an overview of the research literature on the efficacy of group therapy for substance use disorders

and discusses research challenges and important future directions in the study of group therapy. Research on the efficacy of group therapy for substance use disorders has generally found that it is associated with superior outcomes compared to no treatment or treatment as usual. Studies examining the combination of group therapy with other forms of treatment, such as pharmacotherapy, have been mixed, with some studies finding additive benefits and others finding no benefit. However, group therapy appears to be equally as effective as individual therapy and may offer cost benefits relative to individual treatment. Group therapy for co-occurring substance use disorders and other psychiatric disorders, such as bipolar disorder and posttraumatic stress disorder, is associated with benefits for both disorders. Due to a number of difficulties with conducting research on group therapy, this treatment modality remains understudied compared to individual therapy. Additional research is needed to identify the most effective types of group therapy and its optimal delivery method, either alone or in combination with other therapies.

53.1 Introduction

The term "group therapy" encompasses a number of treatment approaches that share in common the presence of at least two independent (i.e., not related) patients and a therapist who conduct meetings with the goal of eliminating or reducing substance use or substance use disorder (SUD) symptoms (Weiss et al. 2004). Specific treatments falling under this umbrella term may emphasize the interactions among members and the therapist (process or supportive therapy groups), the provision of information and skills (psychoeducational or behavioral therapy groups), or both. The content of groups also varies and may include components such as psychoeducation, cognitive-behavioral or motivational interventions, "check-ins" about use and other symptoms, encouragement to attend 12-step or other mutual help groups, relational interventions, skills training, and contingency management, among others.

The vast majority of programs that specialize in treating SUDs report offering some form of group therapy (more than 94 %; United States Department of Health and Human Services 2010). The predominance of group therapy in these settings may be attributable – at least in part – to the potential cost savings of a group rather than an individual approach. Cost analyses have suggested that group therapy is associated with substantially less therapist time per patient compared to individual therapy (Sobell et al. 2009) and that it has both the lowest cost and best cost-effectiveness ratio of psychosocial treatment approaches (French et al. 2008). In addition, patients are generally satisfied with group therapy as indicated by similar (if not superior) retention rates compared to individual therapy and strong self-ratings of treatment satisfaction (e.g., Sobell et al. 2009). Studies of patient preference for group versus individual therapy are few; however, at least one study has identified preference for group therapy over individual therapy (Schmitz et al. 1994). Thus, group therapy appears to be a highly acceptable and low-cost approach to treating SUDs.

Despite the widespread use of group therapy, this approach has been studied far less extensively than individual therapies. In this review, we aim to characterize the current research on the use of group therapy for patients with SUDs, with a focus on randomized controlled trials. We will limit our definition of group therapy to treatments that focus on substance use or associated symptoms and not on treatments targeted specifically to other symptoms or co-occurring disorders (e.g., group cognitive-behavioral therapy for depression in patients with SUDs). Where possible, we will attempt to characterize the nature of the group therapy approach from a content (e.g., cognitive-behavioral, psychoeducational, etc.), composition (e.g., targeted substance, single or mixed gender, dual diagnosis), and timing (e.g., acute care, aftercare) perspective. We conclude with a commentary on limitations and challenges in conducting research on group therapy and an integration of findings from the literature to date.

53.2 Efficacy and Effectiveness of Group Therapy

53.2.1 Is Group Therapy Effective for the Treatment of SUDs?

Although the majority of group therapy studies have compared two (or more) types of group therapy, several studies have attempted to answer the basic question of whether group therapy leads to improvement in SUD symptoms. These studies compare either treatment as usual (usual care at a facility) to treatment as usual plus group therapy or group therapy to no group therapy.

53.2.1.1 Comparing Group Therapy to Usual Care or No Group Therapy

Studies of the effect of group therapy on SUD outcomes in general have suggested that group therapy is effective in reducing substance use and associated impairment. Stephens and colleagues (2000) randomly assigned 291 treatment-seeking marijuana users to 14 sessions of group cognitive-behavioral therapy, two sessions of individual motivational treatment, or a waitlist control. Participants in both active treatment groups reported significantly greater reductions in marijuana use and consequences of use than the waitlist control group throughout treatment and 16 months of follow-up. Group therapy and brief individual therapy were not significantly different on any outcomes. In a similar study, two sessions of group therapy were significantly more effective for reducing nicotine use in undergraduate smokers compared to a waitlist control group (Omer et al. 1998).

However, not all studies have yielded positive results. In a study of interventions to prevent relapse among abstinent smokers following 3 months of treatment with group therapy and/or nicotine replacement therapy, participants were randomly assigned to receive one of two counseling groups or no group treatment (Razavi et al. 1999). Abstinence rates were not significantly different across conditions after 12 months (range from 50 % to 58 %), suggesting that adding group counseling as a relapse prevention strategy after acute treatment was not beneficial for increasing abstinence rates.

53.2.1.2 Adding Group Therapy to Pharmacotherapy

Because pharmacotherapy is a first-line treatment for dependence on some substances of abuse (e.g., heroin, nicotine), a number of trials have tested whether adding group therapy to medication can enhance outcomes. A trial of adding 12 sessions of group cognitive-behavioral therapy to the opioid antagonist naltrexone for opioid-dependent individuals found no difference between those who received group therapy and those who received naltrexone alone (Tucker et al. 2004). However, it is important to note in this study that fewer than 10 % of the group therapy condition participants attended all group sessions. Moreover, participants in both conditions were permitted to engage in additional psychotherapy (including individual), with more than 85 % of participants electing to do so. Thus, it is unclear whether the results reflect a failure of group therapy, an underdosing of group therapy, or an effect of adjunctive treatment that was received by both groups (e.g., individual therapy).

Luthar and colleagues conducted two studies examining a relational psychotherapy group for heroin-dependent mothers (Luthar and Suchman 2000; Luthar et al. 2007). This relational intervention used a supportive orientation focused on enhancing women's functioning and parenting. A study comparing this approach to methadone maintenance treatment as usual (including group counseling and case management) in 61 heroin-dependent mothers (Luthar and Suchman 2000) found modest benefits of relational therapy for some parenting measures (e.g., risk of child maltreatment, affective interactions), but not others (e.g., limit setting, instrumental behaviors). Modest benefits were seen for depressive symptoms at posttreatment; however, this was no longer significant at follow-up. The relational group was associated with greater opioid abstinence, but not cocaine abstinence. This treatment was then examined in a larger study of 127 heroin-dependent mothers receiving methadone maintenance compared to methadone maintenance plus a recovery training group therapy focused on psychoeducation and skills training (Luthar et al. 2007). Although the relational therapy was associated with some benefits at posttreatment, many of these benefits were reversed over a 6-month follow-up, with the comparison condition associated with better functional and child maltreatment outcomes.

Studies of the addition of group therapy to medication for nicotine dependence have yielded mixed results. In a study of 154 nicotine-dependent women randomized to receive combinations of bupropion or placebo along with either cognitive-behavioral or supportive group therapy, a complex and mixed set of results emerged (Schmitz et al. 2007). Specifically, cognitive-behavioral therapy resulted in significantly higher abstinence rates than did supportive therapy among those taking bupropion. However, supportive therapy was associated with superior outcomes among participants receiving placebo. The combination of bupropion and cognitive-behavioral therapy did not result in better abstinence rates compared to either placebo condition (Schmitz et al. 2007).

A study by Smith and colleagues (2001) randomized 677 smokers following an initial brief treatment (nicotine replacement therapy and one session of individual counseling) to six sessions of cognitive-behavioral group therapy, a motivational enhancement/supportive group therapy, or no group therapy; all participants also

continued to receive nicotine replacement therapy. There were no significant differences among the three treatment conditions in terms of self-reported cigarette use; however, smokers who had not achieved abstinence during the initial treatment period had better outcomes in the motivational/supportive treatment relative to the cognitive-behavioral or no group conditions.

Overall, group therapy for SUDs appears to be superior to either waitlist or no treatment. Studies examining group therapy as an aftercare strategy or as added to pharmacotherapy are more mixed. In these studies, results imply that the effects of treatment may vary based on the subgroups (e.g., adding group therapy as aftercare may be effective for initial treatment nonresponders; Smith et al. 2001). Additionally, mixed patterns of results regarding combination group therapy with pharmacotherapy imply that certain therapies may better complement certain medications; however, additional studies are needed to understand whether such interactions exist and can be used to maximize outcomes.

53.2.2 Is Group Therapy as Good as Individual Therapy?

Several studies have tested whether the same type of treatment is more effective when delivered in a group or individual format. The largest well-controlled study of this association was conducted by Sobell and colleagues (2009) in a sample of 264 individuals with "non-severe" alcohol and drug use problems (those with a history of severe dependence were excluded). Participants were randomly assigned to four sessions of a cognitive-behavioral or motivational intervention in a group or individual format. Participants experienced significant reductions in self-reported alcohol and drug use and consequences of substance use. Results also indicated no differences in substance use outcomes for individual versus group administration for either alcohol or drug use and no differences in treatment retention.

In another study of group versus individual delivery of a motivational therapy, John and colleagues (2003) randomized 343 alcohol-dependent inpatients in German psychiatric hospitals to receive either three sessions of individual therapy or nine sessions of group therapy for enhancing motivation for alcohol abstinence following detoxification. Those in the group therapy condition reported more self-help group attendance; however, there were no differences in other forms of treatment-seeking and overall service utilization between groups. There were also no differences in alcohol outcomes between these groups, with fewer than 30 % in each group reporting abstinence at 6 months after detoxification.

Studies comparing individual and group cognitive-behavioral therapy have yielded similar results. A study of the use of 9 weeks (12 sessions) of cognitive-behavioral relapse prevention in group or individual format for 47 cocaine-dependent patients following inpatient treatment found similar outcomes for both groups over time on rates of abstinence as well as drug-related problems and measures of functioning (Schmitz et al. 1997). By the end of treatment, fewer than 50 % of both groups had remained abstinent, although gains in functioning and impairment were largely sustained over 24 weeks of follow-up; at the final

assessment point, the average days of cocaine use in the previous month were low (2 days for individual and less than 1 day for group).

A similar study also compared individual to group relapse prevention as part of an aftercare program for 132 patients with alcohol and drug dependence (Graham et al. 1996). Patients received 12 weekly sessions of either 45–60 min individual or 60–90 min group therapy. Group and individual therapy had similar outcomes for treatment adherence and retention and self-reported alcohol and drug use. However, group therapy was associated with better social support at 12-month follow-up. A study conducted in Brazil randomized 155 mixed alcohol- and drug-dependent patients to receive 17 sessions of cognitive-behavioral therapy in either group or individual format (Marques and Formigoni 2001). This study also found no significant differences in session attendance or in self-reported alcohol or drug use outcomes between groups when controlling for baseline levels of use.

A Norwegian study tested 12 weeks of 90-min group therapy (with same-gender composition) or 7 h of individual delivery of a short-term therapy based on social learning theory, focusing on skill acquisition toward individualized treatment goals (abstinence or harm reduction) (Duckert et al. 1992). Study participants who responded to advertisements and reported "alcohol problems" were randomized to one of these conditions and followed for 21 months. Although there was a higher rate of abstinence among women in individual therapy at the 3-month follow-up, there were no differences between groups at any subsequent time throughout the follow-up period. At the end of 21 months, almost 70 % had reduced their alcohol consumption from pretreatment levels and half of the total sample reduced alcohol use by at least 50 %.

Although relatively few studies have specifically tested individual versus group therapies using the same group content, the available research very clearly suggests that individual and group therapies are generally equivalent in terms of both retention and clinical outcomes. Thus, it seems that high-quality treatment can be administered as effectively in group as in individually delivered formats.

53.2.3 What Types of Group Therapy Are Most Effective?

The majority of studies examining group therapy for SUDs have focused on comparing two or more types of group therapy that vary in terms of content or approach. For example, several studies have compared skills training to other interventions and have yielded mixed results. Eriksen et al. (1986) randomized 24 alcohol-dependent participants to eight sessions of social skills training or counseling. The social skills training group reported fewer drinking days, drank less alcohol overall, and had better employment outcomes. A comparison of coping skills and interactional (interpersonal) groups for alcohol use disorders found no overall differences between the conditions in terms of alcohol use; however, individuals rated high on psychopathy had better outcomes with the coping skills group and those low on psychopathy had better outcomes in the interactional group, both following treatment (Kadden et al. 1989) and at 2-year follow-up (Cooney et al. 1991). A later study by this group randomized 250 alcohol-dependent patients

to either a random treatment assignment or matched treatment assignment based on level of psychopathy (Kadden et al. 2001). Results of this study were mixed, with higher rates of abstinence in the randomized condition, but fewer alcohol-related consequences in the matched condition.

Several studies have compared cognitive-behavioral therapies to other therapies or control conditions. Kaminer et al. (2002) randomized 88 adolescents presenting for outpatient substance abuse treatment to receive either cognitive-behavioral or psychoeducational group therapy. Results suggested an early benefit for cognitive-behavioral therapy; however, this was moderated by gender and age (with younger males responding better to cognitive-behavioral therapy) and the benefits were not maintained at 6-month follow-up. Both groups exhibited similar changes in substance use and functioning over time (Kaminer et al. 2002).

Similarly mixed results were found by Pomerleau et al. (1978) in a study of 32 alcohol-dependent men comparing behavioral therapy to psychodynamic group therapy. Results indicated better retention and less alcohol use in the behavioral therapy condition (consisting of several behavioral interventions, such as stimulus control and shaping), but higher rates of abstinence among completers of the psychodynamic therapy. A later study of male alcohol-dependent patients in a Veterans Administration hospital found no differences between cognitive-behavioral and interpersonal therapies on alcohol use outcomes (Ito et al. 1988). A study comparing 6 weeks of 12-step counseling (usual care) to behavioral skills training therapy, transactional analysis therapy, or their combination (Olson et al. 1981) found that all conditions were associated with superior outcomes compared to transactional analysis alone.

A comparison of six sessions of cognitive-behavioral group therapy for smoking cessation compared to a health education control plus nicotine replacement therapy in a sample of 154 African American smokers found greater rates of abstinence (past week) among those in the cognitive-behavioral therapy condition through 6 months of follow-up, with 31 % versus 14 % of participants abstinent at the end of follow-up (Webb et al. 2010).

Telch et al. (1984) compared supportive therapy, behavioral therapy (covert sensitization), and a control therapy in 28 alcohol-dependent patients in an outpatient setting. Although those in the supportive therapy reported lower daily drinking, there were no differences among groups on alcohol craving or randomly collected blood-alcohol levels across the three conditions.

Little research has compared group therapy to family therapy; however, a comparison of a process group therapy, family therapy, and family education for adolescents with SUDs suggested that family therapy was most effective in achieving drug abstinence (Joanning et al. 1992).

Results comparing types of group therapy have been largely inconclusive. Moreover, given dramatic variability across studies, it is difficult to make any generalizations based on the existing literature. Although some studies have found evidence for superiority of one type of group therapy over others, these results have often been limited to only certain outcomes or patient subgroups. At this time, more well-controlled studies are needed to determine what types of group therapy are most effective.

53.2.4 Comparing Group Therapies for Co-occurring Disorders

Other psychiatric disorders commonly co-occur with SUDs (Conway et al. 2006; Grant et al. 2004). Accordingly, numerous studies of group therapy for SUDs have examined therapies targeted to both the SUD and the co-occurring psychiatric disorder.

Weiss et al. (2000) compared usual care to usual care plus 12–20 sessions of an integrated group therapy for SUDs and bipolar disorder in a sample of 45 participants. Results indicated that the group therapy was associated with significantly lower SUD severity, more months abstinent, and longer durations of abstinence relative to usual care alone. In a subsequent study, 62 outpatients with co-occurring bipolar disorder and substance dependence were randomly assigned to 20 sessions of either the integrated treatment or group drug counseling (Weiss et al. 2007). Patients in the integrated group therapy had fewer days of substance use following treatment and throughout 3 months of follow-up; however, mood outcomes were similar between groups. Weiss and colleagues (2009) then tested the implementation of a 12-session version of the treatment with drug counselors without previous training in cognitive-behavioral therapy. Sixty-one participants were randomized to the integrated treatment or group counseling and results indicated better outcomes for both substance (e.g., likelihood of abstinence) and mood symptoms (e.g., greater reduction in risk for a mood episode) in the integrated treatment group.

In a study comparing dialectical behavioral therapy (DBT), which included a group therapy component, to treatment as usual for 28 women with co-occurring borderline personality disorder and substance dependence, there was significantly greater treatment adherence, more days abstinent, and more negative urine screens in the DBT group (Linehan et al. 1999). These findings for benefits of DBT were replicated in heroin-dependent women when compared to individual therapy (Linehan et al. 2002).

In a study conducted in Australia, James et al. (2004) randomized 63 participants with co-occurring alcohol or drug use and a psychotic disorder to receive either usual care and one session of substance use education or six sessions of an integrated treatment for both disorders. The integrated dual disorder treatment group was associated with significantly greater improvement in psychiatric symptoms, substance use, and SUD severity. In a similar study, Bellack et al. (2006) randomized 129 outpatients with a diagnosis of drug dependence and serious mental illness (psychotic or major affective disorder) to receive an integrated behavioral treatment (Behavioral Treatment for Substance Abuse in Severe and Persistent Mental Illness) or supportive group discussion twice weekly for 6 months. Results indicated that the integrated treatment was associated with more negative urine screens as well as better treatment retention and functional outcomes (e.g., quality of life).

Results for co-occurring depression and anxiety disorders have been more mixed. Lydecker and colleagues (2010) compared an integrated cognitive-behavioral therapy for co-occurring depression and SUDs to 12-step facilitation in a sample of 206 veterans with a current substance dependence diagnosis and

a lifetime diagnosis of major depressive disorder. Both treatments were associated with significant improvements in both depression and substance use outcomes; however, there was evidence for better maintenance of gains in reduction in substance use in the integrated treatment group.

Studies comparing Seeking Safety (Najavits 2002), an integrated treatment for co-occurring SUDs and posttraumatic stress disorder to usual care or alternative group treatments, have found both positive results (e.g., Najavits et al. 2006) and mixed results (e.g., Zlotnick et al. 2009). In a large trial of Seeking Safety, Hien et al. (2009) randomized 353 women with posttraumatic stress disorder symptoms and a diagnosis of a drug or alcohol use disorder to receive either 12 sessions of Seeking Safety or a comparison health education treatment. Results indicated significant improvement in posttraumatic stress disorder symptoms in both groups with no differences between groups and no significant effects of either treatment on alcohol or drug use outcomes; however, this may have been attributable to a low level of substance use at study entry.

Group therapy targeting co-occurring SUDs and other disorders has been successful in some cases (e.g., bipolar disorder and psychotic disorders), with more mixed results for anxiety and depressive disorders. Nonetheless, integrated group therapies are promising for the reduction of symptoms of both SUDs and co-occurring disorders and are an important area for further study.

53.2.5 How Can We Maximize Outcomes in Group Therapy?

Because the evidence generally supports the effectiveness of group therapy for SUDs, recent research has begun to examine ways to maximize its effectiveness. Several studies have tested ways to enhance group therapy by adding adjunctive interventions or manipulating group factors.

53.2.5.1 Adjunctive Treatments

Contingency management involves providing patients with reinforcers (incentives such as money or vouchers) for engaging in beneficial behaviors, such as providing negative urine drug screens or attending treatment sessions. Several studies have examined the addition of contingency management to group therapy to enhance attendance. Petry et al. (2011) examined the addition of a contingency management group to standard outpatient care (including group counseling and monitoring with urine toxicology screens) in community-based outpatient substance abuse treatment clinics. The addition of contingency management was associated with better program attendance (including more days of attendance and longer duration in treatment) and longer durations of drug abstinence. Other research has similarly found benefits of adding incentives for attending group sessions (Ledgerwood et al. 2008), although one study found only modest effects for attendance incentives (Alessi et al. 2007).

Santa Ana et al. (2007) randomized 101 dually diagnosed inpatients from a detoxification unit of a psychiatric hospital to receive two sessions of either a motivational enhancement group therapy or a group therapy control condition

in addition to standard care, to enhance adherence to aftercare. Results indicated that group motivational enhancement resulted in more aftercare sessions attended and fewer drinking days and heavy drinking days.

Studies examining the addition of adjunctive individual therapy to group therapy suggest that the benefits of this approach are modest, at best. In a large study of behavioral therapies for cocaine dependence, 487 individuals were randomized to one of four treatments, including 24 sessions of group counseling alone, or in combination with 36 sessions of one of three individual therapies: cognitive therapy, supportive-expressive psychodynamic therapy, and 12-step oriented drug counseling (Crits-Christoph et al. 1999). The best substance use outcomes were seen for the group drug counseling plus individual drug counseling intervention, followed by group drug counseling alone (Crits-Christoph et al. 2001). However, there were no differences among conditions on other functional outcomes (e.g., interpersonal functioning). Thus, the addition of individual drug counseling, and not other individual therapies, was associated with enhancement of some group therapy outcomes. Another study examined group counseling compared to group counseling plus individual relapse prevention therapy for cocaine dependence (McKay et al. 1997). Results at 6-month follow-up indicated greater likelihood of cocaine abstinence in group therapy alone, but fewer days of cocaine use among those who were not abstinent in the group plus individual therapy condition.

53.2.5.2 Intensity and Group Composition

Coviello et al. (2001) randomized 94 patients with cocaine use disorders to group therapy programs of varying intensities over a 4-week treatment program, including either 6 h of treatment (four of which were group) or 12 h of treatment (seven of which were group) per week (Coviello et al. 2001). There were no significant differences between study cohorts in terms of severity of substance use problems or other functional outcomes; on average, patients in both conditions improved on these measures.

Several studies have examined gender-specific group therapy for SUDs (e.g., Carroll et al. 1995; Copeland et al. 1993; Greenfield et al. 2007). Greenfield et al. (2007) compared a women-only relapse prevention group therapy, the Women's Recovery Group, to mixed-gender Group Drug Counseling. Results demonstrated higher satisfaction among women in the Women's Recovery Group (WRG) and similar drug use outcomes between groups. The WRG also appeared to have better alcohol use outcomes and better maintenance of gains 6 months following treatment. Moreover, the WRG seemed to have particularly beneficial effects on substance use outcomes for women with high psychiatric severity (Greenfield et al. 2008).

Several considerations may be valuable in attempting to enhance group therapy outcomes. First, adding incentives for attendance appears to enhance retention and achieve a higher dose of therapy. Second, treatment targeted to a population of interest (e.g., women) may yield added benefits relative to more general group therapy. However, studies of the addition of individual to group therapy remain somewhat inconclusive and require more study. Results to date suggest that the type of individual therapy added to group therapy may be important to determining

outcomes and that those who are not able to achieve abstinence in group therapy alone may benefit from individual therapy. Nonetheless, additional research is needed to better understand the potential benefits of combining group and individual therapies.

53.2.6 Summary and Integration of the Literature

Although research on group therapy for SUDs varies widely in the types of group therapy, substance of abuse, population of interest, and timing and delivery of treatment, several trends emerge from the existing literature. In general, studies adding group treatment to minimal or no treatment suggest that group therapy is associated with improved substance use and often also functional outcomes (e.g., Stephens et al. 2000; Weiss et al. 2000). Although not all studies have found evidence for this effect (e.g., Razavi et al. 1999), studies predominantly support group therapy as an effective intervention for SUDs. Results are mixed for adding group therapy to more powerful treatments (e.g., certain pharmacotherapies), with some evidence for no benefit for adding group therapy (e.g., Tucker et al. 2004) and others finding benefits for some outcomes or in certain subgroups (e.g., Luthar and Suchman 2000; Schmitz et al. 2007). However, many of these studies have been limited by either small sample sizes or uncontrolled designs (e.g., no limitations on additional adjunctive treatments); it thus remains unclear whether group therapy can achieve additive benefits when combined with pharmacotherapy.

Likewise, comparisons of different types of group therapy have generally yielded variable results. The relative effectiveness of different types of group treatment may depend on the fit of the intervention to the target population. For example, several integrated group therapies (such as those for SUD patients with co-occurring psychosis or bipolar disorder) have been associated with better outcomes than general alcohol and drug counseling therapies (e.g., Bellack et al. 2006; Weiss et al. 2007). Thus, the degree to which the treatment "fits" the population may be critical to understanding which treatment works best for what population.

Studies comparing individual to group delivery of substance abuse treatment (predominantly motivational enhancement or cognitive-behavioral therapy) have not found significant differences between individual and group therapy on substance use or other functional outcomes or differences in treatment retention. Although there is limited evidence for greater social functioning following group therapy (Graham et al. 1996) and greater patient preference for individual therapy (Sobell et al. 2009), the evidence overall seems to support the equivalence of these approaches for both drug and alcohol use disorders.

Given the mixed findings on effectiveness, strategies to maximize outcomes are of particular importance. The addition of incentives for attending treatment appears to improve retention, maximizing the "dose" of therapy that patients receive. Because the findings examining the addition of individual therapy to group therapy have been mixed, contingency management may be the best available strategy to enhance outcomes of group therapy.

The mixed outcomes reported above are likely due in part to the heterogeneity of studies and populations, including the dose (i.e., number of sessions) administered and the timing of when treatment occurs. In addition, many studies have used small sample sizes, which substantially limit the ability to identify differences in outcomes, particularly when comparing two active treatments, such as pharmacotherapy versus pharmacotherapy plus group therapy, or two types of group therapy. Thus, it is clear that more research is needed to understand what types of group therapy are most effective and under what conditions.

53.2.6.1 Why Is There so Little Research on Group Therapy for SUDs?

The domains of variability in conducting research on group therapy are substantial. Features such as open versus closed enrollment, group content/approach, and group composition (size and member characteristics) are all specific to group therapy research and are not relevant to studies of individual therapies. Additive designs may be of less concern than comparative designs for which conclusions about differential effects become more complicated. For example, comparing a single-gender group to a mixed-gender group might involve both differences in content (e.g., gender-specific group material) as well as composition (e.g., all women vs. men and women). Comparing individual to group therapy is even more challenging given the lack of clear guidance on equating the dosing of treatments. For example, if both group and individual sessions were 60 min, patients in individual therapy may gain a higher dose of therapy through more attention. However, if group sessions were longer, patients in group would be receiving more time in treatment. How to equivalently dose these types of therapy remains an open question (e.g., is a 90-min individual session equivalent to a 90-min group session).

The study of group therapy is also complicated by the number of potential variables that might contribute to the treatment's effectiveness. For example, active ingredients may include both the content of the group (e.g., the intervention components) and the format (e.g., group composition). Thus, studies can test one or both of these components, such as testing a group versus individual treatment or testing two types of group content or composition (e.g., single- vs. mixed-gender groups). Given the variability of studies conducted to date and – not surprisingly – variability in results, future well-designed research on group therapies will be important as we attempt to enhance outcomes and understand the best treatment approaches for patients with SUDs.

53.3 Conclusion

Group therapy is the predominant method of delivery of psychosocial treatments for SUDs. This approach is associated with lower cost than many other options as well as high satisfaction among patients. Evidence for the effectiveness of group therapy is mixed and interpretation of the literature is limited by the heterogeneity of studies and the absence of many large, well-controlled studies. Nonetheless, as a whole, group therapy appears to be an effective treatment for a range of SUDs,

particularly when the treatment is specific and well-defined; group treatment may be a particularly effective option for those with co-occurring psychiatric and substance use disorders. Studies suggest that group therapy is generally as effective as individual therapy, although the specific types of group therapy associated with the optimal outcomes remain somewhat unclear.

Acknowledgments Dr. Weiss's effort on this chapter was supported in part by award K24 DA022288 from the National Institute on Drug Abuse.

Abstract

To address a growing public health problem with youth cannabis use, five Western European countries – Belgium, France, Germany, the Netherlands and Switzerland – collaborated on a cannabis treatment research effort. After deliberation, the research priority chosen was to implement and rigorously evaluate a treatment program for adolescents with cannabis use disorders – virtually unavailable in Western Europe at the time. Adolescent cannabis use disorders were even denied by some policy makers as bona fide public health problems. The most promising candidate for the treatment program to be studied, based on cross-national expert analyses and an exhaustive review of research findings to date, was Multidimensional Family Therapy (MDFT), developed in the USA. When pilot training with candidate clinicians began, some claimed it was "too American." Some did not understand its innovation at first glance, stating that aspects of MDFT interventions were already part of daily clinical work. Others worried whether the senior role of psychiatrists would be jeopardized, and if the approach engaged in too much outreach, and would be a threat to in-office work. Still others said the model might be too practical, and ignore the need for depth-oriented, psychodynamic treatment – still dominant in parts of Europe. While at the outset MDFT presented as a cultural shock, concerns disappeared when the approach was taught, attempted and integrated into the regular practice settings. The multi-country randomized controlled trial was designed with considerable discussion and collaboration. Referred to as INCANT (International Cannabis Need of Treatment), this study, the first independent replication of MDFT, showed that most adolescents with cannabis use disorders in these five countries have multiple behavioral problems, including criminality, truancy and mental co-morbidity. MDFT proved to be more effective than a high level treatment as usual in reducing cannabis dependence and on other problem behavior measures as well. Positive outcomes were seen in all the five countries. And given the clinical outcomes, the therapist competence and fidelity outcomes, and the capacity of the sites to absorb this new clinical approach, MDFT was found to be feasible and adaptable to representative regular clinical care Western Europe settings, adding expanded treatment alternative to standard care. The challenges

of conducting a multi-national randomized controlled trial in real world, non-research settings foreshadowed subsequent efforts to sustain implementation of this evidence-based treatment program. While retaining the core principles, structure and interventions of the approach, the MDFT implementation strategy has been adapted in each of these European countries, as they vary in accreditation requirements, reimbursement rules, public and private position of treatment centers for youth with multiple problem behavior, regard for certain professional groups (e.g., social workers), and referral processes. Facilitating MDFT implementation in Europe has been like executing an EU financial crisis policy, but we are getting there.

54.1 Introduction

Adolescent health, substance misuse and correlated problem behaviors have become indisputable priorities on the global public health landscape (The Lancet 2012). But due to many intersecting issues at multiple influence levels, over two decades of scientific advances in adolescent intervention specialties have failed to yield widespread dissemination of evidence-based approaches. Standard clinical practice for drug involved youth around the world remains disconcertingly dissimilar from the evidence-based interventions reported in research journals, practitioner reviews, policy recommendations, and science-based intervention registries. Effectiveness studies and implementation trials in the adolescent treatment specialty are more frequent in recent years (Becker and Curry 2008). And, cross-national surveys and basic science research on youth substance misuse have added significantly to a useable knowledge base. But relative to need, the research-rooted knowledge about effective interventions remains underdeveloped, and at least in the treatment realm, collaborative transnational controlled trials are rare. The multisite study of Multidimensional Family Therapy (Multidimensional Family Therapy 2014a; Liddle 2010) is the first independent replication of MDFT as well as, to the best of our knowledge, the only study of its kind to date (Rigter et al. 2010, 2013; Schaub et al. 2014) – a multi-national controlled trial of an evidence-based therapy for youth substance misuse. Although an instrumental part of the contemporary process to be sure, controlled studies cannot guarantee transfer or dissemination of a program past a research project's endpoint. This article describes the implementation history, plan and outcomes of MDFT in Western Europe (Rowe et al. 2013), a research-based treatment with significant dissemination activity in the United States (Multidimensional Family Therapy 2014a) evolving into an internationally established treatment program (European Monitoring Centre for Drugs and Drug Addiction 2014b).

Before addressing implementation, we first outline key features of the clinical approach. MDFT is a comprehensive, family-centered and developmentally-oriented intervention for clinically-referred adolescents (Liddle 2010). The intervention has strong outcomes for adolescent substance abuse and delinquency in

a series of randomized controlled trials. Comparison conditions in these studies included active treatments or usual care in non-research community clinics (Hogue et al. 2014; Von Sydow et al. 2013; Williams and Chang 2000). MDFT treatment process and implementation studies (Hogue and Liddle 2009) support the model's putative mechanisms of change (Henderson et al. 2009, 2010; Hogue et al. 2008; Diamond et al. 2006; Schmidt et al. 1996), and economic analyses indicate MDFT is less expensive than standard care (Zavala et al. 2005).

The MDFT research program began with National Institute on Drug Abuse funded studies in 1985 (Multidimensional Family Therapy 2014c; Sherman 2010; Liddle 1999), and continues today at the Center for Treatment Research on Adolescent Substance Abuse (Center for Treatment Research on Adolescent Drug Abuse 2014), University of Miami, Miller School of Medicine. Core to MDFT is the idea that an adolescent's problems are influenced by interacting factors from interconnected life domains (Fogel and Thelen 1987; Gottlieb 1991; Granic and Hollenstein 2003; Thelen and Smith 1994); hence, the term "multidimensional" (Liddle and Rigter 2013). MDFT addresses four domains/systems in the life of the youth: the adolescent him- or herself, the parent(s), the family, and systems outside of the family such as friends, school, work, prosocial activities, and (when applicable) juvenile justice authorities. Improvement of functioning in all life domains helps the adolescent to abandon problem behaviors including drug taking and heavy drinking.

The approach includes interventions such as:

- Enhancing treatment engagement and motivation of the youth and parent(s)/guardian(s)
- Self examination and generation of alternatives for youth problem behavior (through individual sessions and by utilizing family support and structure)
- Relapse prevention (relative to substance abuse and other problem behaviors)
- Improving communications and relationships between family members
- Strengthening parental functioning, and parenting skills
- Coordination with other systems (school, work, justice) to facilitate positive outcomes for the youth.

MDFT is manualized but flexible. The approach has been tested and exists in different versions that vary according to individual case characteristics, treatment setting, and treatment parameters that might be dictated by the clinical setting. Guiding principles orient the clinician to treatment guidelines and protocols that specify how to conduct core sessions with the four main units of intervention – the youth, parent(s), family, and the systems of influence that are relevant to the youth's and family's current circumstances. Clinical skill and judgment remain critical within these structures. On average, there are 2 sessions per week for 4–6 months, with the adolescent alone, the parent alone, the family (parent plus youth and other family members as needed), and key parties in influential systems (e.g., school or juvenile justice) present. MDFT therapists work in teams of three to six members, including the supervisor and often a therapist assistant, who may assist with a range of community interventions.

54.2 MDFT in Europe: The History

Fifteen years ago, EU member states were debating cannabis policy. Cabinet members from five Western European countries (Netherlands, France, Belgium, Switzerland and Germany) agreed that the discourse was uninformed due to insufficient data on the effects of cannabis. A common cannabis research and development project was commissioned to fill the gaps in knowledge. Rigter was appointed project leader. A Steering Group was convened between 2000 and 2010 with representatives from the federal Ministries of Health in Belgium, Germany, the Netherlands, Switzerland, and from the government substance abuse office in France. Its work began by consulting experts from Australia, Europe, and the USA to identify cannabis research priorities, which were jointly discussed in a conference in Brussels (Spruit 2002). Based on expert recommendations, a literature review, and the Steering Committee's own deliberations, the evaluation and implementation of a treatment program for adolescents with cannabis use disorder was defined as the multi-national group's principal priority.

This decision was not undisputed. Initially, some reported that in their countries, adolescent cannabis use disorder was rarely seen, yet these countries lacked treatment services specifically for youth or mechanisms to identify adolescents with these problems. The Steering Committee opted for the aforementioned priority, understanding that most adolescents with a cannabis use disorder also manifest other problem behavior such as criminality and school failure, necessitating a treatment program to focus not only on cannabis use, but on commonly related problems as well (Spruit 2002).

Which treatment program was to be chosen? A systematic literature review was conducted (Rigter et al. 2004), from which MDFT emerged as the superior treatment candidate on the basis of its research evidence and clinical scope (Brannigan et al. 2004; Vaughn and Howard 2004). Cannabis was targeted effectively in MDFT studies in the US, and other elements of adolescent problem behavior were changed as well (Rowe 2010). The Steering Committee opted for MDFT, and MDFT developer Liddle agreed to collaborate. The Steering Group organized a meeting in Zurich in 2004, where Liddle presented MDFT to a critical jury of high ranking European addiction scientists. MDFT passed the test; the Steering Group decided to test the effectiveness of MDFT in Western Europe, and if study results warranted, follow the trial with implementation in practice. This research effort was named INCANT – International Cannabis Need of Treatment study. Steering Group members nominated outpatient clinical sites in their countries for participation in the study. To assess site interest, and viability in terms of case flow and appropriateness, clinicians' background, research capacity, and infrastructure stability, Rigter, the study Principal Investigator, Liddle and MDFT researcher and trainer Rowe made screening visits to each prospective clinical center in early Summer 2004. The selected sites for the multisite research included: Brugmann Hospital (an outpatient substance abuse treatment department of a university hospital in Brussels, Belgium), Centre Emergence (substance abuse treatment in Paris, France), Therapieladen

(substance abuse treatment in Berlin, Germany), the partnering Dutch centers of De Jutters (forensic youth [mental health] care) and Parnassia-Brijder (substance abuse treatment) in The Hague, and centers in Basel and Bern in Switzerland. All sites had links with university-based or other research institutes.

Government departments in the five countries funded a pilot study in 2005. It addressed three questions: (a) Could clinicians from the selected clinical sites be trained as MDFT therapists and supervisors, (b) Did the selected sites have sufficient access to adolescents with cannabis use disorder for INCANT recruitment purposes? and (c) Could these clinical settings conduct a rigorous community-based randomized controlled trial? These challenges were all met successfully by the clinical sites (Rigter 2005). All European candidate MDFT therapists had experience treating youth and many had strong foundations in family-based interventions. Their backgrounds varied from social workers with additional therapist training (Berlin, The Hague) to psychologists (all sites), a child and adolescent psychiatrist (Paris), and a psychiatric nurse (Brussels). In preparing for the pilot, sites debated the appropriate educational degrees of the MDFT therapist candidates (such as social work, as one example), but in the end, no specialties were excluded. Using the same standardized training methods, materials, and certification procedures developed in U.S. based controlled trials (Hogue et al. 2008), senior MDFT trainers from the Center for Treatment Research on Adolescent Drug Abuse at the University of Miami trained the diverse cohort of European clinicians in MDFT. Candidates were trained to adequate levels of adherence to MDFT protocols during the pilot study (Rigter 2005). The initial two Swiss sites had difficulties identifying appropriate referral sources for the trial and were replaced for INCANT by Phénix, an outpatient substance abuse treatment center in Geneva.

The Steering Group was satisfied with the findings of the pilot study, advising their respective government departments to fund the larger scale INCANT randomized controlled trial. The INCANT trial, initiated in 2006 and completed in 2010, compared MDFT to active individualized treatment as was routinely delivered in each site (Rigter et al. 2010). The control treatment, Individual Psychotherapy (IP), shared common elements across the five sites: therapy sessions were held only with the adolescent and targeted substance abuse and other problem behaviors. Despite commonalities, details of the IP's theoretical orientation differed among the five sites/countries. In The Hague and Brussels, IP was cognitive behavioral therapy. Psychodynamic ideas were influential with the IP clinicians in Geneva and Paris. And, IP therapists in Berlin followed a more eclectic treatment approach, borrowing from both mentioned treatment orientations.

All sites had sufficient access to adolescents with cannabis use disorder – per their usual case referrals, and sometimes via outreach and collaboration with other treatment centers (Berlin), juvenile judges (Switzerland) or media calls (Brussels). The sites would need to recruit 60–120 adolescents/families each for the INCANT trial. In the pilot and the subsequent randomized trial, sites differed in primary referral routes (Phan et al. 2011). Belgium and France recruited mainly through schools and families. In The Hague and Switzerland, most study adolescents were mandated to treatment by probation officers or other justice-related authorities.

In Berlin, the authorities offered troubled youth a sheltered living arrangement with pocket money, and some coercion to accept treatment as well (Rigter 2005).

Results of the randomized trial (n = 450) showed that across sites, irrespective of IP theoretical orientation, MDFT outperformed IP on major outcome measures. Most prominent was the larger reduction of the rate of cannabis disorder for MDFT participants compared with IP youth up to the 1 year follow-up (Rigter et al. 2013; Schaub et al. 2014). Retention rates for MDFT participants were twice as high than for IP adolescents (Rowe et al. 2013). This effect was consistent across all sites, and these clinical outcomes and retention rates are consistent with the U.S.-based trials. INCANT MDFT therapists demonstrated adherence and competence on treatment fidelity measures, suggesting that MDFT could be adopted with strong adherence in diverse cultures and systems in Western Europe (Rowe et al. 2013).

54.3 Facilitating MDFT Acceptance in European Youth Care Practice

In INCANT, MDFT proved to be transferable to the Western European locales that were part of the trial. This finding, of course, does not confirm that MDFT can be implemented and sustained in any practice setting. Making implementation work requires manpower, funding capital, persistence and tenacity, and continuous support for treatment agencies adopting the treatment program.

Next we discuss several implementation challenges, drawing from our experience with MDFT in the Netherlands, where implementation has advanced most rapidly and broadly, but also painting a broader European picture.

54.3.1 Facilitating Interest Among Therapists

For many therapists, MDFT means stretching beyond one's comfort zone: from conducting one session once every 2 or 3 weeks to doing several sessions per week; from scheduling sessions at the office to also seeing the family at their home and in the community; from a focus on one disorder or problem behavior to a comprehensive approach; from solely treatment sessions to treatment plus case management extending to all major domains in the life of an adolescent.

Difficulties in changing practice patterns are always a worry in evidence based therapy transfer. In the case of the Netherlands, for instance, we met with genuine interest from therapists all over the country. Some clinicians had their interest piqued by word-of-mouth, or by video-intensive presentations by INCANT MDFT therapists. Dissatisfaction with the outcomes and limited scope of their own professional work might have been another reason therapists were curious about and open to MDFT. The appeal of working in teams – as defined in MDFT – was another influential factor. Clinicians also learned that they could have a role in expanding MDFT services, which helped in committing them to the treatment program. Our subsequent experience with Finland has been similar in these ways.

In discussing the challenges and worries about the transfer potential of North American based prevention intervention programs in Europe, Burkhart (2013) sheds considerable light on a still to be fully illuminated process. We have also concluded that these idiosyncratic responses to an intervention's philosophy, clinical features, even training requirements and methods are among the probably many germane intervention characteristics. In France and Switzerland, for instance, we found psychodynamic traditions to remain influential and that adoption of more practical, family systems, and outcome-oriented treatment programs such as MDFT can be a stretch. Initially, concerns were voiced that one's freedom as a therapist could be curtailed by following a treatment manual. Clinical presentations by INCANT MDFT staff emphasized the how-to aspects of the approach. Aspects of clinicians' current thinking, practice habits, and previous training were used as ways to learn about a new approach. But vital to the clinician change process was a supportive and guiding type of supervision to help therapists with cases in their own clinical settings. Hardly a simple administrative decision, implementation involves multiple and intersecting processes within an organization or system of care. At the therapist level, changing a clinical mind set may involve direct or indirect challenges to ingrained views, and transforming treatment paradigms by offering training in and considerable support to learn new methods.

Perhaps there was a time when researchers believed that publication of study outcomes will yield recommendation adoption. But experience and the burgeoning literature in specialties such as implementation science demonstrate the complexity of practice change. Scientific journals do not target clinicians. Therapists need to be informed in terms relevant for daily practice. We have written MDFT materials in Dutch, English, German and French. We also produced a DVD with basic facts about MDFT and with interviews with an adolescent and his mother, therapists, and a juvenile judge (in Dutch, with English and German subtitling; see video at Multidimensional Family Therapy 2014d). Country-specific websites offer information for therapists and centers (and for teenagers and parents); see for instance (Multidimensional Family Therapy 2014e). Following a community of practice model, we update MDFT information through e-mails, e-newsletters, social media, and face to face substantive clinical meetings for therapists. But as has been the case in MDFT's dissemination in North America, materials play only a supporting role in influencing clinicians. Therapists and managers of treatment agencies experience the worth of MDFT during on-site visits. Videos demonstrate the approach in action, and live sessions with local clinicians being coached in the main MDFT methods seem critical to address their particular realities and questions. As in MDFT itself, relationships and gaining hands-on experience with the approach are instrumental.

54.3.2 The Treatment Agency

Multiple factors and levels of process interact with therapist variables to create a context of receptivity and change in adopting an evidence-based program.

The treatment agency, particularly the *manager* of the department where the MDFT team will be housed, are key in this regard. Although often interested in MDFT, managers are challenged to integrate this program, or any program for that matter, into local routines and financial structures. We facilitate this integration, a *systems intervention* in and of itself, in various ways. Implementation staff visit the management of a treatment center a few times before the contract for training is signed, and afterwards once every 6 months. In the Netherlands, we also convene regular meetings with all managers together. Topics of discussion include: (a) reimbursement of MDFT; (b) where and how to enroll cases to be treated with MDFT (referral policies, relationships with other treatment sectors); (c) how to arrange coverage for MDFT therapists to be available after regular working hours without violating labor regulations; (d) ethical and legal issues, including the protection of the privacy of clients; and (e) treatment innovation. This is all critical for implementation success. We are extending this systematic approach of administrative collaboration to other European countries.

In all Western European countries where MDFT is being implemented, treatment agencies are facing a mix of public and private policies. In the Netherlands, an agency has some leeway to choose its own course in offering treatments. In Belgium, MDFT was to be paid through federal or regional government budgets as long as the treatment was deemed 'experimental' – and anything not performed by a medical doctor will remain experimental for a long time. In Flanders at least, treatment agencies now have more freedom to opt for MDFT if insurance companies agree to pay the bill. In Germany in 2012, the federal government opened positions for treatment centers to take part in an MDFT implementation project. Major adolescent substance abuse treatment centers did apply (in Cologne, Dresden, Hamburg and Munich) and are now part of a four-center implementation effort. Without the government subsidy, these agencies would not have signed up for MDFT. Treatment innovation is difficult in Germany, because local, state and federal authorities and insurance agencies – although all supporting MDFT by now – are in deadlock about who is to take the initiative to get MDFT established and financed. An additional complication is that in Germany, therapists are expected to pay from their own pocket for any training in a new treatment program. In all other Western European countries, the treatment agency pays to train an entire MDFT team. Implementation of MDFT in Germany is proceeding, but future prospects – when the federal subsidy ends – are uncertain. Of note, too, is the position of national professional organizations, such as in Germany, the German Association for Systems Therapy and Family Therapy (DGSF). In a systematic literature review carried out under the umbrella of DGSF (Von Sydow et al. 2007), MDFT was found to be an effective therapy. DGSF is in favor of giving MDFT a place within the DGSF framework, but MDFT concepts need to be harmonized with DGSF concepts first, and this will take time. Terms like 'supervisor' have different meanings in MDFT and DGSF contexts. MDFT accreditation by DGSFT is necessary to convince therapists to personally pay for training in MDFT.

In France, the INCANT trial and ongoing liaison efforts of the MDFT team leader (Phan) combined to convince government services (MILDT; and the Ministries of Health and Justice) to support MDFT after the research study ended. Adolescent substance abuse centers were willing to meet a call to have teams of therapists trained in MDFT, with subsidy from MILDT. Teams are in training in Lille and Dijon. Teams focusing on forensic or residential care will follow in the suburbs of Paris. The aim of the French government is to have at least one MDFT team per region (country).

All in all, implementing a treatment program in a country requires adequate knowledge of national, regional and local policies and politics. Local experts must be fully on board. For lasting implementation, it does not suffice to have good research data or to win over therapists; one also needs the enduring support of the management of treatment centers and of policy makers at all levels of the youth care sector. One needs to have staff to make this happen, and to pay for that staff, one needs funding capital. In the Netherlands, we were fortunate to secure charity funding. All other European MDFT countries, except Finland, rely on government subsidies so far, which is insecure in times of economic crisis.

54.3.3 Requirements for a MDFT Program

Implementing MDFT in Europe was a joint aim of the MDFT experts at CTRADA and pioneers in Europe, headed by Rigter. MDFT developers saw throughout the INCANT pilot and trial that MDFT would disseminate throughout Europe only if the MDFT leaders in each country experienced personal ownership – a sense of being pioneers themselves. Rigter established "MDFT Academy" in 2008, a Dutch-based foundation to offer MDFT training to teams of therapists in Europe. Liddle granted MDFT Academy the free-of-charge right to train MDFT teams in Europe, provided training principles and procedures would conform to established MDFT standards developed in research trials and applied in US-based implementation efforts. MDFT representatives from Western European countries founded "MDFT Europe" in 2010, a body for agreeing on MDFT (training) practices in Europe in order to ensure consistency and uniformity.

It is made clear from the outset what it takes for a treatment institute to offer MDFT. MDFT Academy uses a set of MDFT program requirements as formulated in the MDFT manual (Liddle 2007). All MDFT supervisors and therapists must be certified (see below). Candidates for MDFT therapist training must have a university (usually psychiatrist, psychologist, pedagogue) or college (social work) degree, with additional education in psychosocial therapy. They need to have at least 3 years of experience in treating adolescents and have a basic knowledge of family therapy. An MDFT therapist is pragmatic, non-judgmental, skilful in communication, willing to work irregular hours, and receptive to feedback, seeing that there is always more to be learned. He or she is open to teamwork, intervision and supervision. The same is true of a MDFT supervisor, who also should have leadership skills.

54.3.4 Training

Important are (a) the course materials, and (b) the training interventions. The key training document is the MDFT Manual (Liddle 2007) and accompanying protocols, which have been translated in European languages (Dutch, German, French) and adapted to local practice (e.g., regulations, referral mechanisms, assessment tools as used by youth probation officers and other professionals).

American and European trainers use parallel presentation materials, core MDFT videos, and written case vignettes to cover the introductory didactic training. Instruction DVDs target the same topics, but key treatment sessions shown for training purposes are increasingly from local (Dutch, German, etc.) practice. Training interventions include plenary content and protocol review days (all trainees come together); the systematic evaluation of treatment session recordings for MDFT adherence and competence, and of supervision session recordings for supervision skills; regular site visits by the MDFT trainer to the MDFT team for on-site case review and other feedback; regular consultation telephone calls between the trainer and the supervisor and the whole team; annually, fully documenting 1 case by the trainee (session planning, case assessment, treatment plan) with feedback from the trainer; an extensive written exam; and booster training of the team and, separately, of the supervisor.

54.3.5 Certification and Licensing

The full training in MDFT takes 2 years. The Basic Level certificate is issued at the end of Year 1, the Master Level certificate after Year 2.

In Europe, teams with at least three Master Level certified members receive a free-of-charge license to practice MDFT. Once every 3 years, teams are required to refresh their license, allowing MDFT Academy to check if MDFT is still carried out properly.

54.3.6 Trainers

MDFT trainers achieve their status by developing through the ranks, first as an MDFT therapist, then supervisor, before being invited for trainership. Trainers are trained by G. Dakof (Multidimensional Family Therapy 2014b) and by MDFT Academy. At present, there are 8 Dutch trainers, 1 Flemish and 1 French-speaking trainer in Belgium, 3 trainers in Germany, 1 in France, and 1 in Switzerland.

54.3.7 MDFT Teams Trained in Europe

Between 2008 and Spring 2013, 35 Dutch teams have been trained in MDFT or are presently in training. Add to this number 2 teams in Belgium, 5 in Germany,

5 in Finland, 5 in France, and 1 in Sweden, and the European total approximates 60. There are 50 teams in the United States, yielding 110 MDFT teams worldwide.

As is the case in the U.S. uptake of MDFT, the European teams originate not only from addiction treatment, but also from youth care, mental health, and forensic settings. In Europe, MDFT has evolved beyond the narrow connotation of being an addiction treatment. In accordance with the evidence base, MDFT is seen as a treatment program for adolescents with diverse, often multiple problem behavior, regularly including delinquency and substance abuse.

54.3.8 Accreditation

'Accreditation' in Europe requires that a treatment program is evidence-based. Although MDFT is included in North American evidence-based practice registries (Substance Abuse and Mental Health Services Administration 2014; Sherman 2010; Crime Solutions 2012; Division 53, American Psychological Association 2012; California Evidence-Based Clearinghouse 2012), European policy makers and scientific bodies are keen to make their own assessments. In the Netherlands, approval by the National Accreditation Committee on Justice-Related Behavioral Interventions is required for the Ministry of Justice to fund forensic treatment settings. This Committee uses ten criteria to evaluate interventions. The treatment program must be effective and should be based on a strong theory explaining how multi-problem behavior arises. Risk and protective factors are to be specified and clearly linked to concrete interventions, including skills training. The treatment program must be phased, with emphasis on motivating cases in the beginning and on providing continuity of care at the end. The program should include quality assurance control, making sure it is carried out competently, and should adhere to the therapy's basic principles. MDFT Academy filed the dossier requested and, in 2011, the Committee mentioned accredited MDFT. The Netherlands Youth Institute (NJI) followed suit, and has accredited MDFT for use in all youth care sectors. Although other European countries have less formal mechanisms of accreditation, they may use, at least in part, the positive verdicts in the Netherlands.

Accreditation is not just an issue of individual European countries. The EMCDDA (European Monitoring Centre of Drugs and Drugs Abuse) is the European Union 'drug tsar' office, so to speak. The EMCDDA reviewed adolescent drug abuse treatment programs and affiliated researchers conducted meta-analyses. MDFT outcomes were judged to be strong (European Monitoring Centre for Drugs and Drug Addiction 2014a), and this independent evaluation is consistent with others that support the individual studies and overall research base of MDFT.

54.3.9 Reimbursement

Accreditation is the green light for funding agencies to pay for a treatment program. MDFT is now being paid from all relevant reimbursement schemes in the

Netherlands and Finland, including government sources and private health and social insurance companies. It is being funded by the (federal) governments in Belgium, Germany and France, yet a challenge here is to convince insurance companies and local authorities to take over reimbursing MDFT.

54.3.10 Innovation

A treatment program that is inflexible because it is based on just one protocol-dictated model application will not meet lasting approval of therapists in the heat of their daily work. A treatment program that is open to innovations in practice that will both retain model fidelity and address local needs is more likely to be accepted widely by practitioners.

In Europe, we regularly get feedback from trainees such as: MDFT is wonderful, but I work in setting X or Y (for instance, residential youth care, or a day treatment program) or with a special population such as adolescents with sub-normal IQ (mild mental handicap) or with emerging signs of other mental disorders. And then they ask: Can MDFT be made applicable in those settings and for those target groups as well? The answer often is not a simple yes or no. We will carefully assess the possibilities of developing new applications of MDFT, and will accept the challenge if the prospects are good and if we have the proper means (manpower, time, money, interested treatment centers).

Special 'modules' have been developed in the Netherlands for incorporating MDFT in residential settings, such as juvenile detention centers or residential youth care institutes. The aim is to start with MDFT during intramural residency of the youth, and to continue this program on an outpatient basis once the youth has been released. This approach is also pursued in the USA, for instance through the DTC (Detention to Community) project (Liddle 2010). One other novel application of MDFT is to offer the therapy to adolescents/families on an outpatient basis to avoid residential out of home placement of the youth (Henderson et al. 2011). In 2011, the MDFT team of one residential youth care institute in the Netherlands succeeded in convincing 81 % of referred adolescents/families to opt for outpatient MDFT rather than for the indicated residential placement. None of these adolescents who participated in the outpatient alternative required out of home placement post treatment.

54.4 Conclusion

Implementation is complex, hard work. We have given an overview of MDFT implementation hurdles and breakthroughs in Europe. MDFT has been disseminated in the Netherlands more quickly than in other European countries, because there was money to fund training infrastructure and start up activities. Other European countries are now gearing up, with continued MDFT dissemination to be seen in the next few years.

One might say that these other European countries could replicate the Dutch model, but this would be a misapprehension of implementation realities. The exact path traveled in the Netherlands will not necessarily work in Belgium, Finland, France, Germany, Switzerland, or any other country. Implementation should always acknowledge the basic principles of the treatment program but procedures must and can be adapted to local circumstances.

International collaboration can speed up implementation. There is close working relationship between European stakeholders in disseminating MDFT and setting quality standards, and there is tight collaboration between Europe and the source of MDFT, the USA (www.mdft.org). Important here has been the decision of the MDFT personnel to consider this treatment program as a public asset rather than a commercial product.

The implementation outcomes of MDFT in a European context discussed in this chapter and elsewhere (Rowe et al. 2013) add to published reports of MDFT implementation in the U.S. (Liddle et al. 2002, 2006). These studies showed that MDFT can be successfully transported to usual care American juvenile justice, mental health, and addiction care settings with multi-ethnic youth presenting with a range of problem behaviors (substance abuse, delinquency, symptoms of other mental and behavioral disorders), and taught to staff from various professional backgrounds (psychiatrists, psychologists, social workers, nurses, juvenile justice court staff, judges, lawyers) (Liddle et al. 2006).

The pursuit of international projects that have included independent replication of previous outcomes contributes to a treatment system's development, and offers another metric by which its usefulness can be assessed. The knowledge base about how an intervention should and can be adapted, culturally, emerging institutionally (systems of care), or procedurally (intervention structure, methods), are in an early developmental stage. Although guidance is emerging about the international transport of evidence-based interventions, numerous controversies have been specified as well (Andréasson 2010). International work, like travel in general (De Botton 2002), offers perspective and insight unavailable at home. In the case of MDFT, the international implementation described in this chapter offers a case study of the complex and sensitive intervention adoption process. This effort has enriched our knowledge of the change principles that guide clinical work with adolescents and families across cultures and settings, and our dissemination work as well.

Couples Therapy in Treatment of Alcoholism and Drug Abuse

55

Timothy J. O'Farrell

Contents

Abstract

Couples therapy has been developed and studied as an approach to treating married or cohabiting individuals seeking help for alcoholism or drug abuse, starting in the 1970s. Behavioral Couples Therapy (BCT) is a specialized form of couples therapy that has received substantial research support. BCT sees the substance-abusing patient together with the spouse or live-in partner for outpatient couple counseling sessions. BCT aims to build support for abstinence

Author Note: This chapter is adapted from a clinical guideline developed for the Behavioral Health Recovery Management project, a project of Fayette Companies, Peoria, IL, and Chestnut Health Systems, Bloomington, IL, that was funded by the Illinois Department of Human Services' Office of Alcoholism and Substance Abuse. This chapter also draws heavily from the book *Behavioral Couples Therapy for Alcoholism and Drug Abuse*, copyright 2006 by Guilford Press. and to improve relationship functioning. BCT promotes abstinence with a "recovery contract" that involves both members of the couple in a daily trust discussion ritual to reward abstinence. BCT improves the relationship with techniques for increasing positive activities and improving communication.

Research shows that BCT produces greater abstinence and better relationship functioning than typical individual-based treatment and reduces domestic violence and emotional problems of the couple's children. Most research on BCT has been done in the USA. Four BCT studies have been done internationally outside the USA, in Canada, India, the Netherlands, and Australia. Despite the promise of BCT in countries that have developed health and addiction services, it seems unlikely that countries with less developed health systems would make use of BCT as currently practiced in the USA. Possibly, some components of BCT – such as the daily trust discussion in which the addicted person states their intention not to use that day to a family member who thanks the person for their efforts – might be adapted for use more broadly.

55.1 Introduction

Historically, alcoholism and drug abuse have been viewed as individual problems best treated on an individual basis. However, over the past 35 years, there has been a growing recognition that couple and family relationship factors often play a crucial role in understanding and treating substance abuse. *Behavioral Couples Therapy* (i.e., "BCT") for alcoholism and drug abuse is one approach that has developed out of this recognition.

Viewed from a couple perspective, there are several antecedent conditions and reinforcing consequences of substance use. Poor communication and problem-solving, arguing, lying and distrust, financial stressors, and nagging are common antecedents to substance abuse. Additionally, caretaking by the non-substance-abusing spouse following drinking or drug use can inadvertently reinforce substance use. Further, spouses' resentments, while understandable, can lead to ignoring rather than reinforcing abstinence. BCT was designed to address these couple factors in the recovery process.

55.2 Behavioral Couples Therapy

55.2.1 Description of the Approach

55.2.1.1 Overview of BCT

Behavioral Couples Therapy (BCT) was designed for married or cohabiting individuals seeking help for alcoholism or drug abuse. BCT sees the substance-abusing patient together with the spouse or live-in partner. Goals of BCT are to build support for abstinence and to improve relationship functioning. BCT promotes abstinence with a recovery contract that involves both members of the couple in

Table 55.1 Components of *recovery contract*

Daily trust discussion
Alcohol/drug abuser states intention to stay abstinent *that day*
Spouse thanks alcohol/drug abuser for efforts to stay abstinent
Patient thanks spouse for support
Couple does not argue about past or future substance use
Medication to aid recovery
Self-help involvement
Weekly urine drug screens
Other weekly activities to support recovery
Progress recorded on calendar

a daily trust discussion ritual to reward abstinence. BCT improves the relationship with techniques for increasing positive activities and improving communication. BCT also fits well with 12-step or other self-help groups, individual or group substance abuse counseling, and recovery medications. BCT can be easily integrated into a variety of orientations to addiction treatment, including 12-step and cognitive-behavioral addiction programs.

BCT is founded on two fundamental assumptions. First, family members can reward abstinence. Second, relationship distress and conflict are powerful triggers for substance abuse and reduction of these triggers improves treatment outcomes. BCT typically consists of 12–20 weekly outpatient couple sessions over a 3–6-month period. Generally, couples are married or cohabiting for at least a year, without current psychosis, and one member of the couple has a current problem with alcoholism and/or drug abuse. The couple starts BCT soon after the substance abuser seeks help. BCT can start immediately after detoxification or a short-term intensive rehab program or when the substance abuser seeks outpatient counseling. The remainder of this section on clinical procedures for BCT is written in the form of instructions to a counselor who wants to use BCT.

55.2.1.2 Building Support for Abstinence with the Recovery Contract

BCT uses a recovery contract as a major support for abstinence. The first part of the contract is the "daily trust discussion" in which the patient states his or her intent not to drink or use drugs that day (in the tradition of "one day at a time"), the spouse expresses support for the patient's efforts to stay abstinent, and the patient thanks the spouse for the encouragement and support. For patients taking a recovery-related medication (e.g., disulfiram, naltrexone), this is done as part of the trust discussion. The spouse records performance of the trust discussion and other recovery supports (self-help meetings, drug screens, medication) on a calendar that is provided. The calendar provides an ongoing record of progress that the therapist reviews and praises at each session. Finally, the couple agrees not to discuss substance-related conflicts which can trigger relapse, reserving these discussions for the counseling sessions. Table 55.1 summarizes the components of the recovery contract.

Typically, it takes three or more sessions before the contract goes smoothly. In the first BCT session, the couple rehearses the trust discussion part of the contract in

session and agrees to try it each day for the coming week at home. In the next BCT session, if they did it faithfully at home, the couple signs the contract for a specific time period. In each subsequent BCT session, the counselor reviews the contract performance in the past week and the couple does the trust discussion in session to highlight its importance. Self-help meetings, drug urine screens for patients with a current drug problem, and recovery-related medication are part of the contract for many patients – each activity helps the patient stay abstinent and demonstrates to the spouse the patient's commitment to abstinence and a changed lifestyle.

It is important for couples to see that the recovery contract does not conflict with 12-step beliefs. For patients, stating that they do not intend or plan to drink or use drugs in the next 24 h does not constitute a guarantee or conflict with having a disease over which they are powerless. For spouses, being part of the trust discussion or observing the patient take recovery medication in no way makes them responsible for the patient's recovery.

Recovery Contract Case Example #1

Figure 55.1 presents the recovery contract and calendar for Mary Smith and her husband Jack. Mary was a 34-year-old teacher's aide in an elementary school who had a serious drinking problem and also smoked marijuana daily. She was admitted to a detoxification unit at a community hospital after being caught drinking at work and being suspended from her job. Her husband Jack worked in a local warehouse and was a light drinker with no drug involvement. Mary and Jack had been married for 8 years, and Jack was considering leaving the marriage, when the staff at the detoxification unit referred them to the BCT program.

The therapist developed a recovery contract in which Mary agreed to a daily "trust discussion" in which she stated to Jack her intent to stay "clean and sober" for the next 24 h and Jack thanked her for her commitment to sobriety. The couple practiced this ritual in the therapist's office until it felt comfortable and then also performed the discussion at each weekly therapy session on Wednesday evening. As the calendar in Fig. 55.1 shows, they did this part of the contract nearly every day, missing only on an occasional Saturday because their schedule was different that day and sometimes they forgot. Mary agreed to at least two AA meetings each week and actually attended three meetings per week for the first 2 months.

Jack was pleased to see Mary staying sober and going to AA. However, he was upset that weekly drug urine screens were positive for marijuana for the first few weeks, taking this as evidence that his wife was still smoking marijuana even though she denied it. The therapist explained that marijuana could stay in the system for some time particularly in someone who had been a daily pot smoker. The therapist suggested Jack to go to Al-Anon to help him deal with his distress over his wife's suspected drug use. After a few weeks, the drug screens were negative for marijuana and stayed that way lending further credence to Mary's daily statement of intent. Jack found Al-Anon helpful and the couple added to their contract that one night a week they would go together to a local church where Mary could attend an AA meeting and Jack an Al-Anon meeting.

Recovery Contract Case Example #2

If both members of a couple have a current substance problem and both want abstinence, then BCT often is workable. This was the case of Sue and Gene – a dual-problem couple. Sue came to BCT after detox for heavy daily drinking plus cocaine and marijuana 3–4 times per week. Gene had similar problems but did not need detox.

RECOVERY CONTRACT

In order to help (patient) Mary with his/her recovery and to bring peace of mind to (partner) Jack, we commit to the following:

Patient's Responsibilities	Partner's Responsibilities
☒ DAILY TRUST DISCUSSION (with medication N.A. if taking it)	
• States his/her intention to stay substance free that day (and takes medication if applicable).	• Records that the intention was shared (and medication taken if applicable) on calendar.
• Thanks partner for supporting his/her recovery.	• Thanks patient for his/her recovery efforts.
☒ FOCUS ON PRESENT AND FUTURE, NOT PAST	
• If necessary, requests that partner not mention past or possible future substance abuse outside of counseling sessions.	• Agrees not to mention past substance abuse or fears of future substance abuse outside of counseling sessions.
☒ WEEKLY SELF-HELP MEETINGS	
• Commitment to 12-Step mtgs: AA mtgs 7pm Tues at church 10am Sat at hospital	• Commitment to 12-Step mtgs: Al-Anon mtg 7pm Tues at church
☒ URINE DRUG SCREENS	
• Urine Drug Screens: weekly at counseling sessions	
☐ OTHER RECOVERY SUPPORT	
• _____	• _____

EARLY WARNING SYSTEM

If, at any time the trust discussion (with medication if taking it) does not take place for two days in a row, we will contact (therapist/phone #: Dr. Tim O'Farrell 123-456-7899) immediately.

LENGTH OF CONTRACT

This agreement covers the time from today until the end of weekly therapy sessions, when it can be renewed. It cannot be changed unless all of those signing below discuss the changes together.

Both wanted to "quit for good" to get their three school-age children back. Sue's parents were given temporary custody when Gene was arrested for drunk-driving. Sue, also intoxicated, and the kids were in the car. Sue and Gene had 6 months of weekly BCT. Their "dual recovery contract" shown in Fig. 55.2 had (1) a daily trust discussion, (2) taking Antabuse daily together, (3) three AA meetings per week, and (4) weekly urine screens.

About 5 weeks after starting BCT, Sue used cocaine on Friday night when she went to the local bar with a girlfriend. At the next BCT session, her urine was positive for

DUAL RECOVERY CONTRACT

In order to help with their recoveries Sue and Gene agree to the following.

Sue's Responsibilities	Gene's Responsibilities
☒ DAILY TRUST DISCUSSION (with medication if taking it)	
• States intention to stay substance free that day (takes medication Antabuse if applicable).	• States intention to stay substance free that day (takes medication Antabuse if applicable).
• Thanks partner for recovery efforts and support.	• Thanks partner for recovery efforts and support.
• Records these actions on calendar.	Records these actions on calendar.
☒ FOCUS ON PRESENT AND FUTURE, NOT PAST	
• Agrees not to mention partner's past substance abuse or fear about future use.	• Agrees not to mention partner's past substance abuse or fear about future use.
☒ WEEKLY SELF-HELP MEETINGS	
• Commitment to 12-Step mtgs: AA mtgs 3x/wk	• Commitment to 12-Step mtgs: AA mtgs 3x/wk
☒ URINE DRUG SCREENS	
• Urine Drug Screens: weekly at couple sessions	• Urine Drug Screens: weekly at couple sessions
☐ OTHER RECOVERY SUPPORT

cocaine. The following Friday, they were both found in the bar. They planned to just socialize, but when cocaine was offered, they did not refuse, but just did one line of cocaine each. The next night, they went to the bar again and each used multiple lines of cocaine. This relapse was a turning point. They got more committed to their recovery. They planned things to do Friday and Saturday nights, starting with an AA meeting together on Friday night. Each got a sponsor and some sober friends.

After weekly BCT, they had quarterly checkups for two more years. They regained custody of their children and stayed abstinent except for a few isolated days for Gene and a 5-day relapse for Sue, which led to a few crisis sessions with the BCT counselor to help them get back on track.

Other Support for Abstinence

Reviewing urges to drink or use drugs experienced in the past week is part of each BCT session. This includes thoughts and temptations that are less intense than an urge or a craving. Discussing situations, thoughts, and feeling associated with urges helps identify potential triggers or cues for alcohol or drug use. It can help alert the therapist to the possible risk of a relapse. It also identifies successful coping strategies (e.g., distraction, calling a sponsor) the patient used to resist an urge, and it builds confidence for the future.

Crisis intervention for substance use is an important part of BCT. Drinking or drug use episodes occur during BCT as with any other treatment. BCT works best if you intervene before the substance use goes on for too long a period. In an early BCT session, negotiate an agreement that either member of the couple should call you if substance use occurs or if they fear it is imminent. Once substance use has occurred, try to get it stopped and to see the couple as soon as possible to use the relapse as a learning experience. At the couple session, you must be extremely active in defusing hostile or depressive reactions to the substance use. Stress that drinking or drug use does not constitute total failure and that inconsistent progress is the rule rather than the exception. Help the couple decide what they need to do to feel sure that the substance use is over and will not continue in the coming week (e.g., restarting recovery medication, going to AA and Al-Anon together, reinstituting key elements of the recovery contract, entering a detoxification unit). Finally, try to help the couple identify what trigger led up to the relapse and generate alternative solutions other than substance use for similar future situations.

55.2.1.3 Increasing Positive Activities to Improve the Relationship

Most substance abuse patients need help to improve their relationships. BCT works to improve the couple's relationship functioning by increasing positive couple and family activities and teaching communication skills. Table 55.2 summarizes BCT interventions for improving the couple's relationship. We will consider positive activities first.

BCT aims to increase positive couple and family activities in order to enhance positive feelings, goodwill, and commitment to the relationship. BCT methods used to increase positive activities include "catch your partner doing something nice," "shared rewarding activities," and "caring days."

Table 55.2 Improving the *relationship in BCT*

Increasing positive activities
Catch your partner doing something nice
Shared rewarding activities
Caring day assignment
Teaching communication
Listening skills
Expressing feelings directly
Communication sessions

Catch Your Partner Doing Something Nice

Couples struggling with substance abuse often complain that love and caring have gone out of their relationship. This procedure can help couples begin to change this state of affairs. Catch your partner doing something nice makes both members of the couple more aware of the benefits they are already getting from the relationship. It increases how often the man and woman notice and acknowledge pleasing or caring behaviors on a daily basis.

Specifically, Catch your partner doing something nice asks each person to notice and acknowledge one nice thing each day that their partner did. They can do the daily acknowledging when they do the trust discussion at home. Also, they should practice during BCT sessions acknowledging their partner's most pleasing behavior in the prior week.

Shared Rewarding Activities

The upset and unhappiness that comes with a substance abuse problem can cause a couple to stop doing things together. Often, a pattern develops where the couple spends less time together, becoming more distant from each other, and the patient spends more time using substances. They no longer do activities they once enjoyed. The spouse often fears that the substance-abusing member will get intoxicated and embarrass the family. They may not enjoy each other's company anymore. The goal of shared rewarding activities is to reverse this pattern and to put fun back in the relationship.

The couple starts by making a list of possible activities. Each activity must involve both spouses, either by themselves or with their children or other adults and can be at or away from home. Then, the couple plans an activity to do in the coming week. Finally, the couple is encouraged to refrain from discussing problems or conflicts during their planned activity.

Increasing shared fun activities helps both the couple's relationship and the patient's recovery. Shared fun activities can bring the couple closer together. In addition, patients who do enjoyable substance-free activities with their spouse and children have better recovery rates after substance abuse treatment (Moos et al. 1990).

Caring Day

In the caring day assignment, each person plans ahead to surprise their partner with a day when they do some special things to show their caring. This can involve doing a number of little things throughout the day or a bigger, special gesture of caring.

This is important because the stress and unhappiness of living with substance abuse often causes partners to hold back caring actions and feelings out of anger and disappointment. Therefore, active efforts like caring day are needed to increase caring and to help repair the damage done to the relationship by the substance abuse and other problems. The BCT therapist encourages each partner to take risks and to act lovingly toward the spouse rather than wait for the other to make the first move.

55.2.1.4 Teaching Communication Skills to Improve the Relationship

Inadequate communication is a major problem for alcoholism and drug abuse patients and their spouses. Once the patient is abstinent, inability to resolve conflicts and problems can cause substance abuse and relationship tensions to recur. Teaching couples how to resolve conflicts and problems can reduce family stress and decrease risk of relapse. BCT teaches communication skills of effective listening and speaking and use of planned communication sessions.

As BCT defines it, good communication exists when the intended message of the speaker matches the message received by the listener. Barriers to good communication include (1) "filters" that affect how the listener interprets the speaker's message and (2) the "All Talk and No Listen" syndrome when both partners think they are right and are unwilling to listen to each other. The BCT therapist emphasizes that the couple needs to learn both "listening" and "speaking" skills.

Listening Skills

Effective listening helps each spouse to feel understood and supported. It slows down couple interactions to prevent quick escalation of angry exchanges. The listener restates and checks the accuracy of the message received from the speaker (*What I heard you say was _____. Did I get that right?*). When the listener has understood the speaker's message, roles change and the first listener then speaks. Teaching a partner to communicate support and understanding by summarizing the spouse's message and checking the accuracy of the received message before stating their own position is often a major accomplishment that has to be achieved gradually.

Expressing Feelings Directly

Effective speaking skills consist of expressing positive and negative feelings directly using "I" messages:

I feel _____ (emotion), when you _____ (behavior), because _____ (specific reason).

After presenting the rationale and instructions, the therapist models correct and incorrect ways of expressing feelings and elicits the couple's reactions to these modeled scenes. Then, the couple role-plays a communication session in which spouses take turns being speaker and listener, with the speaker expressing feelings directly and the listener using the listening response. During this role-playing, the therapist coaches the couple as they practice reflecting the direct expressions of

feelings. Next, the therapist assigns for homework similar communication sessions, 10 to 15 min each three to four times weekly. Subsequent therapy sessions involve more practice with role-playing, both during the BCT sessions and for homework.

Communication Sessions

These are planned, structured discussions used for in-session and at-home practice of communication skills. The couple talks privately, face-to-face, without distractions. Each spouse takes turns expressing their point of view without interruptions.

The therapist discusses with the couple when and where they plan to have their assigned communication practice sessions. Assess the success of this plan at the next session, and suggest any needed changes. Just establishing a communication session as a method for discussing feelings, events, and problems can be very helpful for many couples.

Communication training in BCT starts with positive or neutral topics and then switches to real problems, first on less sensitive issues and finally working up to major charged issues. Before the couple learns how to negotiate charged issues "on their own," the BCT therapist is a very active negotiator, problem-solver, and guide to help the couple find at least temporary solutions to heated conflicts that arise.

55.2.1.5 Relapse Prevention and Continuing Recovery in BCT

Most couples who attend BCT sessions faithfully experience a period of stable abstinence and get along better while they are attending the weekly BCT sessions. BCT provides a supportive structure. It encourages couples to do many actions that support recovery for the substance abuser and for the relationship. However, when the structure of the weekly BCT sessions ends, there is a natural tendency for backsliding. Many couples stop or decrease activities that supported recovery and find themselves vulnerable to relapse. Therefore, it is critical to help couples maintain the gains they made in BCT and prevent or minimize relapse.

Once it has been determined that weekly BCT sessions will be ending soon, the therapist helps the couple prepare for this. This involves completing a Continuing Recovery Plan that specifies activities to do to maintain abstinence and relationship recovery after weekly couple sessions end. In this plan, the couple chooses which activities from previous BCT sessions they wish to continue (e.g., daily trust discussion, AA meetings, shared rewarding activities, communication sessions).

To prevent relapse, BCT helps couples to identify upcoming situations that might increase the risk for relapse and develop a plan of action for addressing them. In addition, BCT helps couples to identify early warning signs of relapse (e.g., stopping self-help attendance, changes in mood) and a plan for addressing these problems. Also, BCT therapists help couples to identify sources of support for coping with relapses (e.g., AA sponsors, friends) and how to get help from others during these events. Couples are encouraged to contact the BCT therapist if a relapse were to occur, so that the therapist can help the couple to navigate this issue and minimize the relapse.

After weekly BCT ends, couple checkup visits with the counselor every few months for an extended period can encourage continued progress. These ongoing contacts can review the couple's success with continuing activities to promote recovery and with their action plan to prevent or minimize relapse. These contacts also help to evaluate whether there is a need for additional BCT sessions.

Couples who have more severe problems or who had trouble during weekly BCT sessions may benefit from more frequent "booster session" contacts in the year after weekly BCT ends. Such BCT booster sessions seek to maintain gains achieved during weekly BCT, deal with problems that are still unresolved or that emerge later, and prevent or minimize relapse (O'Farrell 1993). Research shows that BCT with booster sessions produces better drinking outcomes than standard BCT, with the benefits of BCT booster sessions especially evident for couples with more severe addiction problems (O'Farrell et al. 1998).

Finally, continued contacts with the couple can address relationship issues still unresolved or those that emerge later. This is important because many substance abusers continue to have relationship problems even after a period of stable abstinence has been established, and couple and family issues often appear after a period of recovery.

55.2.1.6 Contraindications for BCT

A few contraindications for BCT should be considered. First, couples in which there is a court-issued restraining order for the spouses not to have contact with each other should not be seen together until the restraining order is lifted or modified to allow contact in counseling.

Second, couples are excluded from BCT if severe intimate partner violence (IPV) has occurred in the past 2 years or if one or both members of the couple fear that taking part in couples treatment may stimulate violence. Although IPV is quite common among substance abuse patients, most of this violence is not so severe that it precludes BCT. The best plan in the vast majority of cases is to address the violence in BCT sessions by teaching a commitment to nonviolence, communication skills to reduce hostile conflicts, and coping skills to minimize conflict if the substance abuser relapses (for details, see O'Farrell and Fals-Stewart 2006; O'Farrell and Murphy 2002). Research reviewed below shows that violence is substantially reduced after BCT and virtually eliminated for patients who stay abstinent.

Finally, if both members of the couple have a current substance abuse problem, BCT may not be effective. In the past, if both members of a couple had a substance abuse problem, we would not treat them together unless one member of the couple has at least 90 days abstinence. However, in a recent project, we successfully treated couples in which both the male and female partner had a current alcoholism problem and both wanted to work together in BCT to get sober (Schumm et al. 2012). Thus, if both members of the couple want to stop drinking or if this mutual decision to change can be reached in the first few sessions, then BCT may be workable. Case example #2 earlier in this chapter illustrates the successful use of BCT with such a dual-problem couple.

55.2.2 Evidence to Support the Approach

Most of the research on BCT has focused on two *primary outcomes*, namely, substance use and relationship functioning. This is understandable, given that BCT for substance abuse is designed primarily to have a direct effect on these areas of functioning. However, studies show that BCT has broader effects on important *secondary outcomes*, including reduced partner violence and improved adjustment for children of couples getting BCT. These are called secondary outcome domains, not to diminish their importance but rather to signify that these outcomes were not the primary targets of the initial BCT intervention.

55.2.2.1 BCT Primary Clinical Outcomes: Abstinence and Relationship Functioning

The primary goals of BCT are to build support for abstinence and to improve relationship functioning among married or cohabiting individuals seeking help for alcoholism or drug abuse. Primary clinical outcome domains examined in randomized studies of BCT reflect these goals. Improved substance use outcomes include measurement of days drinking or using drugs and extent of substance-related problems. Improved relationship functioning generally is measured with relationship adjustment questionnaires. A meta-analysis of 12 controlled studies found that BCT produced better substance use and relationship outcomes than more typical individual-based treatment (IBT) for married or cohabiting alcoholic and drug-abusing patients. This meta-analysis showed a medium effect size favoring BCT over individual treatment (Powers et al. 2008). An expanded and updated meta-analysis reported similar findings (Meis et al. 2013). It should be noted that a medium effect size is considered a clinically significant difference (Rosenthal 1991) when evaluating health-related interventions.

Schumm et al. (2014) is the latest BCT study. It is presented here as an example. This study conducted a randomized clinical trial comparing BCT plus IBT with IBT alone for women alcoholic patients. Married or cohabiting female alcohol-dependent patients ($N = 105$) seeking outpatient treatment in the Boston area were randomly assigned to 26 treatment sessions over a 20-week period consisting of either (a) BCT plus 12-step oriented IBT or (b) IBT for the patient alone. Outcome data were collected from patients and spouses during and immediately after treatment and at quarterly follow-ups for 12 months after treatment. Results in the year after treatment showed that BCT patients, when compared with their IBT-only counterparts, had more days abstinent, fewer substance-related problems, and greater relationship happiness by the male partner. The Schumm et al. results are significant because they add to the studies showing that BCT is effective with both women and men substance-abusing patients.

55.2.2.2 BCT and Intimate Partner Violence Outcomes

Intimate partner violence (IPV) is a major problem among men and women entering treatment for substance use disorders (Chase et al. 2003; Stuart et al. 2009). In two naturalistic studies of male alcoholics, male-to-female IPV was significantly

reduced in the first and second year after BCT and nearly eliminated with abstinence. O'Farrell et al. (2004) found that in the year before BCT, 60 % of alcoholic patients had been violent toward their female partner, five times the comparison sample rate of 12 %. In the year after BCT, IPV decreased significantly to 24 % of the alcoholic sample but remained higher than the comparison group. Among remitted alcoholics after BCT, IPV prevalence of 12 % was identical to the comparison sample. Results were similar for the second year after BCT. An earlier second study of male alcoholics (O'Farrell and Murphy 1995) found nearly identical results as the first study. A third study (Schumm et al. 2009) found an identical pattern of reduced IPV after BCT with female alcoholic patients.

These three studies show very substantial reductions in IPV in the first and second year after BCT. Using structural equation modeling, O'Farrell et al. (2004) found that these IPV reductions most likely result from BCT primary outcomes of reduced drinking and improved relationships. In other words, greater sobriety and better communication after BCT reduce IPV.

55.2.2.3 BCT and Child Adjustment Outcomes

Children living with a parent who abuses alcohol or other drugs often have significant emotional and behavioral problems. Kelley and Fals-Stewart (2002) conducted two studies (one in alcoholism, one in drug abuse) to find out whether BCT for a substance-abusing father, with its demonstrated reductions in domestic violence and reduced risk for family breakup, also has beneficial effects for the children in the family. Results were the same for children of male alcoholic and male drug-abusing fathers. BCT improved children's functioning in the year after the parents' treatment more than did individual-based treatment. Further, only BCT showed reduction in the number of children with clinically significant impairment. These results occurred even though the children themselves did not receive any treatment.

These two studies showing child functioning improves after parents undergo BCT raise the question of why might BCT be helpful to the couple's children. Parents who take part in BCT are not only improving their own relationship but also may be helping their children. Conceptually, BCT might have positive "trickle-down" effects on children because it has a positive impact on factors often associated with poor functioning among children who live with substance-abusing parents (i.e., parental substance use, partner violence, relationship conflict). Additionally, BCT methods to improve communication and reduce parental conflict are likely to make for a healthier home environment for children, ultimately leading to better children's adjustment.

55.2.3 International Considerations

Most of the research on BCT has been done in the USA. Four BCT studies have been done internationally outside the USA, in Canada, India, the Netherlands, and Australia.

55.2.3.1 Canada

O'Farrell et al. (2010) successfully transported a BCT program from Boston where it had been researched to a community clinic in Calgary. On-site BCT training in Calgary was followed by telephone consultations for 6 months. A quasi-experimental evaluation compared outcomes of (a) 38 alcoholic patients who received BCT plus treatment as usual (TAU) with (b) 33 alcoholic patients who received TAU only. The latter group was referred to the BCT program but did not enter it due to logistics or refusal. At baseline, the two groups were similar on demographics, substance use, relationship problems, and comorbid mood or anxiety diagnoses. At 6-month follow-up, patients treated in BCT, as compared to patients who got TAU only, were significantly more likely to be abstinent from alcohol and drugs and together rather than separated and to have higher relationship adjustment scores. Implementation of BCT was considered successful because BCT had better outcomes than individual-based TAU as expected from controlled trials of BCT and because the BCT program in Calgary continues to operate.

55.2.3.2 India

Nattala et al. (2010) randomized 90 male alcohol-dependent patients admitted for 3 weeks at an inpatient facility in Bangalore to either (a) dyadic relapse prevention (DRP), (b) individual relapse prevention (IRP), or (c) TAU. In DRP, which was based on BCT treatment manuals from the USA, both the patient and a family member (75 % spouses) planned and rehearsed how the dyad could work together to prevent relapse. IRP also focused on preventing relapse, but only the individual patient took part. Monthly follow-ups encouraged progress and collected outcome data for 6 months after leaving the treatment center. Results for this 6-month period showed that DRP performed better than IRP and TAU on quantity of alcohol consumed, drinking days, and family problems. The authors concluded that their study provided evidence for the effectiveness of Western-based family-oriented intervention for alcohol-dependent patients in India.

55.2.3.3 The Netherlands

Vedel et al. (2008) in Amsterdam randomized alcoholics to stand-alone BCT ($n = 30$; 10 90-min sessions) or individual cognitive- behavioral therapy (CBT; $n = 34$; 10 45–60-min sessions). Results showed both BCT and CBT significantly decreased drinking from before to after treatment, but BCT was not found to be significantly better than CBT (although a small to medium effect size favored BCT over CBT). Marital satisfaction of the spouse increased significantly after treatment in BCT but not in CBT, with a large effect size favoring BCT over CBT. At 6-month follow-up, BCT and CBT did not differ on drinking or marital outcomes.

Study authors concluded: "Stand-alone BCT is as effective as CBT in terms of reduced drinking and ... more effective in terms of enhancing relationship satisfaction. However, BCT is a more costly intervention, given that treatment sessions lasted almost twice as long as individual CBT sessions" (Vedel et al. 2008, p. 280). The suggestion that BCT is less cost-effective than CBT is based on the 90-min

BCT sessions used in this study, whereas many other studies have used 50–60-min BCT sessions (e.g., O'Farrell et al. 1998) the same as used for CBT.

55.2.3.4 Australia

Halford et al. (2001) in Brisbane randomly assigned 61 women whose husbands drank heavily but were not currently in alcohol treatment to BCT, supportive counseling, or stress management. All three treatments eased the wife's emotional distress, but neither BCT nor the other treatments improved the man's drinking or the couple's relationship. The lack of impact of BCT is not surprising when one considers that BCT has always been studied when the alcoholic has already sought help, not as a method for engaging treatment-resistant alcoholics. The 6 of 21 women assigned to BCT who actually engaged their husband in BCT completed this therapy and benefited from reduced drinking and happier relationships. This study suggests BCT may have limited usefulness when the alcoholic refuses to change or will not enter treatment with the spouse.

55.2.3.5 Other Countries

Results of these four small-scale studies of BCT outside the USA are encouraging. They show some initial ability to apply BCT and generally favorable outcomes. In addition, governments in other countries have recognized the favorable outcomes reported for BCT in the research literature and they have recommended that clinicians use BCT in treating addiction problems. For example, in the UK in 2008, BCT was one of only two therapeutic interventions which the National Institute of Clinical Excellence (NICE, the main UK body reviewing treatments that should be provided as part of the National Health Service) recommended for use in drug treatment services.

Despite the promise of BCT in countries that have developed health and addiction services, it seems unlikely that countries with less developed health systems would make use of BCT as currently practiced in the USA. Possibly, some components of BCT – such as the daily trust discussion in which the addicted person states their intention not to use that day to a family member who thanks the person for their efforts – might be adapted for use more broadly.

55.3 Conclusion

Behavioral Couples Therapy (BCT) is designed for married or cohabiting individuals seeking help for alcoholism or drug abuse. BCT aims to build support for abstinence and to improve relationship functioning. BCT promotes abstinence with a "recovery contract" that involves both members of the couple in a daily trust discussion ritual to reward abstinence. BCT improves the relationship with techniques for increasing positive activities and improving communication.

Research shows that BCT produces greater abstinence and better relationship functioning than typical individual-based treatment and reduces domestic violence and emotional problems of the couple's children. Most research on BCT has been done in the USA. Four BCT studies have been done internationally outside the USA, in Canada, India, the Netherlands, and Australia.

Network Therapy in Addiction Treatment 56

Marc Galanter

Contents

Abstract

Individual therapists in office practice are often considered to have limited effectiveness in treating alcohol and drug dependence. In this chapter, the author describes network therapy, an approach developed to assure greater success in such treatment. A cognitive-behavioral model of addiction related to securing abstinence is reviewed by the role of social cohesiveness as a vehicle for engaging patients in treatment, along with a related technique for enhancing an addicted patient's commitment to the therapy. This is done by using the patient's family and peers as a therapeutic network to join the patient at intervals in therapy sessions.

56.1 Introduction

This approach can be useful in addressing a broad range of addicted patients characterized by the following clinical hallmarks of addictive illness. When they initiate consumption of their addictive agent, be it alcohol, cocaine, opiates, or depressant drugs, they frequently cannot limit that consumption to a reasonable and predictable level; this phenomenon has been termed "loss of control" by clinicians who treat alcohol- or drug-dependent persons. Second, they consistently demonstrate relapse to the agent of abuse, that is, they attempted to stop using the drug for varying periods of time but returned to it, despite a specific intent to avoid it.

This treatment approach is not necessary for those abusers who can, in fact, learn to set limits on their use of alcohol or drugs; their abuse may be treated as a behavioral symptom in a more traditional psychotherapeutic fashion. Nor is it directed at those patients for whom the addictive pattern is most unmanageable (e.g., addicted people with unusual destabilizing circumstances such as homelessness, severe character pathology, or psychosis). These patients may need special supportive care (e.g., inpatient detoxification or long-term residential treatment).

56.2 Facets of Network Therapy

56.2.1 Key Elements of Network Therapy

Three elements are essential to the network therapy technique. The first is a cognitive-behavioral approach to relapse prevention, independently reported to be valuable in addiction treatment (Marlatt and Gordon 1985). Emphasis in this approach is placed on triggers to relapse and behavioral techniques for avoiding them, rather than on exploring underlying psychodynamic issues.

Second, support of the patient's natural social network is engaged in treatment. Peer support in AA has long been shown to be an effective vehicle for promoting abstinence, and the idea of the therapist's intervening with family and friends in starting treatment was employed in one of the early ambulatory techniques specific to addiction (Johnson 1986). The involvement of spouses (McCrady et al. 1991) has since been shown to be effective in enhancing the outcome of professional therapy.

Third, the orchestration of resources to provide community reinforcement suggests a more robust treatment intervention by providing a support for drug-free rehabilitation (Azrin et al. 1982). In this relation, Khantzian points to the "primary care therapist" as one who functions in direct coordinating and monitoring roles in order to combine psychotherapeutic and self-help elements (Khantzian 1988). It is this overall management role over circumstances outside as well as inside the office session that is presented to trainees to maximize the effectiveness of the intervention.

56.2.2 CBT and Social Support

Cognitive-Behavioral Therapy. This format for treatment has been shown to be effective for a wide variety of substance use disorders, including alcohol (Morgenstern and Longabaugh 2000), marijuana (Stephens et al. 2002), and cocaine dependence (Carroll 1998). It is premised on the original findings by Wikler (1973) on conditioning models of drug-seeking in heroin-addicted subjects.

The CBT approach is goal oriented and focuses on current circumstances in the patient's life. In network therapy, reference both in individual and conjoint sessions can be made to salient past experiences. CBT sessions are typically structured, so, for example, patients begin each network session with a recounting of recent events directly relevant to their addiction and recovery. This is followed by active participation and interaction of therapist, patient, and network members in response to the patient's report. CBT emphasizes psychoeducation in the context of relapse prevention, so that circumstances, thoughts, and interpersonal situations which have historically precipitated substance use are identified, and the patient (and network members as well) are taught to anticipate where such triggers can precipitate substance use.

The process of guided recall, noted previously, is particularly important because it allows the therapist both individual sessions with the patient alone and network sessions – in conjunction with network members along with the patient – to guide the patient to recognize a sequence of conditioned stimuli (triggers) which play a role in drug-seeking. Such triggers may not initially be apparent to the patient or network members but, with encouragement and prompting, can emerge over the course of an exploration of the circumstances which have led, either in the past, or in a recent "slip," to substance use.

56.2.2.1 Social Support

This issue has been studied in a variety of data sets in relation to the recovery from substance use disorders. For example, in the federal Project MATCH, three modalities, Twelve-Step facilitation, motivational enhancement, and cognitive-behavioral approaches, were compared. In a secondary analysis of findings from this multisite study, it was found (Zywiak and Wirtz 2002) that certain aspects of social support were most predictive of abstinence outcomes. Two social network characteristics that had a positive effect on outcome were the size of the supportive social network in the person's life and the number of members who were abstainers (or recovering alcoholics). I have found that nonproblem drinking participants are important to a long-term clinical outcome. As a matter of fact, a large number of network members, when their participation is effectively maintained over time, can counter a variety of circumstances that may undermine a patient's abstinence. Additionally, they can provide varied aspects of support relative to the patient's experience in recovery. And indeed, they should be free of substance-related problems. Of interest in this context, it has been reported that men are more typically encouraged by their wives to seek help, whereas women are more often encouraged by mothers, siblings, and children (Beckman and Amaro 1986).

56.2.2.2 Community Reinforcement

Family involvement in substance abuse treatment has long been shown to be effective in improving outcome, and there are numerous approaches that make use of social network involvement in treatment, including Behavioral Couples Therapy (Fals-Stewart et al. 2000), Marital Therapy (O'Farrell 1986), and the Community Reinforcement Approach (Azrin et al. 1982; Meyers et al. 2003).

More specifically, a Community Reinforcement and Family Training (CRAFT) Program includes many aspects of treatment that were employed in network therapy. The CRAFT approach was developed to encourage drinkers to enter therapy and reduce drinking, in part by eliciting support of concerned others as well as to enhance satisfaction with life among members of the patient's social network who were concerned about his or her drinking. As in network therapy, the CRAFT program includes a functional analysis of the patient's substance use, that is to say, understanding the substance use with respect to its antecedents and consequences. Like network therapy, it also serves to minimize reciprocal blaming and defensiveness among the concerned significant others and to promote a patient's sobriety-oriented activities.

In one large trial in which concerned significant others were randomized to one of three conditions, a comparison was made between Al-Anon-facilitated therapy, an approach similar to the Johnson Institute interventions, and the CRAFT model (Fuller et al. 1986). In that study, the CRAFT intervention was found to be more effective in engaging treatment-refusing, alcoholic subjects. Similar positive findings were obtained in studies on CRAFT with illicit drug users (Kirby et al. 1999; Meyers et al. 2002). On the other hand, in another study, concerned significant others were successfully trained to apply a modified Johnson Intervention technique in the absence of a therapist, and this approach was found to be successful in itself (Landau et al. 2004).

56.2.3 Starting a Network

Patients should be asked to bring their spouse or a close friend to the first session. Alcoholic patients often dislike certain things they hear when they first come for treatment and may deny or rationalize even if they voluntarily sought help. Because of their denial, a significant other is essential to both history taking and implementing a viable treatment plan. A close relative or spouse can often cut through the denial in a way that an unfamiliar therapist cannot and can therefore be invaluable in setting a standard of realism in dealing with the addiction.

Once the patient comes for an appointment, establishing a network is a task undertaken with active collaboration of patient and therapist. The two, aided by those parties who join the network initially, must search for the right balance of members. The therapist must carefully promote the choice of appropriate network members, however, just as the platoon leader selects those who will go into combat.

56.2.4 Defining the Network's Membership

The network will be crucial in determining the balance of the therapy. This process is not without problems, and the therapist must think in a strategic fashion of the interactions that may take place among network members. The following case illustrates the nature of their task.

A 25-year-old graduate student had been abusing cocaine since high school, in part drawing from funds from his affluent family, who lived in a remote city. At two points in the process of establishing his support network, the reactions of his live-in girlfriend, who worked with us from the outset, were particularly important. Both he and she agreed to bring in his 19-year-old sister, a freshman at a nearby college. He then mentioned a "friend" of his, apparently a woman whom he had apparently found attractive, even though there was no history of an overt romantic involvement. The expression on his girlfriend's face suggested that she did not like this idea, although she offered no rationale for excluding this potential rival. However, the idea of having to rely for assistance solely on two women who might see each other as competitors was unappealing. The therapist therefore finessed the idea of the "friend," and both she and the patient moved on to evaluating the patient's uncle, whom he initially preferred to exclude, despite the fact that his girlfriend thought him appropriate. It later turned out (as expected) that the uncle was perceived as a potentially disapproving representative of the parental generation. The therapist encouraged the patient to accept the uncle as a network member nonetheless, so as to round out the range of relationships within the group, and did spell out my rationale for his inclusion. The uncle did turn out to be caring and supportive, particularly after he was helped to understand the nature of the addictive process.

56.2.5 Defining the Network's Task

As conceived here, the therapist's relationship to the network is like that of a task-oriented team leader rather than that of a family therapist oriented toward insight. The network is established to implement a straightforward task: aiding the therapist in sustaining the patient's abstinence. It must be directed with the same clarity of purpose that a task force is directed in any effective organization. Competing and alternative goals must be suppressed or at least prevented from interfering with the primary task.

Unlike family members involved in traditional family therapy, network members are not led to expect symptom relief for themselves or self-realization. This lack of expectation prevents the development of competing goals for the network's meetings. It also provides the members protection from having their own motives scrutinized and thereby supports their continuing involvement without the threat of an assault on their psychological defenses. Because network members have – kindly – volunteered to participate, their motives must not be impugned. Their constructive behavior should be commended. It is useful to acknowledge

appreciation for the contribution they are making to the therapy. There is always a counterproductive tendency on their part to minimize the value of their contribution. The network must, therefore, be structured as an effective working group with high morale.

56.2.6 The Use of Twelve-Step Programs

Use of self-help modalities is desirable whenever possible. For the alcoholic, certainly, participation in Alcoholics Anonymous or Narcotics Anonymous is strongly encouraged. Groups such as Narcotics Anonymous, Pills Anonymous, and Cocaine Anonymous are modeled after AA and play a similarly useful role for drug abusers. One approach is to tell the patient that he or she is expected to attend at least two Twelve-Step meetings a week for at least 1 month, so as to become familiar with the program. If after a month the patient is quite reluctant to continue, and other aspects of the treatment are going well, the patient's nonparticipation may have to be accepted.

Some patients are more easily convinced to attend Twelve-Step meetings; others may be less compliant. The therapist should mobilize the support network as appropriate, so as to continue pressure for the patient's involvement with Twelve-Step groups for a reasonable trial. It may take a considerable period of time, but ultimately a patient may experience something of a conversion, wherein the patient adopts the group ethos and expresses a deep commitment to abstinence, a measure of commitment rarely observed in patients who undergo psychotherapy alone. When this occurs, the therapist may assume a more passive role in monitoring the patient's abstinence and keep an eye on the patient's ongoing involvement in a Twelve-Step program.

56.2.7 Use of Pharmacotherapy in the Network Format

For the alcoholic, medications like disulfiram or buprenorphine may be of marginal use in assuring abstinence when used in a traditional counseling context (Fuller et al. 1986) but becomes much more valuable when carefully integrated into work with the patient and network, particularly when the drug is taken under observation. A similar circumstance applies to the use of oral naltrexone for stabilizing abstinence in an opioid-dependent person. In the case of alcohol, it is a good idea to use the initial telephone contact to engage the patient's agreement to abstain from alcohol or drugs for the day immediately prior to the first session. The therapist then has the option of prescribing or administering medications at that time, or after an appropriate waiting time or detoxification. For a patient who is earnest about seeking assistance, this is often not difficult, if some time is spent on the phone making plans to avoid the drug context during that period. If it is not feasible to undertake this on the phone, it may be addressed in the first session. Such planning with the patient almost always involves organizing time with significant others and therefore serves as a basis for developing the patient's support network.

The administration of a medication under observation is a treatment option that is easily adapted to work with social networks. For example, a patient who takes disulfiram cannot drink; a patient who agrees to be observed by a responsible party while taking disulfiram will not miss his or her dose without the observer's knowing. This may take a measure of persuasion and, above all, the therapist's commitment that such an approach can be reasonable and helpful.

As noted previously, individual therapists traditionally have seen the addicted person as a patient with poor prognosis. This is largely because in the context of traditional psychotherapy, there are no behavioral controls to prevent the recurrence of drug use, and resources are not available for behavioral intervention if a recurrence takes place – which it usually does. A system of impediments to the emergence of relapse, resting heavily on the actual or symbolic role of the network, must therefore be established. The therapist must have assistance in addressing any minor episode of relapse so that this ever-present problem does not lead to an unmanageable relapse or an unsuccessful termination of therapy.

56.2.8 Format for Medication Observation by the Network

1. Take the medication every morning in front of a network member.
2. Take the pill so that that person can observe you swallowing them.
3. Have the observer write down the time of day the pills were taken on a list prepared by the therapist.
4. The observer brings the list in to the therapist's office at each network session.
5. The observer leaves a message on the therapist's answering machine on any day in which the patient had not taken the pills in a way that ingestion was not clearly observed.

56.2.9 Meeting Arrangements

At the outset of therapy, it is important to see the patient with the group on a weekly basis for at least the first month. Unstable circumstances demand more frequent contacts with the network. Sessions can be tapered off to biweekly and then to monthly intervals after a time.

To sustain the continuing commitment of the group, particularly that between the therapist and the network members, network sessions should be held every 3 months or so for the duration of the individual therapy. Once the patient has stabilized, the meetings tend less to address day-to-day issues. They may begin with the patient's recounting of the drug situation. Reflections on the patient's progress and goals, or sometimes on relations among the network members, then may be discussed. In any case, it is essential that network members contact the therapist if they are concerned about the patient's possible use of alcohol or drugs and that the therapist contact the network members if the therapist becomes concerned about a potential relapse.

56.2.10 Adapting Individual Therapy to the Network Treatment

Network sessions can be scheduled on a weekly basis at the outset of treatment. This is likely to compromise the number of individual contacts. Indeed, if sessions are held once a week, the patient may not be seen individually for a period of time. The patient may perceive this as a deprivation unless the individual therapy is presented as an opportunity for further growth predicated on achieving stable abstinence assured through work with the network.

When the individual therapy does begin, the traditional objectives of therapy must be arranged so as to accommodate the goals of the substance abuse treatment. For insight-oriented therapy, clarification of unconscious motivations is a primary objective; for supportive therapy, the bolstering of established constructive defenses is primary. In the therapeutic context that is described here, however, the following objectives are given precedence.

Of first importance is the need to address exposure to substances of abuse or exposure to cues that might precipitate alcohol or drug use (Galanter 1993). Both patient and therapist should be sensitive to this matter and explore these situations as they arise. Second, a stable social context in an appropriate social environment – one conducive to abstinence with minimal disruption of life circumstances – should be supported. Considerations of minor disruptions in place of residence, friends, or job need not be a primary issue for the patient with character disorder or neurosis, but they cannot go untended here. For a considerable period of time, the substance abuser is highly vulnerable to exacerbations of the addictive illness and in some respects must be viewed with the considerable caution with which one treats the recently compensated psychotic.

Finally, after these priorities have been attended to, psychological conflicts that the patient must resolve, relative to his or her own growth, are considered. As the therapy continues, these come to assume a more prominent role. In the earlier phases, they are likely to reflect directly issues associated with previous drug use. Later, however, as the issue of addiction becomes less compelling from day to day, the context of the treatment increasingly will come to resemble the traditional psychotherapeutic context. Given the optimism generated by an initial victory over the addictive process, the patient will be in an excellent position to move forward in therapy with a positive view of his or her future.

56.2.11 The Technique

56.2.11.1 Start a Network as Soon as Possible

1. It is important to see the alcohol or drug abuser promptly, because the window of opportunity for openness to treatment is generally brief. A week's delay can result in a person's reverting back to drunkenness or losing motivation.
2. If the person is married, engage the spouse early on, preferably at the time of the first phone call. Point out that addiction is a family problem. For most drugs, you can enlist the spouse in assuring that the patient arrives at your office with a day's sobriety.

3. In the initial interview, frame the exchange so that a good case is built for the grave consequences of the patient's addiction, and do this before the patient can introduce his or her system of denial. That way you are not putting the spouse or other network members in the awkward position of having to contradict a close relation.
4. Then make clear that the patient needs to be abstinent, starting now. (A tapered detoxification may be necessary sometimes, as with depressant pills.)
5. When seeing an alcoholic patient for the first time, start the patient on disulfiram treatment as soon as possible, in the office if you can. Have the patient continue taking disulfiram under observation of a network member.
6. Start arranging for a network to be assembled at the first session, generally involving a number of the patient's family or close friends.
7. From the very first meeting you should consider how to ensure sobriety till the next meeting, and plan that with the network. Initially, their immediate company, a plan for daily AA attendance, and planned activities may all be necessary.

56.2.11.2 Manage the Network with Care

1. Include people who are close to the patient, have a long-standing relationship with the patient, and are trusted. Avoid members with substance problems, because they will let you down when you need their unbiased support. Avoid superiors and subordinates at work, because they have an overriding relationship with the patient independent of friendship.
2. Get a balanced group. Avoid a network composed solely of the parental generation, or of younger people, or of people of the opposite sex. Sometimes a nascent network selects itself for a consultation if the patient is reluctant to address his or her own problem. Such a group will later supportively engage the patient in the network, with your careful guidance.
3. Make sure that the mood of meetings is trusting and free of recrimination. Avoid letting the patient or the network members feel guilty or angry in meetings. Explain issues of conflict in terms of the problems presented by addiction; do not get into personality conflicts.
4. The tone should be directive. That is to say, give explicit instructions to support and ensure abstinence. A feeling of teamwork should be promoted, with no psychologizing or impugning members' motives.
5. Meet as frequently as necessary to ensure abstinence, perhaps once a week for a month, every other week for the next few months, and every month or two by the end of a year.
6. The network should have no agenda other than to support the patient's abstinence. But as abstinence is stabilized, the network can help the patient plan for a new drug-free adaptation. It is not there to work on family relations or help other members with their problems, although it may do this indirectly.

56.2.11.3 Keep the Network's Agenda Focused

1. Maintaining abstinence. The patient and the network members should report at the outset of each session any exposure of the patient to alcohol and drugs. The patient and network members should be instructed on the nature of relapse and plan with the therapist how to sustain abstinence. Cues to conditioned drug-seeking should be examined.
2. Supporting the network's integrity. Everyone has a role in this. The patient is expected to make sure that network members keep their meeting appointments and stay involved with the treatment. The therapist sets meeting times and summons the network for any emergency, such as relapse; the therapist does whatever is necessary to secure stability of the membership if the patient is having trouble doing so. Network members' responsibility is to attend network sessions, although they may be asked to undertake other supportive activity with the patient.
3. Securing future behavior. The therapist should combine any and all modalities necessary to ensure the patient's stability, such as a stable, drug-free residence; the avoidance of substance-abusing friends; attendance at Twelve-Step meetings; medications such as disulfiram or blocking agents; observed urinalysis; and ancillary psychiatric care. Written agreements may be handy, such as a mutually acceptable contingency contract with penalties for violation of understandings.

56.2.11.4 Make Use of Alcoholics Anonymous and Other Self-Help Groups

1. Patients should be expected to go to meetings of AA or related groups at least two to three times, with follow-up discussion in therapy.
2. If patients have reservations about these meetings, try to help them understand how to deal with those reservations. Issues such as social anxiety should be explored if they make a patient reluctant to participate. Generally, resistance to Twelve-Step groups can be related to other areas of inhibition in a person's life, as well as to the denial of addiction.
3. As with other spiritual involvements, do not probe the patients' motivation or commitment to Twelve-Step groups once engaged. Allow them to work out things on their own, but be prepared to listen.

56.2.11.5 Cultural Issues

The adaptability of network therapy in different countries is delimited by cultural and economic issues. For example, in national settings where shame is a predominant motivating factor, it is important for the clinician to be attentive to the potential for reluctance on the part of family members to acknowledge a substance abuser's problem. Often, they will be concerned that members of their community would look down on the entire family because of the addiction in one of its members. It would be important to point out to family members that the resolution of the patient's problem provides as an opportunity for resecuring the tarnished status of the family in their community.

Another issue relates to economic concerns. In many clinical settings patients have limited contact with their respective families, or even with drug-free peers. In such circumstances, a network is frequently established among patients in the treatment setting itself, so that mutual support can be elicited once a treatment community has been well established, be it a clinic, residence, or therapeutic community. It is for this reason that indigent patients are best treated in settings where there is an active promotion of mutuality and peer support.

56.2.12 Research on Network Therapy

56.2.12.1 Study on Training Naïve Therapists

A course of training for psychiatric residents naive to addiction and ambulatory treatments was undertaken over a period of 2 academic years. Before beginning treatment, the residents were given a structured treatment manual for network therapy and participated in a 13-session seminar on application of the network therapy technique. Cocaine-abusing patients were eligible for treatment in this study if they could come for evaluation with a friend or family member who could participate in their treatment. In all, 22 patients were enrolled. The treating psychiatric residents were able to establish requisite networks for 20 of these patients (i.e., a network with at least one member). The networks had an average of 2.3 members, and the most typical configuration included family members and friends. Supervisors' evaluation of videotapes of the network sessions employing standardized instruments indicated good adherence to the manualized treatment, with effective use of network therapy techniques. The outcome of treatment (Galanter et al. 1997; Keller et al. 1997; Galanter et al. 2002) reflected retention and abstinence rates as good as, or better than, comparable ambulatory care carried out by therapists experienced in addiction treatment. The study demonstrated the feasibility of teaching the network technique to therapists naive to addiction treatment.

Galanter et al. (2004) evaluated the impact of network therapy relative to a control condition (medical management, MM) among 66 patients who were inducted onto buprenorphine for 16 weeks and then tapered to zero dose. Network therapy resulted in a greater percentage of opioid-free urines than did MM (65 % vs. 45 %). By the end of treatment, network therapy patients were more likely to experience a positive outcome relative to secondary heroin use (50 % vs. 23 %). The use of network therapy in office practice may enhance the effectiveness of eliminating secondary heroin use during buprenorphine maintenance.

56.2.12.2 Adaptations of Network Therapy Treatment

Rothenberg et al. (2002) adapted NT and combined it with relapse prevention and a voucher reinforcement system in the treatment of opioid-dependent patients who were enrolled in a 6-month course of treatment with naltrexone referred to as behavioral naltrexone therapy (BNT). The NT component involved one significant other who could monitor adherence to naltrexone. In addition to the patient

receiving vouchers for each day of abstinence and each pill taken, the network member was reinforced with a voucher for each pill recorded as monitored. The primary treatment outcome was retention in treatment. Patients who used methadone at baseline did more poorly than those using only heroin as demonstrated in the retention rates: 39 % versus 65 % and 0 % versus 31 %, respectively, at 1 month and 6 months.

Copello et al. (2002) combined elements of NT with social aspects of the community reinforcement approach and relapse prevention referred to as social behavior and network therapy (SBNT) in the treatment of persons with alcohol-drinking problems. A number of social skills training strategies are incorporated into the treatment especially those involving social competence in relation to the development of positive social support for change in alcohol use. Every individual involved in treatment is considered a client in his/her own right and the person with alcohol problems is referred to as the focal client. The core element of the approach is mobilizing the support of the network even though this may involve network sessions that are conducted in the absence of the focal client. In their initial feasibility study with 33 clients, there were two cases in which sessions were held with network members in the absence of the focal client and in both cases reengagement of the focal client in treatment was achieved. Out of the 33 clients enrolled in the study, 23 formed a network with the mean number of network members = 1.82 and the mean number of network sessions = 5.24. In a multisite, randomized, controlled trial of 742 clients with alcohol problems, the UKATT Research Team (2005a) compared SBNT to motivational enhancement therapy (MET). Both treatment groups exhibited similar reductions in alcohol consumption and alcohol-related problems and improvement in mental functioning over a 12-month period. Attending more sessions was associated with a better outcome, and SBNT patients with greater motivation to change and those with more negative short-term expectancies were more likely to attend (Dale et al. 2011).

Additional studies involving the UKATT study sample were conducted assessing (1) cost-effectiveness (UKATT Research Team 2005b), (2) client-treatment matching effects (UKATT Research Team 2008), (3) clients' perceptions of change in alcohol-drinking behaviors (Orford et al. 2009), and drinking goal preference (Adamson et al. 2010). The UKATT Research Team evaluated the cost-effectiveness of SBNT relative to motivational enhancement therapy. SBNT resulted in a fivefold cost savings in health, social, and criminal justice service expenditures and was similar to cost-effectiveness estimates obtained for motivational enhancement therapy. The UKATT Research Team (2008) tested a priori hypotheses concerning client-treatment matching effects similar to those tested in Project MATCH. The findings were consistent with Project MATCH in that no hypothesized matching effects were significant. Orford et al. (2009) interviewed a subset of clients (n = 397) who participated in this trial to assess their views concerning whether any positive changes in drinking behavior had occurred and to what they attributed those changes. . . At 3 months after randomization to treatment, SBNT clients made more social attributions (e.g., involvement of others in supporting behavior change) and MET clients made more motivational attributions

(e.g., awareness of the consequences of drinking.) Patients who initially stated a preference for abstinence showed a better outcome than those stating a preference for non-abstinence. This was true both at 3-month and 12-month follow-up (Adamson et al. 2010).

Copello et al. (2006) adapted SBNT for persons presenting with drug problems. Of 31 clients enrolled in the study, 23 received SBNT and had outcomes data available at 3-month follow-up. Reductions in the amount of heroin used per day and increases in family cohesion and family satisfaction were documented. Open-ended interviews with clients, network members, and therapists were conducted in a qualitative investigation of respondents' perceptions of SBNT (49). Major themes that emerged from analysis of the interview responses included the value of SBNT in (1) increasing network support for reducing drug use, (2) promoting open and honest communication between clients and network members about drug use, and (3) increasing network members' understanding of drugs and the focal person's behavior. Williamson et al. (2007) suggest that these features of SBNT may be more prominent when the problem is one of illicit drug use than when the problem involves alcohol use.

CRA and CRAFT: Behavioural Treatments for Both Motivated and Unmotivated Substance Abusing Individuals

Contents

Abstract

The Community Reinforcement Approach (CRA) is a behavioral treatment for substance abuse problems which is based on the belief that a nondrinking and nonusing lifestyle must be accessible and experienced as rewarding in order for individuals to choose it routinely over substance use. As part of CRA, the client's "community" (e.g., family, friends, colleagues, organizations, work) is explored to find new areas of potential reinforcement that can compete with substance use. CRA therapists help clients determine which goals they want to pursue in life, and they then teach clients the skills required to obtain these goals. Community Reinforcement and Family Training (CRAFT) is a treatment for the family members or close friends (Concerned Significant Others, CSOs) of unmotivated, treatment-refusing substance abusers (identified patients, IPs). CRAFT therapists work with CSOs in an attempt to change the home

environment of the unmotivated IPs such that a healthy and enjoyable lifestyle is supported over one dominated by substance use. CRAFT goals include getting IPs to seek treatment but also having CSOs take care of themselves as well. Both CRA and CRAFT have solid empirical support, and each has been used successfully with diverse populations and various drugs of choice.

57.1 Introduction

The Community Reinforcement Approach (CRA) and Community Reinforcement and Family Training (CRAFT) are behavioral treatments based on the belief that the lives of individuals with substance abuse problems will only become and remain healthy if clean/sober behavior that is experienced as rewarding becomes a routine part of their lives. Clinicians work directly with the people with the substance abuse problems in CRA, and thus, it is the clinicians' job to help those clients identify and sample healthier lifestyles. In the case of CRAFT, clinicians must work through family members to identify and support these rewarding behaviors, because the substance-abusing individuals refuse to seek treatment initially. Both CRA and CRAFT have solid empirical support overall, and each has been used successfully with diverse populations and various drugs of choice.

57.2 Understanding and Using CRA and CRAFT

57.2.1 CRA Procedures

57.2.1.1 CRA Functional Analyses

In order to better understand the events that lead to substance use, as well as the positive and negative consequences that follow, a clinician often first conducts a functional analysis (F.A.) of substance-using behavior. The F.A. is a semi-structured interview which highlights the fact that substance use does not occur at random, but instead is preceded by certain events (i.e., antecedents/triggers) and followed by certain consequences. During the F.A., the clinician first works with the client to identify external (people, places, times) and internal (thoughts, feelings) triggers. Later in therapy, this information can be helpful when learning how to alter or effectively cope with triggers that have led to substance use in the past. The second part of the F.A. involves the clinician gathering more information about how the substance of choice is used, such as how much is consumed and over what period of time. These details can be useful in quantitatively gauging progress as therapy proceeds.

Finally, the clinician uses the F.A. to explore the positive and negative consequences that occur after engaging in substance use. Although it may be tempting for clinicians to focus exclusively on the negative consequences, outlining and discussing the positive consequences is vital because they represent the motives

that *sustain* the substance use behavior. For example, a client may state that he enjoys drinking because it allows him to relax and have fun with friends after a stressful day at work. Once these positive consequences are identified, the clinician can help the client generate reasonable alternatives for relaxing and having fun after work: options that do not involve alcohol. The positive consequences of substance use are referred to as short term, while the negative consequences are specified as long term. The latter are broken down into multiple domains: interpersonal, physical, emotional, legal, job, and financial.

The CRA program's second type of F.A. is for prosocial behaviors (e.g., going for a bike ride, relaxing at a coffee shop). A better understanding of the antecedents and consequences surrounding these behaviors helps the clinician see why a prosocial behavior is sometimes chosen over a substance-using one (and vice versa) and identify possible mechanisms for getting the client to select the healthy alternative more often.

57.2.1.2 Sobriety Sampling

Sobriety sampling is a procedure that clinicians use to get clients to agree to "sample" a time-limited period of sobriety. This "trial period" of sobriety feels much more attainable for clients and therefore receives less resistance than a demand for an immediate, indefinite, abstinence commitment. Sobriety sampling is used regardless of whether the final treatment goal is abstinence or moderation. If the goal is abstinence, small, manageable periods of sobriety are linked together over time. If the client hopes to become a moderate drinker/substance user, the clinician still asks for the client to at least start treatment by sampling a period of sobriety. Some of the benefits of sobriety sampling, which are discussed with the client, include providing an opportunity to break old behavior patterns, allowing for experimentation with new coping strategies, and increasing self-efficacy through goal attainment.

Once the client has agreed to sample sobriety, the negotiation over the length of the trial period begins. Frequently the clinician suggests a relatively long period of abstinence, such as 90 days. The client's motivators for abstinence are linked to the goal. For example, a clinician might reason, "Your ex-wife said she won't allow you anywhere near your daughter if you haven't demonstrated that you can be sober for a period of time. You mentioned that your daughter's kindergarten "graduation" is in 2 months and that you'd love to attend it. That might be a good reason to shoot for 2 months of sobriety. What do you think?" If the client is unwilling or feels unable to agree to the suggested period of sobriety, the clinician will negotiate with the client to reach a mutually agreed upon goal.

The final part of sobriety sampling entails setting up a plan such that the client can actively work to achieve the goal. Using information collected during the F.A. for substance use, the client is encouraged to identify alternatives to substance use and to develop plans for handling common triggers. It is often helpful to identify and problem solve any upcoming high-risk situations and to develop specific backup plans.

57.2.1.3 The Treatment Plan: Happiness Scale and Goals of Counseling

The two main tools utilized as part of the CRA treatment plan include the Happiness Scale and the Goals of Counseling form. The Happiness Scale is a 10-item questionnaire that asks clients to rate their happiness on a 10-point scale (where 10 indicates "completely happy") in each of the following areas: substance use, job or educational progress, money management, social life, personal habits, marriage/family relationships, legal issues, emotional life, communication, and general happiness (Meyers and Smith 1995). Information regarding the client's happiness in each of these domains helps set the stage for developing the goals of treatment. For example, the clinician might say, "I see that you've rated your 'social life' a '4.' What would have to change in order for you to be able to rate your 'social life' a '5' or '6'?" The Happiness Scale also can be readministered throughout therapy to track progress in specific domains.

The same ten domains from the Happiness Scale are outlined on the Goals of Counseling form, where the clinician works with the client to set goals that are positive (what the client *wants* as opposed to what he/she does not want anymore), specific, measurable, realistic, and under the client's control. In addition to setting specific goals, the clinician and client work together to identify the necessary steps needed to accomplish each goal. A representative *goal* in the social life area might be to meet a new nonusing person and go for coffee with him/her once in the next month. The initial *steps* toward attaining that goal might be to search the Internet to find out which coffee shops look inviting and then to visit two of the shops in the upcoming week. These weekly steps toward a goal are essentially the homework assignment. Importantly, the clinician checks on progress toward completing the homework weekly and discusses any barriers that have appeared.

Incorporating goals to improve various areas of the client's life is fundamental to the CRA approach, given that the overall objective is to increase sources of substance-free reinforcement in the client's life. Many of these goals, and the strategies (steps) for attaining them, require specific behavioral skills training. The CRA program offers skills training in such areas as communication, problem solving, and drink/drug refusal.

57.2.1.4 Communication Skills

CRA emphasizes the importance of positive communication training as a component of treatment, in part because many individuals who abuse substances report that problematic interactions serve as relapse triggers. Furthermore, effective communication paves the way for the successful implementation of a variety of goal-related tasks, such as interviewing for jobs, asking teachers for extra help, and talking with a partner about relationship struggles. CRA first discusses the rationale for focusing on communication training and then offers clients three communication guidelines for starting a difficult conversation: (1) give an understanding statement, (2) take partial responsibility, and (3) offer to help. Assume, for example, that an adolescent female has been wrongly accused of cheating on a test and has been given detention for a week. The clinician would work with the client to develop the beginning of a conversation with the teacher that sounded somewhat

similar to: "Mrs. Gray, I can see why you thought I was cheating in class yesterday when you heard whispering coming from the back of the room during the test, because I've had trouble with cheating in the past (*understanding statement*). And I know it didn't help for me to get all upset as soon as you started talking to me; I guess it sort of made me seem guilty (*partial responsibility statement*). What can I do to convince you that things are different now and that I don't cheat anymore?" (*offer to help*).

Clients report that when they start a conversation with these communication components they typically are met with less defensiveness from the listener. The message being conveyed is that more than one person contributes to interpersonal problems, and the communicator is willing to take an active role in improving the situation. Clinicians teach these skills by providing relevant examples and engaging the client in role plays complete with specific feedback.

57.2.1.5 Problem-Solving Skills

Given that individuals who abuse substances frequently report using alcohol or drugs as their problem-solving, stress-reduction strategies, CRA includes a problem-solving skills training module. CRA's approach to problem solving, which is based on the work by D'Zurilla and Goldfried (1971), outlines seven main steps: (1) narrowly define the problem, (2) generate potential solutions (brainstorm), (3) eliminate undesired suggestions, (4) select one potential solution, (5) generate possible obstacles, (6) address these obstacles, and (7) assign the specific task (i.e., the homework). As with all homework assignments, the clinician carefully evaluates the outcome of the task at the start of the next therapy session.

This problem-solving procedure allows clients to break down problems into manageable steps, to think creatively about possible solutions, and to realistically assess the likelihood that the proposed solution will work. Once clients have put their proposed solution into action, they are taught to critically evaluate the outcome. If the proposed solution did not meet their needs, they are encouraged either to modify the attempted solution or to select a different solution generated during step #2. Some of the common types of problems for which this exercise is conducted include handling cravings, finding a fun and healthy social activity for a weekend night, and improving study or sleep habits.

57.2.1.6 Drink and Drug Refusal Skills

A critical component of relapse prevention entails having the communication skills to successfully refuse offers of alcohol or drugs. This set of CRA skills can be organized into three domains: (1) learning how to get social support when sobriety is threatened, (2) anticipating and preparing for high-risk situations, and (3) practicing the assertive refusal of invitations to use substances. Social reinforcement often plays a large role in determining behavior. Based on this premise, CRA encourages clients to create social environments that are supportive of sobriety. Clients often benefit from role-playing conversations they hope to have with family members and friends about their desire to sample abstinence and their need for support.

Information gathered during the F.A. can be extremely useful when helping the client identify high-risk situations. Working with personally relevant situations will make the drink/drug refusal role plays more effective. Oftentimes clients are overly confident that they will be able to walk into these situations and "simply not drink" (or use other substances). Despite this confidence, refusal is often much more difficult than anticipated, and thus, clients are encouraged to practice refusing offers assertively.

Without this specialized assertiveness training, clients tend to respond either too passively or too aggressively to substance use offers. Suggested components of an assertive response include (1) saying "no, thanks" without feeling guilty, (2) using appropriate body language (good eye contact, a firm stance, etc.), (3) suggesting alternatives ("No, thanks, but I'll take a soda"), (4) changing the subject ("Did you see that game last night? Unbelievable!"), (5) directly addressing the aggressor about the issue if needed ("I've already said more than once that I'm not smoking. Why is it important to you that I smoke?"), and (6) leaving the situation. Clients are asked to generate their own assertive response style and are coached in its implementation.

57.2.1.7 Job-Finding Skills

CRA incorporates training in a wide variety of skills so that clients are able to utilize social, recreational, familial, and vocational forms of reinforcement to create a more rewarding substance-free lifestyle. Suitable employment can be an excellent source of healthy reinforcement, as it can provide a boost to self-esteem, enjoyable social relationships, and money. Relying heavily on the work outlined by Azrin and Besalel in their *Job Club Counselor's Manual* (1980), CRA offers a step-by-step approach to obtaining a satisfying job and keeping it. The procedure begins by asking clients to carefully consider the types of jobs for which they are best suited, such as ones that are unlikely to contribute to relapse. A system is then established for tracking contacts with potential employers. Clients are assisted with developing résumés and completing job applications in a manner that highlights their strengths. Extensive practice is provided in calling potential employers and going on job interviews. With respect to keeping a job, clinicians help clients anticipate difficult work situations based on previous job problems, and problem-solving skills are used to generate potential solutions.

57.2.1.8 Social/Recreational Counseling

Another primary source of substance-free reinforcement comes from social/recreational activities. Prior to treatment, clients' social and recreational environments are strongly associated with substance use, and consequently identifying enjoyable substance-free social activities often is a difficult task. Importantly, clinicians are careful not to impose their own values as to what constitutes a fun recreational activity, and furthermore they attempt to identify at least some activities that occur during high-risk times (e.g., weekends, evenings) and thereby directly compete with substance use. CRA offers several approaches for developing ideas about

healthy social activities, including the use of problem solving. Once an activity is identified, a homework assignment is made to sample the activity, and as usual, potential barriers (e.g., transportation, money, fear of rejection) are discussed.

Periodically clinicians are doubtful that a client will follow through and sample a new activity despite being motivated to do so. In these cases clinicians utilize a technique, *systematic encouragement*, to increase the likelihood that the client will successfully complete that homework assignment in the upcoming week. Systematic encouragement involves helping the client take the first step toward engaging in the new activity before leaving the session. For example, assume a client is interested in playing basketball at the local YMCA but appears unlikely to make any progress toward pursuing that goal without assistance. The clinician either would help the client search for relevant information on the YMCA website (e.g., the YMCA's operation schedule, whether there are "pickup" games on the basketball court, whether fees are involved) or would conduct a role play in which the client practiced calling the organization to ask these questions directly. Next, a specific plan for getting to the YMCA would be created, and obstacles would be addressed. The clinician would start the next session by reviewing the client's experience at the YMCA, in part to determine the reinforcement value.

57.2.1.9 Relapse Prevention

CRA recognizes the importance of preparing clients for high-risk situations in an effort to prevent a relapse, and helping clients get back on track quickly if a relapse occurs. The initial F.A. is revisited in an effort to prevent an impending relapse, since it already has outlined the antecedents and consequences that surround typical drinking/using situations. In the event that a relapse has occurred, the F.A. is readministered with a focus on the specific relapse episode. The clinician takes a solution-oriented approach to highlighting what triggered the relapse and to identifying alternatives to substance use in that particular situation.

CRA clinicians also borrow from the relapse literature more generally when they draw and label a "chain" to illustrate the events that led to the relapse. At first, clients usually only identify one poor decision that led to their use, but in reality there are a number of small and seemingly unrelated decisions throughout the day that led down that path. With the behavioral chain laid out, clients see that they had the option to change the outcome by making a different decision at multiple points along the chain. Clinicians emphasize the fact that it is much easier to change the course earlier as compared to later in the chain of events.

CRA relapse prevention also includes the Early Warning System, which entails clients setting up a plan for enlisting the support of a concerned family member or friend in the event that a relapse appears imminent. The clinician helps the client both identify an individual who will be available and supportive at an extremely high-risk time and determine precisely what the client would want the individual to do on such an occasion. Finally, the client rehearses the conversation that will take place with the support person and commits to having that conversation as part of the weekly homework.

57.2.1.10 Medication Monitoring

CRA has a medication monitoring procedure that is used with clients who have difficulty taking their prescribed medication. The procedure originally was developed for clients who were taking disulfiram (Antabuse), a medication that causes individuals to get very ill if they ingest alcohol. This "deterrent" to drinking is sometimes introduced to clients who repeatedly are unsuccessful at achieving even short periods of abstinence or who face serious consequences if they drink. But in order for disulfiram to be effective, it must be taken several days per week, and therefore, it is important to incorporate a medication monitoring component. The "monitor," a concerned individual who has daily contact with the client, attends a session with the client in order to learn positive communication skills for administering the disulfiram. For example, the monitor rehearses a conversation such as, "Thank you for taking your pill today. I know this hasn't been easy, but this shows how much you care about our family." In addition to teaching the monitor to express support and appreciation for the client's efforts, a plan is developed (with the client's consent) regarding the steps to take if the client refuses to take his or her medication (e.g., call the therapist). Medication monitoring can be incorporated into the Early Warning System, because if clients are refusing to take their medication, it is often a warning sign of an upcoming relapse. Although initially introduced to monitor disulfiram administration, more recently the medication monitoring procedure has been used to monitor a variety of other kinds of medication, such as for attention deficit hyperactivity disorder (ADHD) and depression.

57.2.1.11 Relationship Therapy

For clients involved in a romantic relationship, improving interactions with the partner can be another powerful source of reinforcement. CRA's relationship therapy focuses on improving communication and problem-solving skills and setting/negotiating reasonable goals. The couple begins by completing the Relationship Happiness Scale, a tool similar to the original Happiness Scale. However, each individual rates his/her happiness *with the partner* on a 10-point scale across ten domains: household responsibilities, raising the children, social activities, money management, communication, sex and affection, job or school, emotional support, partner's independence, and general happiness. Similar to the Goals of Counseling, each partner formulates and writes down what he/she would like the partner to do in several of the ten domains. The partners are coached to state their requests in positive, specific, and measurable terms and then are taught to use positive communication skills to make the request verbally. Homework assignments are made to tackle the negotiated goals. As part of the "Daily Reminder to be Nice" exercise, each partner commits to increasing at least one of seven partner-pleasing behaviors (e.g., expressing appreciation, giving a pleasant surprise) on a daily basis in an effort to reinstate positive behaviors that were more frequent at the beginning of the relationship, but dwindled over time. In subsequent sessions the partners report on any barriers to completing their goals for the week and identify future goals.

57.2.1.12 Caregiver Procedures

When the substance-using client is an adolescent, the adolescent version of CRA (A-CRA) is used (see Godley et al. 2001). For the most part this entails relying on age-modified questionnaires and procedures and the inclusion of sessions for the caregivers (e.g., parents, grandparents), both alone and with the adolescent client. The sessions with just the caregiver(s) are devoted to describing basic parenting practices that support the adolescent's sobriety and to teaching CRA communication and problem-solving skills. The sessions that include the adolescent are similar in structure to the relationship therapy sessions, in that they focus on negotiating goals for the caregivers and the adolescent client, as well as establishing clear strategies for obtaining the goals. Positive communication and problem-solving skills are stressed throughout.

57.2.2 CRA Scientific Support

For the past 40 years, the Community Reinforcement Approach (CRA) has been accruing evidence of its efficacy and effectiveness in treating alcohol and drug problems. The earliest CRA studies were conducted with inpatients on alcohol wards (Azrin 1976; Hunt and Azrin 1973). In both of these small studies, CRA was shown to be significantly better than standard treatment, which at the time was participation in a hospital's Alcoholics Anonymous program. Specifically, at the 6-month follow-up, the participants in the CRA program had fewer days of drinking and institutionalization and more days working compared to those in standard treatment. The second of these studies introduced several new procedures to the original CRA protocol, most notably a disulfiram (Antabuse) compliance monitoring program (Azrin 1976).

The third CRA study was the first to use an outpatient population of problem drinkers (Azrin et al. 1982). The researchers contrasted three treatments: traditional (12-step) treatment with a disulfiram prescription, traditional treatment with the disulfiram compliance program, and CRA with the disulfiram compliance program. The compliance program included not only monitoring of the daily disulfiram use by a loved one but training in positive communication skills as well. As expected, the conditions that included the disulfiram compliance component had the highest abstinence rates, with the CRA program outperforming the traditional program overall at 6 months.

A much larger study ($N = 237$) with an ethnically diverse population was conducted which extended the design of the first outpatient study by examining whether one's willingness to take disulfiram affected the findings (Miller et al. 2001). Although the study revealed less robust results, CRA still showed an advantage over traditional treatment on several outcome measures. The CRA program was modified in another study to make it applicable to a day treatment program for homeless alcohol-dependent individuals (Smith et al. 1998). As predicted, CRA (conducted in group format) was proven

to be more effective than the standard treatment offered at that particular homeless shelter in terms of drinking outcomes.

Although originally developed as a treatment for individuals with alcohol problems, CRA has proven to be promising for other types of substance use, including cocaine (Azrin et al. 1996), tobacco (Roozen et al. 2006), and opioids (e.g., Abbott et al. 1998; Bickel et al. 1997; Roozen et al. 2003). One of the newer studies determined that a computerized version of CRA for opioid-dependent individuals (on buprenorphine maintenance) did as well as a therapist-delivered version of CRA, both of which did significantly better than standard treatment (Bickel et al. 2008). Over the years a series of studies have examined cocaine-dependent individuals treated with a combination of CRA and contingency management (vouchers) for clean urines and found highly favorable results when contrasted with standard treatment (e.g., Garcia-Rodriguez et al. 2009; see Higgins and Abbott 2001). In an effort to identify patterns among CRA study results, Roozen and colleagues conducted a systematic review of 11 randomized controlled trials. They discovered strong evidence that CRA was more effective than usual care when considering the number of drinking days. Furthermore, there was strong evidence that CRA with vouchers was more effective than usual care in achieving cocaine abstinence and more effective than CRA alone. However, there was evidence that the effect of the vouchers dissipated over time after their discontinuation (Roozen et al. 2004). Interestingly, one study determined that the CRA component of the therapy package improved alcohol and employment outcomes compared to vouchers alone in cocaine-addicted individuals (Higgins et al. 2003).

In more recent years CRA has been applied to adolescent populations, most notably as part of the national Cannabis Youth Treatment Study. Similar to the other treatments, adolescent CRA (A-CRA) demonstrated significant pre-post improvements in days of abstinence and days in recovery (i.e., no substance use problems and not institutionalized) and was the most cost-effective treatment within its trial of the study (Dennis et al. 2004). When homeless, runaway youths attending a drop-in center were randomly assigned to CRA or treatment as usual, the CRA participants demonstrated significantly greater improvements in substance use, depression, and social stability (Slesnick et al. 2007). Early results from one multi-site study with over 2,000 adolescents showed that A-CRA was equally effective across ethnic groups (Godley et al. 2011).

57.2.3 International Considerations

CRA has gained international recognition in more recent years. For instance, CRA was implemented successfully within Spain's Public Health System with cocaine-dependent individuals in an outpatient clinic (Secades-Villa et al. 2011). A later study added vouchers to the CRA program and improved treatment outcomes (Garcia-Fernandez et al. 2011). Several Dutch studies and reviews led by Roozen and colleagues already have been noted (e.g., Roozen et al. 2003, 2004, 2006), and a pilot study of CRA with substance-abusing individuals in Mexico detected highly

promising findings (Torres et al. 2005). Finally, the National Drugs Strategy of Ireland has acknowledged CRA as an effective evidence-based approach that can be used as an adjunct to services delivered within the rehabilitation pillar, and Germany has already sponsored a CRA conference. To date, the CRA trainers' manual, *Clinical Guide to Alcohol Treatment*: *The Community Reinforcement Approach* (Meyers and Smith 1995), has been translated into German and Dutch.

57.2.4 CRAFT Procedures

57.2.4.1 Enhancement of the Concerned Significant Other's Motivation

CRAFT begins by enhancing the motivation of the concerned significant other (CSO), the *non*-substance-abusing person who is seeking treatment in an effort to get help for a treatment-refusing loved one who is abusing substances (identified patient, IP). CSOs are told that they can play a pivotal role in helping their family member engage in treatment, in part because they have a wealth of knowledge about the IP's substance use, and the degree of contact between the CSO and IP allows the CSO to make powerful changes in the IP's environment. To start the session, clinicians first ask CSOs to describe the negative consequences they and their IP have experienced as a result of the substance use and the nature and outcome of previous attempts to change the IP's behavior. Overall, these discussions lay the foundation for motivating CSOs to work hard in treatment with a totally new strategy.

Clinicians establish positive expectancies by outlining the research support behind CRAFT, namely, that CRAFT is highly effective in helping IPs engage in treatment (nearly 7 out of 10 times) and in decreasing the distress experienced by the CSO regardless of whether the IP enters treatment. Furthermore, clinicians emphasize that CRAFT is effective across a wide variety of CSO-IP relationships (e.g., spouse, friend, parent), ethnicities, and substances. The clinician then outlines the basic premises involved in CRAFT and the three main goals: (1) decrease the IP's substance use, (2) get the IP to enter treatment, and (3) increase the CSO's happiness independent of the IP's decision to enter treatment.

57.2.4.2 Functional Analysis of IP's Substance-Using Behavior

Similar to the functional analysis (F.A.) that is completed with the substance-using individual during CRA, an F.A. also is completed as part of CRAFT, but with the *CSO* providing the information about the IP. First, the triggers that usually precipitate the IP's substance use are outlined, and then the positive and negative consequences of the use are delineated. The CSO's challenge is to influence/change the IP's environment so that the IP responds in a healthier manner to triggers but in a way that still allows the IP to experience some of the positive consequences (and none of the negative consequences) that have been associated with the substance use. For example, if it is determined that the IP typically views 5 PM as the time to meet with friends to alleviate stress after work (and this typically occurs at a bar), the CSO could help arrange some nondrinking social activities with friends for 5 PM.

Alternatively, the CSO could urge the IP to come straight home after work so that the two of them could go for a relaxing walk in the park. Ideally the exercise and the conversation would serve as a suitable substitute for the "unwinding" in the bar. By choosing a substance-free activity, the IP will not only experience positive consequences but will also experience a reduction in the negative consequences that typically follow substance use. Using a gentle approach, the CSO can help the IP recognize that the negative consequences of substance use (e.g., trouble getting up for work the next day) are eliminated when the IP engages in the substance-free alternative.

It is important to realize that simply making one change in behavior will not suddenly solve the IP's substance use problem. Instead, the CSO typically needs to introduce a number of changes (as outlined in the remaining CRAFT procedures below) before the IP decides to seek treatment.

57.2.4.3 Domestic Violence Precautions

As part of CRAFT, CSOs are taught to modify their own behavior such that only substance-free IP behaviors are "rewarded." Furthermore, CSOs learn to allow IPs to experience the natural negative consequences of substance use. Domestic violence precautions are an important topic to consider before the CSO considers modifying any behavior at home, given that IPs routinely are not pleased with these CSO behavior changes *and* a high correlation already exists between domestic violence and substance use (Klostermann et al. 2010). Thus, CRAFT clinicians always assess the risk for domestic violence, and in some cases CSOs are referred to other programs. At times, functional analyses are used to outline the common triggers for an IP's aggressive behavior, and plans for keeping the CSO safe are stressed. Regardless, CRAFT clinicians regularly ask CSOs to anticipate their IP's probable reaction to a specific change in the CSO's behavior that is under discussion as a potential homework assignment.

57.2.4.4 Communication Skills

Effective communication skills are essential for several CRAFT procedures, including the ultimate invitation for the IP to enter treatment. In the earlier stages of treatment, CSOs' reliance upon positive communication skills can help minimize IP defensiveness and anger when explaining the rationale behind the CSO's own behavior change and when specifically requesting changes in the IP's behavior. The basic components of positive communication for CRAFT are the same as those introduced for CRA: offer an understanding statement, accept partial responsibility, and offer to help. Assume that a mother (CSO) is trying to get her 22-year-old son (IP), who recently received a DUI, to spend time at an alcohol-free music establishment with a nondrinking friend on a Friday night. The CSO might be encouraged to say, "Honey, I know you'd really prefer to be with your old buddies tonight (*understanding statement*), and maybe I shouldn't have meddled by checking to see if Kenny was available (*partial responsibility statement*). But I know you and Kenny still like to get together occasionally, and you both love music. And this place in town has gotten great reviews. Will you give it a try? I'll even arrange your

transportation if you want (*offer to help*)." As noted previously, communication skills are taught through repeated practice in the context of role plays.

57.2.4.5 Positive Reinforcement for Clean and Sober IP Behavior

It is important for CSOs to fully realize that individuals are more likely to repeat behaviors that are reinforced (rewarded), and thus, when CSOs actively reward sober behaviors, they are increasing the likelihood that those sober behaviors will be repeated. CSOs also must understand the distinction between CRAFT's positive reinforcement (which increases the likelihood of clean/sober behaviors) and "enabling," which inadvertently increases the likelihood of substance use. Once the concept of positive reinforcement is explained, clinicians work with CSOs to develop a plan for administering reasonable rewards for the most appropriate times and occasions. The reward always should be inexpensive and readily available, but the type of reward varies based on the CSO-IP relationship, the personal preferences of the IP (i.e., what the IP really enjoys), and what the CSO feels comfortable offering. Some common examples include CSOs giving a compliment, cooking a favorite food, giving a hug, spending pleasant time with the IP, or doing a favor. Since it is imperative that the rewards follow sober behavior, CSOs sometimes require training in discerning whether or not the IP has engaged in substance use recently. If CSOs are interested in explaining the rationale for the reward to their IP, positive communication skills (noted above) are rehearsed. For example, a CSO might say to the IP, "I know it's important to you that I spend some time with you after dinner (*understanding statement*), and I haven't been doing a great job of that lately (*partial responsibility*). So I'm willing to sit and watch TV with you tonight (*offer to help*), but only if you don't get high. You're a lot of fun to be with when you're not using." The importance of the CSO leaving the situation (but without any argument or "drama") if the IP ended up smoking would be stressed.

57.2.4.6 Negative Consequences for Substance-Using Behavior

Just as a behavior is likely to be repeated if it is rewarded, a behavior is *less* likely to be repeated if it is followed by a *decrease* in rewards or an *increase* in negative consequences. CSOs can play an active role in reducing the IP's substance use by withdrawing the same rewards mentioned above (or additional ones) when the IP has been using substances. CSOs typically feel more comfortable removing rewards if they have discussed the rationale for needing to do so with the IP well in advance. Again, positive communication is essential, and the risk for a violent IP reaction is discussed.

CSOs tend to care greatly about the well-being of their IP and consequently find themselves engaging in certain behaviors over time that unintentionally interfere with the natural, negative consequences of their IP's substance use. For example, by helping the IP into bed after a night of drinking, the CSO is preventing the IP from experiencing the full natural (negative) consequences of the decision to use substances. Clinicians discuss the potential ramifications of CSOs changing their own behavior (i.e., *not* helping the IP into bed), including whether it would create more problems than it would solve. For example, an IP might lose a job and thus

financially damage the entire family if the CSO did not call in sick for a hungover IP. But if deemed an appropriate behavior to target, a specific plan for changing the CSO's behavior would be developed. If the CSO wanted to explain the plan to the IP, the conversation would be rehearsed.

57.2.4.7 Helping CSOs Improve Their Own Lives

Unfortunately it is the norm for CSOs to present with a great deal of distress, often in the form of anxiety, depression, or physical symptoms (Orford et al. 1998). A primary goal of CRAFT is to help CSOs improve their own lives, regardless of whether the IP decides to enter treatment. CSOs complete the Happiness Scale (from the CRA protocol) so that their degree of satisfaction across ten personal life domains can be assessed and goals can be set. For example, assume a CSO has become isolated socially and thus rates "social life" a "3." The CSO and clinician might work together to create a plan to broaden the CSO's social network by getting the CSO involved in a new recreational activity or reaching out to an old friend. As always, potential obstacles would be anticipated and addressed, including a possible negative reaction from the IP.

57.2.4.8 Inviting the IP to Sample Treatment

Although CSOs are eager to invite their IP to enter treatment, CRAFT clinicians caution them to lay a solid foundation first. This includes spending some time employing the various CRAFT procedures just outlined, such as rewarding nonusing IP behavior, introducing negative consequences for IP substance use, and relying on positive communication skills throughout. Perhaps not surprisingly, CSOs often report that their IP's substance use has decreased somewhat prior to the IP agreeing to seek treatment. In addition to allowing time for the CRAFT procedures to have an effect, CSOs need to learn the communication skills required for extending the invitation and to identify the ideal time to have the conversation with the IP. Regarding the latter, CSOs are taught to extend the invitation at a time when the IP is most likely to be willing to sample treatment. These "windows of opportunity" may occur when the IP is remorseful about a substance-related negative consequence, upset about a remark about his/her substance use, curious about what the *CSO* is addressing in treatment, and questioning why the CSO's behavior has changed.

"Motivational hooks" are incorporated into the treatment invitation, such as pointing out that IPs can have their own therapist (separate from the CSO's clinician), highlighting that therapy can help the IP in non-substance use domains as well (e.g., finding a job, decreasing anxiety or depression), and suggesting that the IP sample a session or two without making a full commitment to therapy. CSOs should be taught that if their IP initially declines the invitation, they should continue engaging in their new CRAFT-consistent behaviors in order to increase the likelihood of treatment engagement in the near future. Importantly, clinicians need to do preparatory work to ensure that a therapist is available to see the IP without delay as soon as the IP agrees to sample treatment. Furthermore, the IP's therapist should have a theoretical approach consistent with CRAFT, such as a behavioral or cognitive behavioral orientation.

57.2.5 CRAFT Scientific Support

Prior to the development of CRAFT, a few traditional programs were available for the loved ones of treatment-refusing individuals with substance use problems: Al-Anon/Nar-Anon and the Johnson Institute Intervention. Al-Anon (Al-Anon Family Groups 1984) was shown to provide good emotional support (Barber and Gilbertson 1996; Dittrich and Trapold 1984), but many CSOs were uncomfortable with the message to "detach" from their IPs. The Johnson Institute Intervention (JII; Johnson 1986), in contrast, was specifically geared toward working through CSOs in order to get a resistant individual into treatment. After several planning sessions with multiple CSOs, a "surprise party" was scheduled in which the CSOs confronted the IP with the substance use problem and its ramifications. Studies showed that when families actually carried out the entire intervention, the treatment engagement rate was high, but the vast majority of people dropped out of the program before the final meeting with the IP (Liepman et al. 1989), potentially due to concerns over the effect of the intervention on the relationship with the IP (Barber and Gilbertson 1997).

Unilateral Family Therapy (UFT) was introduced in the early 1980s as a type of family therapy that involved individuals other than the IP. Thomas and colleagues conducted several studies with UFT and found promising results, but the studies tended to be small and lacked good experimental controls (e.g., Thomas and Ager 1993; Thomas et al. 1987). Another UFT program with some scientific support was Pressures to Change (e.g., Barber and Crisp 1994; Barber and Gilbertson 1997). Finally, ARISE (A Relational Intervention Sequence for Engagement) is an "invitational" intervention that uses different levels of treatment (e.g., starting with phone conversations with CSOs) and informs the IP about the ongoing meetings with CSOs throughout. Much of the evidence to date has been promising case reports and a pilot study (see Landau and Garrett 2008).

CRAFT, a type of UFT, originally was called CRT (Community Reinforcement Training) when the first small study was conducted by Sisson and Azrin (1986). Twelve female CSOs were randomly assigned into either CRT ($n = 7$) or individual counseling + Al-Anon referrals ($n = 5$). Six of the seven women in the CRT group (86 %) were able to get their problem-drinking IPs into treatment compared to none of the IPs in the comparison group. The second CRAFT study that focused on IPs with alcohol problems was a large NIAAA-funded project that randomly assigned 130 CSOs into one of the three treatment groups: CRAFT, Al-Anon Facilitation Therapy (an individual therapy version of Al-Anon; Nowinski et al. 1992), or the Johnson Institute Intervention. Results indicated that CRAFT-trained CSOs were significantly more effective in engaging unmotivated problem drinkers in treatment (64 %) as compared with the CSOs in the more commonly practiced Al-Anon (13 %) and Johnson interventions (30 %; Miller et al. 1999). Interestingly, CSOs improved in their own functioning independent of treatment condition and whether their IP entered treatment. For those IPs who entered treatment, they did so with their CSOs receiving an average of only 4.7 CRAFT or Al-Anon sessions and 5.7 Johnson Institute sessions.

The success of CRAFT also has been established for treatment-refusing IPs with illicit drug problems. In a pilot project, 62 CSOs from diverse ethnic backgrounds were trained in the CRAFT protocol. As expected, the CSOs were able to get a high percentage of IPs (74 %) into treatment very quickly (less than five CSO sessions) while also reducing the CSOs' own levels of depression, anxiety, and anger (Meyers et al. 1999). At about the same time, a CRAFT (CRT) study was conducted by Kirby and colleagues in which 32 CSOs were randomly assigned to either CRT or 12-step meetings. Engagement rates were 64 % for the CRT-trained CSOs and 17 % for CSOs in the 12-step condition (Kirby et al. 1999).

A large NIDA-funded study was conducted next in which 90 CSOs of illicit drug using IPs were randomly assigned to CRAFT, CRAFT + Aftercare, or Al-Anon/Nar-Anon Facilitation Therapy. An aftercare component was added to one of the CRAFT conditions to mimic the availability of ongoing aftercare groups within the 12-step model. The results demonstrated that the combined CRAFT conditions' engagement rates (67 %) were significantly higher than the Al-Anon/Nar-Anon rates (29 %), but there were no significant engagement differences between the two CRAFT conditions (Meyers et al. 2002). More recently an effectiveness study demonstrated that CRAFT could be successfully transferred from a controlled research setting to a community treatment agency, while maintaining levels of engagement quite similar to previous controlled studies (Dutcher et al. 2009).

CRAFT's success with adults was tested with adolescents in an uncontrolled trial that recruited the parents of 42 drug-abusing, treatment-refusing adolescents (Waldron et al. 2007). A total of 71 % of the parents engaged their adolescents into treatment using CRAFT, and the parents overall experienced a significant reduction in negative symptoms. Another unique application of the CRAFT protocol was a study that delivered CRAFT in a group treatment format (Manuel et al. 2012). Participants were randomly assigned to a CRAFT group or to self-directed CRAFT, with the latter receiving the CRAFT self-help book (Meyers and Wolfe 2004). The intent-to-treat analysis contrasted the CRAFT group engagement rate (60 %) with the self-directed CRAFT rate (40 %) and detected no statistically significant difference. However, for those CSOs assigned to the CRAFT group condition who attended at least one session, 71 % engaged their IP into treatment. The implication is that group CRAFT can be a cost-effective method of getting treatment-refusing IPs into treatment.

CRAFT has been found superior in engaging treatment-refusing substance-abusing individuals compared with traditional programs. Additionally, CRAFT has been shown effective across ethnicities, different types of CSO-IP relationships, and various kinds of drugs of abuse. Furthermore, CRAFT works in less than five CSO sessions on average, and CSOs report psychological improvement regardless of the outcome of their engagement efforts.

57.2.6 International Considerations

The CRAFT training manual, *Motivating Substance Abusers to Enter Treatment: Working with Family Members* (Smith and Meyers 2004), has been translated into

German, Korean, Finnish, and Japanese to date. The self-help version (Meyers and Wolfe 2004) is available in Finnish and Spanish. Therapists have been trained in CRAFT across the world, including Ireland, Wales, Scotland, the Netherlands, Sweden, Finland, Germany, and Canada.

Development and Dissemination of the Matrix Model of Intensive Outpatient Treatment

58

Jeanne Obert, Michael McCann, and Richard A. Rawson

Contents

Abstract

The Matrix Model of intensive outpatient treatment was developed in the 1980s to address the needs of stimulant users. Over time, a manualized treatment protocol was developed and published, and the application of the Matrix Model was extended to other drug and alcohol users. A randomized, controlled, multisite trial was funded by the Center for Substance Abuse Treatment to evaluate the Matrix Model compared to "treatment as usual" with 978 methamphetamine users at eight sites. The results of this study were the basis for the Matrix Model achieving the designation as an evidence-based program. In the late 1990s, the methamphetamine epidemic combined with the funding

requirement that providers use evidence-based treatments resulted in a high demand for training programs in the use of the model. Matrix developed standard training curricula, fidelity instruments, and quality assurance protocols. Training procedures consist of an initial 2-day, core training session followed by more intensive training with the person at each site identified as the "Key Supervisor." Sites are certified after passing a site visit and review of audiotaped sessions. In addition to the dissemination of the Matrix Model across the United States, training has been delivered in 21 countries worldwide with certified programs in South Africa, Nicaragua, Guam, Spain, New Zealand and Abu Dhabi.

58.1 Introduction

58.1.1 Matrix Model Background

The Matrix Model of outpatient treatment was developed at the height of the stimulant epidemic in Southern California in the 1980s (Obert et al. 2000). In the urban areas of Los Angeles, crack cocaine was the major drug problem affecting communities, but 50 miles to the east of downtown Los Angeles, in San Bernardino County, large numbers of methamphetamine (MA) users began to present at the Matrix Institute on Addiction clinic in Rancho Cucamonga (one of three Matrix clinics in the Southern California area) for assistance. At the time, there was no established approach for structuring outpatient services to meet the needs of these two groups of stimulant users. Therefore, with funding from the National Institute on Drug Abuse (NIDA), the authors of the Matrix approach attempted to integrate existing knowledge and empirically supported techniques into a single, multielement manual that could serve as an outpatient "protocol" for the treatment of cocaine and MA users (Rawson et al. 1989, 1995).

The development of the Matrix Model was influenced by an ongoing interaction between clinicians working with patients and researchers collecting clinical research data. As clinical experience with stimulant-dependent individuals was amassed, clinical impressions frequently generated questions that were answered by using relevant research findings. For example, stimulant users in outpatient treatment frequently gave the impression of being unmotivated or uncooperative because they failed to comply with counselors' directions. At the time (mid-1980s), many treatment programs considered these patients to be "in denial" and often confronted them aggressively or discharged them as "not ready for treatment." New information on stimulants and the brain provided an alternate view of these patients for Matrix clinicians. They began to understand that it was not "denial and resistance" but rather a neurobiological issue involving brain chemistry changes that contributed to patients' inability to recognize and deal rationally with their self-destructive behavior.

As Matrix staff worked with these stimulant users, they identified specific clinical issues (e.g., conditioned cues, drug craving, anhedonia) that created challenges for patients. Materials were adopted from the cognitive behavioral and

relapse prevention literature to provide patients with an understanding of these phenomena and with "tools" to deal with them. Matrix staff also identified a set of clinical issues in working with the family members of these patients, and therefore, materials were adapted from the family therapy literature to aid in working with family members. In order to standardize the delivery of a common set of materials across patients, therapists, and clinics, a treatment manual was created that consisted of a session-by-session set of clinical exercises and information (Rawson et al. 1989, 1995). At the Matrix clinics, as in most treatment settings, the patients presented using alcohol and other drugs as well as stimulants. Even those patients who were non-stimulant users found the approach relevant and had a treatment response that was similar to that of the stimulant users.

The initial manual for the Matrix Model of intensive outpatient treatment was produced with funds from NIDA (Rawson et al. 1989) and evaluated in a major multisite trial (see below) by the Substance Abuse and Mental Health Services Administration (SAMHSA; Rawson et al. 2004). The Matrix manual and supportive materials are available at www.ncadi.samhsa.gov. Subsequently, Matrix Model manuals that are not specific to stimulants, that have more family and individual sessions, and that include a section on Medication Assisted Treatment as well as versions that are specifically geared for use with adolescents and with drug courts were published and are available from Hazelden Publishing at www.hazelden.com. Research reports describing clinical experiences with the model, on the application of the entire package of techniques (Rawson et al. 1995, 2004; Huber et al. 1997).

58.2 Elements of the Matrix Model

58.2.1 Description

The 16-week Matrix intensive outpatient treatment protocol is delivered in meetings that occur three times each week. A primary therapist conducts both the individual and group sessions for a specific patient and is responsible for coordinating that patient's entire treatment experience.

58.2.1.1 Program Components

- **Early Recovery Groups** occur biweekly for 4 weeks at the beginning of treatment. The content of these groups is designed to teach basic skills and provide information to help patients stop using drugs and alcohol.
- **Relapse Prevention Groups** are the critical mechanism for supporting recovery and helping patients learn how to maintain abstinence. These groups are delivered biweekly over the entire 16-week treatment period. The content of the materials used in these groups emphasizes cognitive behavioral therapy concepts and skills. Matrix group leaders coach patients through the recovery process. The groups are quite directive and maintain a focus on the topic materials; they are not used as process or psychotherapy groups.

- **Family Education Groups** are designed to explain addiction in simple terms. These groups cover the biology of addiction (e.g., neurotransmitters, brain structure, drug tolerance), principles of learning and conditioning as they apply to addiction, the medical effects of drugs and alcohol on organ systems, and how addiction impacts family relationships. Because Matrix trainers are experienced in working with various cultures within and outside of the United States, important culturally specific materials are included within the Education Group curriculum. Several of the lectures are essential to the understanding of the skills taught in all components of the Matrix program. One of the lectures covers the changes in brain chemistry as the brain recovers from the neurochemical changes produced by drug use (Roadmap for Recovery). Another lecture presents information derived from research about the role of classical conditioning in the development of drug craving and why craving is stimulated by specific cues and emotional states (Triggers and Cravings). The lectures have been produced in DVD format by both the Center for Substance Abuse Treatment (CSAT) and Hazelden.
- **Individual Sessions** provide the therapists and patients with a setting to individualize the treatment experience and address issues that may be too personal to cover in group sessions. Frequently, individual sessions include significant others and/or family members, which allows relationship issues to be addressed. The frequency of individual sessions is geared to the patient's needs and can be adjusted to address crisis situations.
- **Urine/Breath Tests** are conducted randomly on a weekly basis, and the results are used to review and improve the treatment plan, not to police or punish.
- **Social Support Groups** are provided beginning at week 13 of treatment and continue as part of an ongoing continuing-care program. In these groups, patients are able to interact with drug-free friends and are encouraged to engage in new recreational behaviors that promote a drug-free lifestyle.
- **12-Step Meetings** are an adjunct to the Matrix Model and are optimally held on-site one night a week to introduce patients to AA concepts and philosophy. Patients are strongly encouraged to participate in community 12-step groups and use the 12-step program as a long-term source of support.

58.2.1.2 A Positive and Collaborative Therapeutic Relationship

The Matrix Model is characterized by a positive and collaborative relationship between the patient and therapist. Within this model, the therapist is directive but maintains a patient-centered therapeutic stance. The motivational interviewing (MI) techniques developed by Miller and Rollnick (1991) are used to create the positive and motivating therapeutic relationship necessary to deliver the Matrix treatment approach. This caring relationship, described by Rodgers as containing empathy, positive regard, warmth, and genuineness (Rogers 1951), is the basis for both MI and the Matrix Model. A collaborative therapeutic climate that communicates acceptance without judgment and that moves at the patient's pace increases patients' readiness to learn new skills, provides practice for more adaptive coping strategies, and facilitates change.

58.2.1.3 Structure and Expectations

The schedule of the Matrix program provides a structure that gives patients thrice weekly clinic visits across the initial 16 weeks of treatment. Between visits to the clinic, patients are assisted in developing a structure and schedule that helps build routines consisting of low-risk activities and situations. The primary tool in building a structure is creating a daily, hour-by-hour schedule for their activities. Proactively planning future activities and following through on this plan is frequently a new skill for many patients. Mastering this skill of purposely determining behaviors, as opposed to acting with no plan, is an important step toward creating a drug-free lifestyle. Creating a written schedule with patients can help them operationalize how to stay abstinent "one day at a time."

58.2.1.4 Psychoeducation

The Matrix Model includes educating patients about conditioning and neurobiology to help them understand the concept of addiction as a "brain disease" (Obert et al. 2002). The educational materials used in the Matrix program help patients recognize the physiology/neurobiology of addiction and remove some of the confusion they have about their own feelings, thinking, and behavior. This knowledge is used to empower patients to take steps to actively become change agents in building a recovery program. While the Family Education component of the program is a major forum for presentation of psychoeducational materials, an educational aspect of the Matrix program is included in all treatment activities.

58.2.1.5 Teaching Cognitive Behavioral Skills

Knowledge and skills developed as cognitive behavioral therapy exercises (CBT) play a large role in the Matrix Model. The work of Marlatt and Gordon (1985), Carroll and colleagues (1991, 1994a, b), and others has contributed greatly to the content and group treatment activities of the Matrix Model. While this form of cognitive behavioral outpatient therapy is structured and focused on relapse prevention, it has been customized across cultures and continents to address patients' unique experiences, thoughts, and behaviors. The educational aspect of CBT teaches patients how to self-monitor and avoid relapse as they interact with the cues and high-risk situations they encounter. In the group format used in the Matrix Model, patients are asked to report on strategies that worked and those that did not work, what obstacles were encountered, and what changes need to be made to make the interventions successful in the future. Each of the Matrix group sessions is anchored by a specific topic. Patients leave each group with information and skills about recovery and how it applies to their situation. The therapist in these groups combines teaching skills with motivational interviewing strategies to help facilitate the use of the recommended strategies. The Matrix program has sometimes been described as an experience more closely related to taking a course in recovery knowledge and skills than a process of psychotherapy.

58.2.1.6 Positive Reinforcement

Research and empirical evidence supports the use of contingency management (CM) techniques to shape and maintain drug recovery behaviors (Petry 2000; Roll et al. 2006). These techniques are, at their core, the systematic application of positive reinforcement principles to the modification of behavior. As the research evidence has accumulated on the effectiveness of CM (Rawson et al. 2006; Roll et al. 2006), CM strategies have been added as a standard component of the current Matrix Model treatment. Positive reinforcement to promote behavior change can be accomplished in ways other than with CM. One technique for reinforcing positive behavior is the recording of sober days on a calendar. To implement this exercise, patients are asked at the beginning of each session to place colored stickers, or "dots," on a calendar for each drug-free day. This public recording of abstinent days provides an excellent opportunity to explicitly reinforce patients' achievements.

58.2.1.7 Family Involvement

The Matrix Model involves family members in the treatment program in both the individual sessions and the Education Groups. "Family" includes all those people who are part of patients' everyday life. These individuals include biological family members as well as partners, close friends, associates, and extended family members. Family involvement in the Matrix Model leads to better retention of patients in the treatment. It is not uncommon for some patients to not want family members involved, especially those family members who are critical or overly controlling. It is often helpful for therapists to schedule a session with family members to explain the ways in which they can be involved in the treatment process and to encourage them to attend scheduled sessions. Family members are often willing to help support the recovery process and attend treatment when their role is presented as providing supportive and positive assistance, as opposed to asking them to enter "therapy" for their family systems pathology. While getting families to participate is sometimes difficult, it is often possible to find at least one family member who is willing to be a part of the treatment process. Matrix therapists proactively reach out to family members to promote their active involvement in the scheduled treatment activities.

58.2.1.8 Self-help Groups

Research has demonstrated the usefulness of participation in 12-step programs in achieving and maintaining recovery from addiction (e.g., Humphreys et al. (2004)). Attending 12-step meetings is strongly encouraged as part of the Matrix treatment experience. In countries where the 12-step program is not available or is inconsistent with the culture, other types of fellowships and sober social activities can be added to the program. Often, motivational interviewing strategies can be helpful in encouraging involvement in 12-step meetings.

58.2.1.9 Urine and Breath Tests

The Matrix approach requires accurate information on the drug use of patients as they progress through treatment. The most accurate means of monitoring patients

for drug and alcohol use during treatment is through the use of urine and breath alcohol testing. Urine testing is used as a way to reveal continuing drug use, which is a sign that the treatment plan needs revising. Urine and breath alcohol testings done in a clinical setting for clinical purposes are quite different from urine testing that is done for legal monitoring.

58.2.2 Matrix Model Randomized Clinical Trial

The Matrix Model was evaluated in a randomized, controlled study funded by CSAT with 978 methamphetamine users in a national multisite trial (Rawson et al. 2004). The design involved a comparison of the Matrix approach with eight different forms of treatment as usual (TAU). This was not an optimal efficacy design, but it was necessitated by CSAT's desire to provide as much treatment as possible within an evaluation study. The eight sites differed considerably: one site provided treatment in the context of a drug court, another site treated women exclusively, and two sites treated a significant number of Asians and Pacific Islanders. The remaining sites provided care primarily to Caucasian and Hispanic participants. All sites employed outpatient treatment models, but the elements of TAU varied widely at each treatment site.

The participants in the study had on average 7.54 years of lifetime MA use and 11.53 days of MA use in the past 30 days. The preferred route of administration of MA was smoking (65 %), followed by injecting (24 %) and snorting (11 %).

During the application of the Matrix Model, the participant performance in seven of the eight sites was clearly superior in the Matrix condition, compared to the TAU condition (the lone exception was within the drug court, a mandated program, where there was no difference between conditions). Matrix Model treatment resulted in participants attending more sessions, staying in treatment longer, providing more methamphetamine-free urine samples, and having longer periods of methamphetamine abstinence. Compared to those who participated in TAU, 38 % of Matrix clients were more likely to stay in treatment, 27 % were more likely to complete treatment, and 31 % were more likely to have methamphetamine-negative urine test results. However, outcomes at discharge and follow-up were comparable between patients treated in the Matrix Model and those treated with TAU.

Overall, across the study, MA use decreased substantially during treatment. At enrollment, participants reported approximately 11 days of use in the last 30 days, whereas at discharge, the number was reduced to approximately 4 days of use in the last 30 days. At the 6-month follow-up, the number was still approximately 4 days and it decreased even more at the 12-month follow-up (approximately 3 days). This reduction in drug use from enrollment to the 6- and 12-month follow-up points was consistent across sites and conditions. The results of this study were the primary basis for the Matrix Model achieving inclusion in the SAMHSA's National Registry of Evidence-based Programs and Practices.

58.2.3 Dissemination of the Matrix Model

Matrix Model training efforts, both within the United States and internationally, began in the late 1990s, as many areas in the United States and other regions sought direction on approaches for the treatment of amphetamine-type stimulant (ATS) use disorders. In order to accommodate these training requests, a model for dissemination of the Matrix Model was developed that would not be too restrictive (both in terms of cost and fidelity requirements) but would create local expertise to provide ongoing training and supervision of clinical staff and ensure fidelity to the main components of the model. Consultation on the development of a dissemination model was obtained from Texas Christian University, the University of South Florida, and the National Implementation Research Network. The Matrix Model training process ideally begins with a pre-training phone consultation with the organization where staff are to be trained, in order to review the setting, staff, and population to be treated and explain the overall training plan. The first training component is a two-day training on the Matrix Model that is attended by the organizations' clinical and administrative personnel. The organization leadership, with input from Matrix trainers, selects the trainee clinicians to be developed as local Matrix experts. These local experts are referred to as Matrix Key Supervisors. Key Supervisors should be:

- Respected clinical leaders who are both credible to clinicians and knowledgeable about organizational dynamics
- People who possess excellent communication and clinical skills
- Leaders who are committed to actively working to implement the Matrix Model with fidelity and good effect

After attending the core training, Key Supervisors are trained in a two-day training that includes instructions on how to teach the model and monitor fidelity to it, how to supervise clinical staff in delivering the model, and how to train new clinical staff who join the program after the initial training.

58.2.3.1 Matrix Trainers

The trainers who lead the Matrix Model dissemination efforts are skilled teachers with extensive experience training mental health professionals, and they have extensive experience delivering and supervising Matrix treatment. In addition to being knowledgeable about the Matrix materials, Matrix trainers are skilled in helping problem-solve implementation issues, addressing clinician and organizational resistance to change (employing their motivational interviewing skills), and creating a training experience that is a mix of didactic and role-play activities.

58.2.3.2 Certification

The Matrix Institute developed a certification program in response to requests by state agencies for a way to determine which programs were delivering the Matrix Model with adequate training and fidelity to the model. The Matrix certification confirms that the organization has been delivering the model for at least 6 months, has clinicians who are properly trained, and has Key Supervisors who oversee the implementation and supervise the clinical staff.

58.2.3.3 Dissemination Activities

The Matrix Model has been extensively disseminated in the United States. A major impetus for people and agencies to receive this training is that during the past decade, there has been a major push by SAMHSA and professional groups to promote the use of evidence-based practices (EBP). With the designation of the Matrix Model as an EBP via the SAMHSA NREPP program, the Matrix Model represents one of the few EBPs for treating individuals with drug dependence. Matrix dissemination efforts in the United States and internationally have led to over 6,000 individuals and 320 Key Supervisors being trained by Matrix trainers. Matrix trainers have conducted training sessions in 21 countries, in all 50 states, and have trained staff from 2,500 treatment agencies. Fourteen agencies in the United States have received Matrix certification, as have ten international agencies (in South Africa, Spain, Abu Dhabi, Guam, New Zealand, and Nicaragua). The Matrix manuals have been translated into many languages including; Thai, Arabic, Farsi, Spanish, Portuguese, Vietnamese, Slovakian, Afrikaans, and Japanese.

58.2.3.4 International Dissemination Efforts: Examples

In many parts of the world, the use and abuse of ATS are major public health problems, and therefore, effective treatments are in great demand. At present, there are no pharmacotherapies with demonstrated efficacy for ATS use disorders. Demand for training in the Matrix Model appears to be the result of clinical leaders in many parts of the world searching for an integrated package of treatment techniques for ATS disorder treatment that can be systematically implemented and evaluated.

58.2.3.5 South Africa

The first Matrix Model training in South Africa was in 2006, hosted by Substance Misuse: Advocacy, Research, Training (SMART), a nonprofit organization. SMART has hosted five trainings in the Western Cape in 2006, 2008, 2011 (two visits), and 2012. An additional training was hosted by the Bosasa Youth Development Centers in Gauteng, South Africa. Each of these training sessions included at least one core and a Key Supervisor Training, with participants from national, provincial, and city agencies and private treatment centers. Five of the Matrix sites are located in city and provincial community health centers in Cape Town and the Western Cape. While there are many Matrix programs in South Africa, fourteen are presently certified with ten of these within Bosasa. These programs report excellent results with very diverse populations, and it is expected that additional sites will be certified in the future.

58.2.3.6 Spain

The first Matrix Model training in Spain was sponsored by the government of Murcia in 2005. Three major training events have been conducted in the region of Murcia, in which more than 80 professionals and four Key Supervisors have been trained. Despite severe economic obstacles, efforts are underway to ensure continuity of implementation, training, monitoring, and evaluation efforts with the Matrix Model throughout Spain.

58.2.3.7 Abu Dhabi

The National Rehabilitation Center (NRC) in Abu Dhabi, United Arab Emirates, is a regionally significant treatment center in the Gulf region that has been operating since 2002. As increased demand for services was recognized, the NRC began a major expansion of services in 2010. One area of need that was identified was the establishment of a program of outpatient services. In 2011, the NRC hired a psychiatrist trained for 2 years at the Matrix Institute and UCLA. He began implementation of the Matrix approach in a limited manner, and after a 1-year pilot test period, the NRC leadership initiated a plan to fully implement the Matrix program and complete the certification process. Trainings have been conducted in the Matrix Model in Abu Dhabi, and in 2012, a team for four Emirati clinicians (one MD and three psychologists) visited the Matrix offices in Los Angeles for 6 weeks for an intensive training experience in the Matrix Model. At present, they are completing the certification process. One result of the Matrix training has been a very significant expansion of outpatient services at the NRC, as the number of patients in outpatient treatment has increased and the Matrix program has promoted the organization and delivery of a diverse set of services for patients.

58.3 Conclusion

The Matrix Model is a treatment approach comprising a collection of evidence-based strategies, integrated into a single protocol. The research on the Matrix approach (Rawson et al. 1995, 2004; Huber et al. 1997) supports its value as a standardized package, but the treatment elements have been disaggregated into individual elements and applied in a variety of treatment settings in countries and areas including Japan, Vietnam, Egypt, Palestine, Israel, Australia, the Caribbean, Guam, China, Brazil, and Canada. The primary attraction of the Matrix approach is that it has research evidence to support its effectiveness, it uses evidence-based treatment elements, and it has been manualized. Further, in many international sites, the development of outpatient services is in the early phases, and the Matrix Model provides a way of organizing services within a structured framework.

Abstract

This chapter provides an overview of the rationale and evidence for exercise as a treatment intervention for substance use disorders. The benefits of exercise on physical health, including weight and cardiovascular outcomes, are well known; emerging literature also supports the use of exercise in reducing depression and anxiety symptoms. These and other negative affect states are common during withdrawal and early abstinence from substances and may predispose users to relapse. Exercise may facilitate abstinence by enhancing positive mood states via effects on the endogenous opioid system and potentiation of dopaminergic transmission. Furthermore, cognitive deficits have been observed in long-term substance users, and exercise has been associated with improvement in cognitive functioning, particularly executive control tasks. The addition of a new, non-drug-related activity such as exercise may provide a reinforcing alternative behavior that may complement relapse prevention skills taught in common therapy approaches for substance users while promoting health and positive behavioral changes consistent with treatment goals.

59.1 Introduction

There is clear scientific evidence that physical exercise can have a positive effect as an intervention for a variety of medical and psychiatric disorders and symptoms. As noted in the *2008 Physical Activity Guidelines for Americans* (Leavitt 2008) and elsewhere (e.g., Lautenschlager et al. 2008; Palmer et al. 1995), exercise appears to have generally beneficial effects on mood, cognition, and health. In addition, exercise has been shown to have positive effects in mediating many of the conditions that are associated with substance use. Research has shown that individuals addicted to drugs and alcohol experience high levels of negative affect states including depression and anxiety, which may be ameliorated by exercise (e.g., Reed and Ones 2006). Cognitive impairment (Kramer and Erickson 2007), fatigue, and low energy (e.g., Häuser et al. 2010) associated with drug use may also improve as a result of exercise.

Direct experience in treating stimulant users has demonstrated the benefits of exercise. For example, clinicians at the Matrix network of addiction treatment clinics in Southern California observed that anhedonia and cognitive disruption that persisted for months after cessation of use appeared to be significantly less severe among those individuals who engaged in regular exercise as part of their recovery plan (Rawson et al. 2002). This observation became the basis for a recommendation appearing in a clinical guide publication: “the experience at Matrix over the past 20 years has

suggested that if patients can be engaged in a program of physical exercise, they are more able to manage difficult emotional states. An exercise program, three to five times per week, appears to help relieve symptoms" (Rawson 2006). This chapter recounts the experience of the author and colleagues who have employed exercise in a clinical research study conducted in a community-based residential treatment program serving patients with stimulant use disorders; initial discussion provides a brief rationale for exercise as an intervention for substance use disorders.

59.2 Exercise as an Intervention for Health Conditions Associated with Substance Use Disorders

59.2.1 Exercise Is Effective for Medical Conditions and Symptoms

Based on a comprehensive review of the literature, the US Department of Health and Human Services presented the *2008 Physical Activity Guidelines for Americans* (Leavitt 2008), documenting "strong evidence" for general health benefits of physical activity. For adults, improvements ensuing from regular exercise at moderate levels were lower risk of early death, heart disease, stroke, diabetes, high blood pressure, adverse blood lipid profile, metabolic syndrome, and colon and breast cancers. Exercise is helpful for prevention of weight gain, weight loss when combined with diet, and improved cardiorespiratory and muscular fitness, as well as reduced depression and better cognitive function.

Exercise has been shown to reduce fatigue in individuals with multiple medical conditions, including fibromyalgia (Häuser et al. 2010) and ankylosing spondylitis (Durmus et al. 2009). The benefits of exercise in reducing chronic pain have also been extensively documented in prior literature (Hayden et al. 2005), including reductions in lower back pain and functional outcomes from prescribed aerobic (McDonough et al. 2010) and resistance (Shirado et al. 2010) exercise programs.

59.2.2 Exercise Is Effective for Psychiatric Conditions and Symptoms

Aerobic and resistance exercise interventions are useful for a wide range of psychiatric conditions, including anxiety and depression (Zschucke et al. 2013). The majority of studies have demonstrated efficacy of exercise in reducing symptoms of depression in both inpatient (Martinsen et al. 1985) and outpatient (e.g., McNeil et al. 1991) settings; favorable results have been highlighted in several review articles (e.g., Barbour et al. 2007; Martinsen 2008) and meta-analyses (North et al. 1990; Craft and Landers 1998). Exercise has been shown to reduce depressive symptoms in medically compromised populations, including cardiac (Pinto et al. 2013) and cancer (McLellan 2013) patients. The benefits of exercise relative to psychotropic medication (Blumenthal et al. 1999) and

psychotherapy (Greist et al. 1979; Klein et al. 1985; Fremont and Craighead 1987) have also been investigated; equivalent benefits have been found comparing exercise with medication, time-limited or time-unlimited psychotherapy, group therapy, and cognitive-behavioral therapy.

State anxiety has been shown to acutely diminish after individual episodes of exercise (Raglin and Morgan 1987), and aerobic exercise may confer significant benefit in the treatment of adults with moderate to severe panic disorder (Broocks et al. 1998; Ströhle et al. 2009) and obsessive compulsive disorder (Abrantes et al. 2009). The majority of studies have suggested efficacy of exercise in mitigating stress-related symptoms across a variety of study populations, including nonclinical (Lion 1978; Bahrke and Morgan 1978; Blumenthal et al. 1982), clinical (Abrantes et al. 2009), and medically compromised (Prosser et al. 1981) adults. In a study of adults with significant anxiety sensitivity, a 2-week exercise intervention significantly reduced anxiety sensitivity relative to no-treatment control (Smits et al. 2008), an effect which mediated the benefits of exercise on negative affect states including anxious and depressed mood.

Substance dependence is associated with elevated rates of comorbid psychiatric disorders, particularly depressive and anxiety disorders (e.g., Mason et al. 1998; Glasner-Edwards et al. 2008). Severity of psychiatric symptoms has been associated with poorer treatment outcomes in multiple prior studies (e.g., Rounsaville et al. 1986; Cacciola et al. 2001; Glasner-Edwards et al. 2009). Upon cessation of drug use, abstinence syndromes comprising prominent psychiatric features may emerge (e.g., McGregor et al. 2005). Syndromes may be characterized by drug cravings coupled with marked depressive symptoms including anhedonia, dysphoria, irritability, poor concentration, hypersomnia, low energy, and even suicidality (Meredith et al. 2005). The contribution of emotional stress to drug use and relapse has been well documented (e.g., Sinha et al. 2006; Fox et al. 2007; Tate et al. 2008), and considerable evidence is accumulating to suggest that substance abusers exhibit deficits in their ability to process and regulate such stress.

59.2.3 Exercise Improves Cognition

Cognitive deficits have been observed in long-term users of various substances. Chronic opioid use, for example, is associated with deficits in attention, processing speed, working memory, and executive functions (Mintzer and Stitzer 2002) that can negatively impact methadone treatment response (Davis et al. 2002). Methamphetamine users suffer from cognitive impairments during initial months of abstinence, including working memory, selective attention (Simon and Domier et al. 2002), learning (Gonzalez and Rippeth et al. 2004), and decision-making (e.g., Bechara and Damasio 2002; Paulus et al. 2003). Deficits in multiple cognitive domains have been observed in alcohol-dependent individuals, including impairment in visuospatial and perceptuomotor functions, executive functions, and short-term memory in addition to dementia and Korsakoff syndrome (Kopera et al. 2012).

Meta-analyses of randomized, controlled trials confirm that normal and cognitively impaired adults derive cognitive benefits from physical exercise (Etnier et al. 2006; Colcombe and Kramer 2003; Heyn et al. 2004; Angevaren et al. 2008). Improvements are the greatest for executive control processes (e.g., planning, scheduling, working memory, dealing with distraction, multitasking), for participants in combined strength and aerobic training regimens, and when exercise duration is greater than 30 min (Colcombe and Kramer 2003). Angevaren et al. (2008) found largest effects of aerobic exercise on motor and auditory function, and moderate effects were observed for cognitive speed and visual attention. Executive and other cognitive functions have been shown to improve after acute bouts of resistance exercise in middle-aged adults (Chang et al. 2013).

Exercise may hasten or improve recovery from substance dependence by contributing effects on underlying neurobiological processes, such as dopamine activity (Robertson et al. 2012). A recent study demonstrated reversal of methamphetamine-induced striatal dopamine transporter and tyrosine hydroxylase damage after exercise in rodents (O'Dell et al. 2012). In addition, neurotrophic proteins may be regulated in part by exercise and play an important role in regulating neuronal function in the brain and help to sustain normal cognitive, emotional, and behavioral functioning. Brain-derived neurotrophic factor (BDNF), the most widely expressed neurotrophin in the brain, supports synaptic plasticity, facilitates neurogenesis, and modulates neurotransmission (de Cid et al. 2008).

An emerging literature suggests that BDNF may have a role in the pathogenesis of addictive disorders (Heberlein et al. 2011). Treatment interventions that affect BDNF production may mediate synaptic plasticity and neuroprotection, which could in turn ameliorate negative affective symptoms, impulsivity, and other cognitive deficits associated with ongoing drug use and relapse risk. Exercise, for example, has been shown in preclinical (Russo-Neustadt et al. 2000; Seifert et al. 2010) and human (Ploughman 2008) studies to enhance BDNF release in the brain. This is potentially significant because of the purported benefits of exercise on cognitive functioning (Neeper et al. 1995); cognitive deficits have been observed in chronic substance abusers as evidenced by poor performance on memory and attention tasks and learning deficits (Cipolli and Galliani 1987; Guerra et al. 1987). Substance dependence is also associated with poor impulse control and selective processing (Lundqvist 2005). In addition, exercise has been shown to ameliorate negative mood states that may contribute to substance relapse, and prior literature has suggested that low BDNF levels in individuals with substance dependence may predispose to higher rates of psychiatric comorbidity (Angelucci et al. 2007).

59.2.4 Exercise for Reducing Substance Use and Preventing Relapse

An emerging literature on exercise-based interventions for substance use disorders provides preliminary evidence in support of this approach. In a study of cocaine-addicted rodents, rats given access to aerobic activity demonstrated reduction in

cocaine seeking relative to those who did not have access to such activity (Lynch et al. 2010). The majority of clinical research has focused on aerobic exercise as a potential intervention to aid smoking cessation and has shown mixed effects of exercise on smoking abstinence; more consistent positive effects on cigarette cravings, withdrawal symptoms, and smoking-related behaviors after exercise sessions have been demonstrated (Taylor et al. 2006). In an investigation of women enrolled in a 12-week cognitive behavioral smoking-cessation program, subjects were randomized to receive either vigorous aerobic exercise or health education three times a week (Bock et al. 1999). Those who participated in the exercise group evidenced significant reductions in cigarette craving, negative affect, and nicotine withdrawal during most weeks of the program.

More recent observational studies have suggested a preliminary positive effect of exercise in reducing substance use in both treatment-engaged substance users (Brown et al. 2010) and in nontreatment-seeking cannabis users (Buchowski et al. 2011). In the treatment population, it was noted that substance use outcomes were significantly better among substance users who attended at least 75 % of exercise sessions (Brown et al. 2010). An 8–9-week structured exercise program has also demonstrated efficacy in adolescents enrolled in drug treatment programs; adolescents who improved in self-concept, anxiety, and depression risk factors reported reduced substance use relative to those who did not improve on similar measures (Collingwood et al. 1991). Similarly, a prospective investigation of more than 4,000 twins revealed lower rates of illicit drug use and alcohol use consequences in adulthood among physically active adolescents, supporting prior work suggesting a relationship between low physical activity in adolescents and drug use (Korhonen et al. 2009).

In addition to our ongoing study described below, a multisite study is being conducted in the United States by the Clinical Trials Network (CTN), funded by the National Institute on Drug Abuse, investigating the benefits of an exercise component added to residential programs addressing stimulant use disorders. The CTN0037 trial, Stimulant Reduction Intervention Using Dosed Exercise (STRIDE), is a randomized controlled trial to test the effectiveness of the addition of exercise compared to health education to treatment as usual in improving drug treatment outcomes in 330 participants with DSM-IV-diagnosed stimulant abuse or dependence (e.g., cocaine, methamphetamine, amphetamine) and receiving treatment in residential settings; conditions include either Vigorous Intensity High Dose Exercise Augmentation (VIHD) plus Usual Care or Health Education Intervention Augmentation (HEI) plus Usual Care.

59.2.5 Study of Exercise as an Intervention for Methamphetamine Use Disorders

As indicated in the brief review of the literature, an exercise regime may be useful in addressing craving, mood states, and resultant drug-seeking behavior that can lead to relapse. To explore the effectiveness of exercise for stimulant use disorders,

Dr. Richard Rawson and colleagues at the University of California, Los Angeles, are conducting an investigation of the utility and efficacy of an 8-week, evidence-based aerobic and resistance exercise intervention to promote improved treatment outcomes for a sample of 150 individuals in residential treatment for methamphetamine dependence. The study is examining medical, psychiatric, neurocognitive, and behavioral benefits that may accrue during participation in an 8-week exercise intervention, as well as possible sustained beneficial impacts on drug use following completion of the exercise protocol and discharge from the residential treatment program. The project also includes a brain imaging component to collect data leading to an improved understanding of the mechanisms that may underlie observed effects on treatment outcomes and symptom remediation associated with the exercise intervention.

Methamphetamine-dependent individuals are screened to determine eligibility, and those randomized to the exercise intervention participate in supervised progressive endurance and resistance training three times per week for 8 weeks (24 sessions) consistent with current guidelines for comprehensive exercise programs (American College of Sports Medicine [ACSM] 2000). Each session consists of a 5-min warm-up, 30 min of aerobic activity on a treadmill, 15 min of resistance training, and a 5-min cooldown with stretching and light calisthenics. The goal of the aerobic training is to accumulate at least 30 min of continuous aerobic exercise at a target intensity set by data derived from maximal incremental exercise testing as described below. Information derived from the incremental testing is also used to define a safe ceiling for exercise intensity for each participant. The goal of the resistance training is to develop adaptations in muscle strength and body composition to complement the aerobic training program. A total of nine exercises are performed each day for major muscle groups.

Participants randomized to the control condition participate in a health and wellness education session three times a week for 45 min. A counselor provides informational materials, facilitates discussion of educational content, monitors attendance, and documents participants' involvement. Sessions consist of an integrated multimedia educational program addressing a variety of health, wellness, and lifestyle topics such as nutrition, dental care, acupressure, sleep hygiene, and health screening, adapted from a previously implemented wellness manual used by Kinnunen et al. (2008).

All study participants complete a maximal incremental exercise test (XT) on a treadmill ergometer using a symptom-limited incremental protocol with linear increases in the work rate with respect to time (Cooper 2001). This test occurs three times during participation – at baseline, study week 5, and immediately following the intervention phase or upon intervention termination. Aerobic capacity $\left(\dot{V}O_2\text{max}\right)$ and the metabolic or lactate threshold $\left(\dot{V}O_2\theta\right)$, which is the level of oxygen uptake that defines one's ability to perform prolonged work, are measured using indirect calorimetry with an automated metabolic measurement system. The $\dot{V}O_2$max and $\dot{V}O_2\theta$ are used as baseline markers of aerobic fitness as well as for objective indices of each individual's tailored aerobic exercise intervention.

Participants undergo further fitness assessments to determine baseline body composition (skinfolds), muscle strength by 1-repetition maximum (1-RM) for leg press and chest press, and muscle endurance (repetitions to failure using 85 % of their leg press and chest press 1-RM values). The 1-RM represents the maximum weight that can be lifted only once through a complete range of motion. The 1-RM and muscle endurance test data are used to establish baseline values of muscle strength and endurance in the study population and to help guide the development of the individual-tailored resistance training exercise program (NSCA 2010). This test is administered at baseline, week 5, and upon intervention termination. Data obtained from the body composition analysis enable tracking of changes in fat mass and, importantly, changes in the fat-free mass and skeletal muscle mass. These data are obtained using standard skinfold and girth measurement techniques (Lohman et al. 1991) and calculated using the Jackson and Pollack equation (Jackson and Pollock 1978) and MRI-validated equations, respectively (Lee et al. 2000).

A subset of consenting participants (15 from each condition) undergo two positron emission tomography (PET) sessions and two magnetic resonance imaging (MRI) sessions before commencement of the experimental condition and again after the 8 weeks of intervention. Brain region volumes will be determined for subcortical regions including the caudate, putamen, and nucleus accumbens. Dopamine D_2/D_3 receptor availability will be calculated as binding potential (BP_{ND}) using the D2/D3 ligand [(18)F]fallypride. The MRI scan will be used to confirm the absence of structural brain lesions and to aid in localization of volumes of interest.

59.2.6 Preliminary Results from the Exercise Study

Preliminary data from the study based on the 123 participants randomized by the time of this writing suggest that methamphetamine users can safely engage in exercise and can derive significant health benefits over a short period. Data from the first 29 study completers, randomized to either exercise (EX, $n = 15$) or health education (ED, $n = 14$), were analyzed to evaluate exercise-related physical outcomes, including aerobic fitness, body composition, and muscle strength. EX subjects significantly improved maximum oxygen uptake by 0.63 ± 0.22 L/min (21 %), leg press (LP) strength by 24.4 ± 5.6 kg (40 %), and chest press (CP) strength by 20.6 ± 5.7 kg (49 %). For EX subjects, LP and CP endurance improved by ten repetitions (120 %) and seven repetitions (96 %), respectively, and these changes were significantly greater than those seen in ED. Changes in body composition for EX subjects included significant reductions in body weight (average 1.7 ± 2.4 kg, 2 %), % relative body fat (2.8 ± 1.3 %, 15 %), and fat weight (2.8 ± 1.8 kg, 18 %). None of these variables changed significantly in participants receiving ED (Dolezal et al. 2013).

Preliminary data collected from 50 participants revealed an increase in heart rate variability in individuals who participated in the 8-week exercise program, but not in individuals randomized to the health education control group. Heart rate

variability reflects the ability of the autonomic nervous system (ANS) to adapt quickly to stress and changes in the environment and is diminished in stimulant users (Dolezal et al. 2013). In addition, preliminary results from the PET and MRI neuroimaging examination of a subset of participants suggest improvement in dopamine receptor binding after participation in the exercise program. Study participants in the EX condition demonstrated improvement in D2/D3 binding after 8 weeks of exercise according to analysis of PET (using ^{18}F-fallypride); matched outpatient controls did not demonstrate increased dopamine receptor binding after 4 weeks of abstinence only (Robertson et al. 2012).

59.3 Conclusion

Exercise may be a useful approach to aiding individuals with substance use disorders in their efforts to avoid relapse after they have achieved abstinence via treatment. The addition of a new, non-drug-related activity may provide a reinforcing alternative behavior that may be effective in facilitating abstinence by enhancing positive mood states via effects of exercise on the endogenous opioid system and potentiation of dopaminergic transmission (Meeusen 2005). Prior literature demonstrates that exercise can improve anxiety and depression, symptoms that are often associated with initial phases of abstinence after cessation of drug use. Such conditions predispose individuals to relapse and predict poorer treatment outcomes (e.g., Nunes and Levin 2004; Poling et al. 2007). Exercise also improves sleep (Youngstedt 2005) and performance on cognitive tasks, which may be impaired in chronic substance users. In light of the documented associations between stress, negative affect, and substance relapse in addicted populations (Breslin et al. 2002; Marlatt 1996), together with evidence demonstrating stress regulation deficits in substance users, the development of interventions to ameliorate symptoms of depression and anxiety and improve affect regulation may help to reduce relapse risk in this population. Relief of distressing psychological symptoms may serve to complement relapse prevention skills taught in common therapy approaches for substance users and to promote health and positive behavioral changes consistent with treatment goals.

opportunities for utilizing technology are being realized and evaluated in the field of addiction. This chapter reviews progress toward achieving the goals of an Addiction Treatment Technology Test that comprises development of technological applications that advance the addiction treatment delivery system by facilitating better access to care, improving efficiency of treatment delivery, enhancing treatment outcomes, proliferating the translation and implementation of evidence-based interventions, and fostering implementation of cost-effective care. The chapter provides an overview of the types of treatments that have been adapted for technology delivery, a review of studies that have evaluated computer- and Web-based programs, and examples of innovative technology-based applications designed to supplement or enhance traditional psychosocial therapies. We synthesize these findings into general conclusions recognizing the limitations of current knowledge. We additionally discuss the prospects for current use and future possibilities. Understanding optimal models of deployment of addiction treatment may be particularly important in light of evolving healthcare systems (such as those evolving under the Affordable Care Act in the USA). We view the future optimistically and anticipate that continued research exploring novel aspects of addiction and its treatment will reveal interventions that can be effectively deployed using innovative technological approaches. Such technologies can clearly extend the reach of our interventions, which will contribute to improving the lives of those suffering from problems related to addiction.

60.1 Introduction

In the landmark paper published in 1950, "Computing Machinery and Intelligence," Alan Turing asked whether technological devices could exhibit intelligence that was indistinguishable from a human (Turing 1950). According to Turing, the test of achieving this goal would consist of one person conversing putatively with another unseen person and stating that he or she was interacting with another human when, in fact, the other member of the dyad was a computer. This test, often referred to as the Turing test, set the stage for important developments in science (Crick and Koch 2003), new philosophical domains (Boden 1990), a vast stream of science fiction novels (e.g., Stephenson 1995), and continued efforts to develop more humanlike computers and computer programs (e.g., Kurzweil 2012).

Since Turing first framed this challenge, the revolution in information (computer and telecommunications) technology has broadened the scope of what technology can contribute to society far beyond simple machine replacing human considerations. Consider, for example, the amazing fact that there are approximately six billion mobile phone subscriptions worldwide (ITU 2011), while the world's population is a little over seven billion (US Census Bureau 2013). The market penetration of these and related information-based technologies – irrespective of whether they are mobile phones, smartphones, tablet computers, or wireless local areas networks – is rendering a world where information technologies are both more accessible and affordable. Not surprisingly, information technology is

Table 60.1 Potential benefits of various technology-delivered interventions

Facilitate **easier access** to treatment for patients
Allow patients **concurrent access** to treatment, not dependent on therapist availability
Reach patients with **difficulties accessing in-person treatment** (e.g., rural residents, lack of transportation, social anxiety)
Ease the burden associated with therapist training
Ensure integrity and fidelity of treatment delivery
Promote **easier and more rapid dissemination and adoption** of evidence-based treatments
Reduce cost of treatment delivery by reducing therapist time
Facilitate resource reallocation to:
Match treatment to patient need
Facilitate adoption of effective interventions like abstinence-based contingency management programs
Better allocate therapist time to cases or issues requiring specific skills (e.g., dual diagnosis, cognitive deficits, crisis intervention)
Enhance learning and practice of therapeutic information and skills via use of active learning technologies and modalities
Increase access to therapeutic materials (accessed anytime/anywhere through the Internet)
Prompt use of therapeutic skills between clinic visits and post treatment
Increase access to social support through various types of social media
Enhance motivation through scheduled messaging and other tools
Increase probability of active coping with triggers or lapses through automatic or scheduled prompting
Facilitate monitoring of target behavior necessary for implementation of Contingency Management

broadly influencing many aspects of modern life, including healthcare. For instance, a recent review of health information technology (Goldzweig et al. 2009) has identified two major trends. First, an increasing number of commercial electronic health records are available that could foster the continuity of care for patients. Second, and most relevant to this chapter, is the proliferation of patient-focused applications. Such applications include those that (a) are directly accessed by the patient with no professional input, (b) provide a medium to interact with a professional remotely (telephone, videoconferencing), and (c) provide systematic behavioral interventions with minimal to moderate oversight by health professionals. The authors note that these programs putatively "increase efficiency (text-message appointment reminders, Internet-based cognitive behavioral therapy), . . . improve quality (Web-based diabetes management), and . . . provide more accessible care for difficult-to-treat problems (alcohol abuse and eating disorder sites)" (p. 291). Also, they note that these programs often have not been evaluated. These advances are highly welcome, given that difficulty in accessing state-of-the-art or specialty care can result in failure to obtain effective treatment for disease processes while they are still tractable. Yet as important as this expansion in program availability is, equally important is the efficacy of these programs.

The use of technology has many potential benefits for the patient and the provider (see Table 60.1). For patients, treatment delivered via information technology could enhance access in at least three ways. First, technology-delivered treatment does not have limitations in the number of patients seen per unit of time. As such, technology-delivered

treatment can avoid the challenges of waiting lists and can be used by countless numbers of individuals concurrently. Second, technology-delivered treatment can be accessed where the patients live, even if they live in rural or other environments that make the commute to treatment difficult. Third, this type of treatment needs not be restricted to office hours or provider availability. Therefore, this treatment is available in principle all the time and potentially for greater durations of time. Another benefit for patients is that by not directly interacting with a human change agent, they may find it easier to address sensitive issues, such as addiction and other related topics like HIV status, as suggested by several studies (Kobak et al. 1996; Marsch and Bickel 2004).

For the provider of care, there are at least three benefits. First, technology-delivered treatment has the potential to dramatically lower costs; that is because even in hybrid models where therapists also participate and monitor the use of technology-based treatment, less therapist time would be required per case (e.g., Bickel et al. 2008; Budney et al. 2011). Second, treatments that are delivered via technology will be conducted with fidelity. One reason for the loss of efficacy of providing evidence-based treatments in many community-based systems of care is that the treatment is provided without being faithful to intended procedures, which, in turn, renders the treatment both not evidence based and less likely to be effective. Third, providing treatment via technologies permits new scientific information to be rapidly and continuously incorporated into contemporary treatment without the effort and expensive task of training therapists in each novel innovation. Collectively, these and other potential benefits provide a strong case for incorporating this novel approach into routine care.

Fortunately, opportunities for optimally utilizing technology have begun to be realized and evaluated in the field of addiction. Given this increased activity in the space of technology-delivered treatment for addiction, we can consider what might constitute a modern-day Turing test, perhaps labeled the Addiction Treatment Technology Test. This test would consist of the development of technological applications that advance the addiction treatment delivery system by facilitating better access to care, improving efficiency of treatment delivery from both the patient and provider perspective, enhancing treatment outcomes, proliferating the translation and implementation of evidence-based interventions, and fostering implementation of cost-effective care. We hope that the posing of an Addiction Treatment Technology Test, like the framing of the Turing test, will prompt the development and improvement of information technology as related to such therapeutic ends.

In this chapter, we review the current status and postulate future directions of technology-delivered treatments for substance use disorders. In doing so, we first briefly review and describe the types of treatments that have been adapted for technology-delivered treatment. Second, we concisely review those studies that have evaluated computer- and Web-based programs. Third, we provide examples of innovative technology-based applications designed to supplement or enhance traditional psychosocial therapies. Finally, we synthesize the findings into general conclusions with recognition of the limitations of current knowledge, prospects for current use, future possibilities, as well as assessment of the status of the field with respect to the Addiction Treatment Technology Test.

60.2 Technology Development, Testing, and Application

60.2.1 Psychosocial Interventions and Their Translation to Technology-Based Delivery

60.2.1.1 Evidence-Based Psychosocial Interventions

Behavioral or cognitive behavioral interventions are the most common types of psychosocial therapies used to treat substance use problems that have been subjected to empirical evaluation in controlled studies. They, in addition to a number of pharmacotherapies, are typically considered as representative of the majority of the evidence-based treatments for substance use disorders. No universal definition exists for what comprises a behavioral treatment or an evidence-based intervention. Thus, this chapter will focus on psychosocial therapies that have received empirical support in clinical trials, been translated for computer- or Web-based delivery, and then been tested in controlled studies.

Four psychosocial approaches meet these criteria. **Motivational enhancement therapies (MET)**, based on the principles of motivational interviewing, use a client-centered, semi-directive approach to facilitate active change by assisting individuals in exploring and resolving ambivalence about change, setting individualized goals, and promoting self-efficacy about their ability to change. MET provides a very brief (one to four sessions) course of treatment that involves a very specific, nonjudgmental counseling style designed to lead the individual to set clear goals and take action toward change without providing prescriptive instruction or skills training. MET has been studied as a stand-alone intervention and has also frequently been combined with other approaches, most frequently with CBT. **Cognitive behavioral therapies (CBT)** have received empirical support in multiple trials across most substance use disorders. Multiple names have been used to describe highly similar types of CBT, such as coping skills training, relapse prevention, and MATRIX. All these approaches include psychoeducation about a cognitive behavioral model of substance use, teaching and practice of skills related to achieving abstinence or reduction in use, general coping skills training to strengthen alternative coping behaviors to substance use and to support lifestyle modification, and teaching of skills to help maintain abstinence and deal with lapses or relapses.

The community reinforcement approach (CRA) focuses on behavioral analytic model of substance abuse, focusing on encouraging behavior that can increase nondrug sources of reinforcement (e.g., gainful employment, participation in prosocial recreational activities, improving relationship quality) that can compete with drug use in addition to providing many common elements of CBT. **Contingency management (CM)** interventions utilize the basic principles of behavior analysis to systematically use reward or punishment to obtain targeted changes in behavior. Incentive-based CM targeting drug or alcohol abstinence or other therapeutic behavior (e.g., treatment attendance, participation in recreation or vocational activities, medication compliance) has received much empirical support over the past 20 years.

60.2.1.2 Computer/Web Translations of Evidence-Based Interventions

CBT/CRA

One of the earliest demonstrations of translating a CBT-type intervention for computer delivery tested a smoking cessation program developed for and completely delivered on the CompuServe computer network (Schneider et al. 1990). Self-selected participants ($n = 1{,}158$) signed on to the program after viewing an advertisement. They then completed an online consent and were randomized to four conditions: (1) a computerized smoking cessation program plus a stop smoking online forum, (2) the program without the forum, (3) a sham program with the forum, and (4) a sham program without the forum. This program was available for 6 months, 24 h a day, and had a menu of "modules" that guided the participant to set a quit date and provided instructions for using CBT-type strategies for initiating and maintaining quit attempts, dealing with urges, and coping with common problems, and it also showed a progress graph. The forum provided a place where participants could view others' written comments related to quitting and the program. The active program engendered significantly better smoking abstinence rates at 1 and 3 months than the sham program, with no significant effect observed for the online forum. Of note, no difference between the active and sham conditions was observed at a 6-month follow-up, and, generally, the active use of the programs was considered poor (only 9 % used the program for more than 3 weeks).

A program to deliver an effective treatment for mild to moderate alcohol problems, Behavioral Self-Control Training (BSCT), using an early Windows application was evaluated in a trial using a randomized, wait-list control design (Hester and Delaney 1997). Twenty heavy drinkers received 8 weekly, computerized BSCT sessions at a treatment clinic immediately after a pretreatment assessment; the other 20 participants received the treatment after a 10-week waiting period. The program instructed the participant on goal setting, self-monitoring of drinking, drink refusal skills, evaluating and coping with triggers, functional analysis, and relapse prevention. Both the immediate and delayed treatment conditions resulted in significant reductions in drinking with pretreatment levels averaging 35.2 and 42.2 drinks per week, respectively, and 12-month follow-up levels averaging 14.5 and 23.0 drinks per week, respectively. Note that the delayed group's reduction was not initiated until they received BSCT.

More recently, a more complex software program, the Therapeutic Education System (TES), translated CRA and CBT components to an interactive, Web-based delivery platform and evaluated its initial efficacy in trial of opioid- and cocaine-dependent outpatients (Bickel et al. 2008). The TES includes over 65 interactive, multimedia modules focused on basic CBT skills, skills to increase psychosocial functioning (e.g., employment status, family/social relations, financial management, communication, decision-making, management of negative moods, time management, and recreational activities) and, skills to assist in the prevention of HIV, hepatitis, and sexually transmitted infections. TES uses a number of types of informational technology to assist in the teaching and practice of these skills.

Programming utilizes a fluency-based teaching approach to continually assess (via interactive quizzes) a participant's understanding of the material and adjusts the pace and level of repetition to promote learning of the information and mastery of the skills. An experiential learning environment is also created via the use of interactive videos of actors modeling various behaviors to promote learning through the modeling. Interactive exercises enhance learning (e.g., graphics and animation) and personalize content (e.g., personalized functional analysis). TES can also facilitate CM programs with a flexible system for tracking and reinforcing target behaviors (e.g., abstinence) and monitoring incentive earnings (see more on this in the CM section below). Last, TES can provide therapists access to summaries of patient TES activity and progress, facilitating integration of TES activities with counseling sessions.

The initial efficacy trial of TES-delivered CRA/CBT involved 135 opioid and cocaine dependent patients seeking treatment at a buprenorphine clinic (Bickel et al. 2008). Participants were randomized to one of the three 23-week programs: (1) TES sessions three times per week with biweekly counselor contact and incentives (CM) for abstinence, (2) therapist-delivered CRA/CBT with incentives for abstinence, or (3) standard drug counseling. Abstinence outcomes for cocaine and opioids did not differ between the TES-delivered and therapist-delivered conditions (mean weeks of continuous abstinence: 7.9 and 8.0, respectively), and both these CRA/CBT conditions were superior to standard counseling (4.7 mean weeks of abstinence). TES- and therapist-delivered CRA/CBT also engendered comparable outcomes on measures of treatment retention, Addiction Severity Index scores, and therapeutic alliance with their counselor. The TES reduced time spent with counselors by 80 %, with a concomitant estimated reduction in cost of over 70 %. Another trial evaluated this TES program for methadone-maintained patients in the context of better understanding the relationship between cognitive functioning and treatment outcome (Acosta et al. 2012). TES-delivered care enhanced abstinence outcomes for patients with lower cognitive functioning when it partially substituted for standard counseling, suggesting that the learning technologies and self-paced aspect of TES may help attenuate the usually observed negative impact of lower cognitive function on substance use treatment outcomes.

Another innovative, six-session program, computer-based training in CBT (called CBT4CBT) uses videotaped vignettes to illustrate the CBT skills taught within the program, focusing on (1) understanding and changing patterns of substance use, (2) coping with craving, (3) substance refusal skills, (4) problem-solving skills, (5) identifying and changing thoughts about substances, and (6) improving decision-making skills (Carroll et al. 2008). An initial randomized efficacy trial compared outcomes for 77 adults entering outpatient treatment for various types of substance dependence. Participants received an 8-week course of either weekly standard care (individual and group drug counseling) or standard care plus CBT4CBT delivered via a computer in a private office in the clinic. CBT4CBT participants achieved more drug abstinence than those in the standard-only condition (66 % vs. 47 % negative urine samples). Six-month follow-up assessments continued to show significantly better drug use outcomes for CBT4CBT, indicating

that the positive effects endured over time (Carroll et al. 2009). There were statistically significant increases in mean ratings of the quality of participants' coping responses for those assigned to CBT4CBT compared to treatment as usual, and these differences remained significant 3 months after treatment completion. Moreover, quality of coping responses mediated the effect of treatment on participants' duration of abstinence during the follow-up period (Kiluk et al. 2010). Last, the clinic cost of adding CBT4CBT approximates just $39 per participant (Olmstead et al. 2010).

MET and MET/CBT

Early efforts to translate the content and practice of MI or MET for delivery via computer were manifested in the Drinker's Check-Up (DCU), developed as both a Windows and Web-based application (Hester et al. 2005). This program integrates a computerized substance use-related assessment module with personalized feedback and decision-making modules. This self-directed program provides most of the active components of MET: provide personalized feedback, assessment of motivation to change, develop discrepancies using decisional balance exercises, negotiation and acceptance of personal goals, development of a change plan, and information on alternative sources of help related to goals. Sixty-one adults with mild to severe alcohol problems were randomly assigned to receive the one-session, 90-minute DCU immediately or after a delay of 1 month (wait-list control design). Participants completed the DCU on a computer at the clinic. Various quantity and frequency of drinking measures and alcohol problem score outcome showed significant reductions with large effect sizes in both groups at 1-month post DCU and at a 12-month follow-up.

A Web-based version of the DCU was evaluated in a large convenience sample of active duty military personnel (Pemberton et al. 2011). Compared with those randomized to a no-intervention control condition, DCU reduced quantity and frequency measures of drinking at a one-month follow-up, and this reduction was maintained at 6 months. A version of the DCU adapted for use with heavy drinking college students was evaluated in two studies: one trial used a similar wait-list control design, and one compared it to an assessment-only condition (Hester et al. 2012). Results from both studies supported the efficacy of the DCU for reducing heavy drinking in this at-risk population.

Another MET-based computerized intervention [Motivational Enhancement System (MES)] was designed for postpartum women who reported drug use before pregnancy (Ondersma et al. 2005). Similar to the DCU, the MES delivered three primary components during one session: (1) personalized feedback, (2) evaluation of pros and cons of drug use and related change, and (3) exploration of readiness to change and related goal setting. The initial evaluation of MES involved randomization of 30 women either to the MES or to an assessment-only control group. The assessments and MES were completed in their hospital rooms on laptops with an integrated touch screen. MES engendered greater levels of motivation to change drug use, but no differences between conditions were observed on self-reports of drug use. A subsequent study, using the same experimental design, extended the

initial findings with 107 postpartum women (Ondersma et al. 2007). More reduction in self-reported indicators of illicit drug use (nonsignificant effects, but mild to moderate effect sizes) was observed for the MES participants at a 4-month follow-up. The MES has been adapted and piloted for alcohol reduction in pregnant women (Tzilos et al. 2011). This same research group adapted the MES for smoking using the 5-As brief intervention model for smoking cessation and tested it in combination with a CM incentive program (also computer assisted: Ondersma et al. 2012). Findings from this study of 110 pregnant smokers suggested that the computerized 5-As program improved abstinence and increased discussion with a health professional about smoking cessation.

The TES program described above was modified to add an MET component similar to the DCU in an initial study of outpatient treatment for cannabis use disorders (Budney et al. 2011). Parallel, nine-session MET/CBT therapist- and computer-delivered programs were compared in an initial quasi-experimental trial in which both groups also received abstinence-based CM. The computerized condition also involved three brief supportive therapy sessions. Cannabis use and abstinence outcomes did not differ between conditions during treatment, and no differences were observed on other secondary outcomes such as problems related to marijuana, self-efficacy, or use of coping skills strategies. The mean amount of therapist time per case was approximately tenfold greater in the therapist-delivered condition, suggesting substantial cost savings associated with the computerized MET/CBT. Preliminary findings reported from a second trial replicated and extended these findings, suggesting that the computer- and therapist-delivered MET/CBT showed comparable outcomes both during treatment and throughout a 12-month follow-up period.

A research group from Australia developed a similar computer-delivered CBT-type program to treat cannabis or alcohol problems *and* depression (Kay-Lambkin et al. 2009, 2011). This eight-session program focuses on the usual CBT skills, using a motivational interviewing (MI) style to interact with the participant related to goal setting and change planning. It concurrently provides content underscoring the relationship between substance misuse and depressive symptoms. In a randomized trial, 97 adults with major depressive disorder and problems with alcohol or cannabis use first received a one-session, brief MI interview targeting depressive symptoms and substance misuse followed by one of three conditions: (1) no further treatment, (2) nine sessions of CBT/MI delivered by a psychologist, or (3) nine sessions of CBT/MI delivered by a computer with concomitant 10–15 check-in sessions with a therapist at the end of each session. Acceptability, treatment retention, and therapeutic alliance did not differ between the CBT/MI conditions. The CBT/MI conditions produced better cannabis, alcohol, and depression outcomes than the brief intervention alone. The computerized intervention showed the largest effects on substance use outcomes. The therapist-delivered CBT showed better short-term outcomes on depression, but similar outcomes to the computer condition at 12 months.

A larger replication trial compared the same two CBT/MI conditions and a ten-session supportive, person-centered therapy (PCT) (Kay-Lambkin et al. 2011).

Both CBT/MI conditions produced superior alcohol and depression outcomes compared with PCT, and computer-delivered CBT/MI was associated with greater reductions in alcohol than the therapist-delivered CBT/MI. No significant differences were observed for cannabis outcomes, although reductions favored the two CBT/MI conditions. Of note, the computerized intervention required only 16 min on average of therapist time compared with 57 min for therapist-delivered CBT/MI, and unlike the therapist-delivered model, it did not require a clinician trained to deliver CBT/MI.

60.2.1.3 Contingency Management (CM)

An Internet-based, automated program was developed to increase access to an abstinence-based reinforcement CM program for tobacco smoking cessation (Dallery and Glenn 2005). Instead of coming to a clinic to provide objective evidence of smoking abstinence via carbon monoxide breath sampling, a Web-based software program (i.e., Motiv8 Systems™) enables participants to video themselves at home self-administering a carbon monoxide (CO) test via a webcam. Twice per day the participant videos and records the result (i.e., the display on the CO device), which is then delivered to the "treatment team" via the Internet. The video clips shows the CO monitor being reset, the participant exhaling into the monitor, and the CO reading. Upon receipt of the evidence for smoking reduction or abstinence, Motiv8 electronically delivers incentive earnings via an email. A website that is always available to participants displays their incentive earnings and provides links to Internet vendors (e.g., Amazon) from which they can purchase items using their incentive earnings. Several small studies, mostly using within-subject reversal experimental designs, have demonstrated the efficacy of this CM intervention with adult heavy smokers (Dallery and Glenn 2005; Dallery et al. 2007), adolescent smokers (Reynolds et al. 2008), and adult smokers in a rural setting (Stoops et al. 2009). Creative, alternative models using Motiv8 have explored methods to increase the potential of dissemination. One study illustrated how collecting up-front deposits from participants that could be earned back by demonstrating successful tobacco abstinence may be an effective way to offset the cost of the incentive program (Dallery et al. 2008). Another study tested a model in which a small group of smokers work together through a Web-based discussion board integrated with the Motiv8 system (Meredith et al. 2011). Achievement of group smoking cessation goals is required to earn incentives. Ideally, participants provide encouragement and feedback to each other, which can putatively enhance the longer-term maintenance of the positive effects achieved with the abstinence incentives. This series of studies clearly demonstrates the potential efficacy of delivering a CM intervention remotely, which increases the possibilities for effective delivery of this potent intervention model.

The TES platform described earlier also includes programming to assist with the administration of CM programs (see Bickel et al. 2008; Budney et al. 2011). When participants log into their TES program, the initial screen displays their available incentive earnings, cumulative earnings, a graphic display of

cumulative drug testing results, and a place for messages (e.g., social reinforcement or encouragement). The data needed to provide this information can be either entered manually by staff or sent directly from a computer integrated with drug testing analyzers. Although this does not fully automate a CM program, it helps systematize delivery and eases staff burden associated with administering CM.

The Therapeutic Workplace (TWP) is a novel, employment-based treatment intervention that has considerable potential for promoting sustained abstinence from alcohol and drugs while simultaneously addressing some of their interrelated problems of poverty, unemployment, and homelessness. The TWP integrates an abstinence-based reinforcement (CM) program (using the Motiv8 platform) with a CM-based employment program. A sophisticated, Web-based training and employment system trains, hires, and pays participants to work each day, using behavior analytic principles of learning and reinforcement (Silverman et al. 2001, 2005). The application operates from a PC server that is networked with staff and participant workstations. TWP software establishes users with a bar-coded picture ID card. The program records each trainee's arrival time and determines whether the trainee arrived to work on time. On days in which urine collection is required, the software requests urinalysis results, and if required test results are negative, the software grants access to the workroom. Drug-positive results deny access. Computerized typing, keypad, and data entry training programs are delivered to all participants, who take placement tests to determine at which step to begin training. The software monitors performance and automatically moves participants through each step of the program as they meet the speed and accuracy requirements.

An Activities and Earnings section of the participant's home page displays earnings for the current day, account balance, and key parameters that can affect earnings. The Base Pay section shows the current day's base pay hourly rate, minutes spent out of the workroom, hours worked, hours that earned the base pay rate, and total base pay earnings. The Administrative section shows additional administrative pay. The Training section data on training activities, number of correct and incorrect responses, the amount earned completion bonuses (Bonus), and the earnings for each program. For participants who advance to paid operators, the Data Entry section includes information for all work batches completed on the current day including the pay rate, the number of errors and amount lost for each, and the total earnings. Each participant has an Inbox to receive files and messages. Purchases from earnings are requested and tracked through the software.

The TWP has demonstrated effectiveness across multiple controlled studies in diverse subpopulations of substance abusers including heroin- and cocaine-using treatment-resistant young mothers (Silverman et al. 2001, 2002) and unemployed injection drug and crack cocaine users (Donlin et al. 2008; DeFulio et al. 2009; Dunn et al. 2013), homeless alcohol dependent (Koffarnus et al. 2011), and opioid-dependent adults (Everly et al. 2011). Such strong empirical support for the TWP and its Web-based technology clearly demonstrates how a technology-based system can produce cost-effective, sustainable effects with great potential for dissemination.

60.2.2 Computerized Interventions for Related Problems

60.2.2.1 HIV Education

A prototype, text-only version of the TES programming was first employed in a study comparing computer-delivered and therapist-delivered HIV/AIDS education among 30 opioid-dependent, injection drug users (IDUs) receiving buprenorphine treatment (Marsch and Bickel 2004). The computer-assisted instruction incorporated fluency-building technology that requires a predetermined level of accuracy and speed in responding, which adjusts based on the participant's level of responding. The program also provides performance feedback and remediation for errors. Participants who received computer-based instruction learned significantly more information and retained significantly more of that information at a 3-month follow-up. Interestingly, the participants in the computer-based condition liked the teaching medium more, and more were interested in receiving additional HIV services than those in the therapist-delivered condition (80 % vs. 20 %).

A second randomized trial with adolescents enrolled in substance abuse treatment compared a one-session, small-group, infectious disease educator-delivered HIV and other sexually transmitted infection prevention program to an enhanced TES program added to the educator-delivered program (Marsch et al. 2011). Again, results indicated this Web-based program increased prevention knowledge and intentions to more carefully choose partners, and it was also perceived as more useful than the educator-delivered intervention provided alone. These findings are consistent with many other HIV and infectious disease prevention studies with other populations, indicating that computer-based or Web-based education comprises an effective method that is attractive to at-risk populations and cost-effective (Noar et al. 2011). Some evidence suggests that technology-delivered compared with human-delivered assessment and instruction can result in more accurate reporting of the sensitive information encompassing risk behavior and more engagement from the patient as it may be perceived as less threatening (Des Jarlais et al. 1999; Kurth et al. 2004).

60.2.3 Innovative Technologies to Enhance Effective Psychosocial Treatments

Exciting and innovative applications of diverse technological devices and platforms to supplement or deliver specific components of psychosocial interventions are either being contemplated for development and testing or are active in ongoing research projects. Below, we provide brief examples of applications that may become available in the near future.

First, programmed Short Message Systems (texting) could facilitate the use of CBT/CRA skills (Whittaker et al. 2012). A few of many possibilities for this include prompting relapse prevention activities at certain times of the day, delivering educational messages that enhance learning of skills, providing motivational messages that maintain efforts directed toward recovery activities, and offering

regular reminders of specific goals and planned actions. Providers and patients could together develop and program messages to be sent at specific times and as often as deemed useful. With cell phone ownership having become the norm, almost all patients could benefit from this type of intervention if it proves efficacious in supplementing CBT/CRA.

Second, smartphones (i.e., cell phones with computing ability), Internet connectivity, and in some cases global position systems (GPS), offer even more possibilities than utilization of SMS (Gustafson et al. 2011; Marsch 2012). Access to the Internet and the ability to run software applications (Apps) translate into capability for delivering the same types of psychosocial therapy programs described above for the personal computer, but with the added benefit of access anywhere at anytime. Capitalizing on the mobile dimension of smartphones and their GPS capability, researchers have begun to develop and test "warning" systems that prompt coping responses from the user when she or he goes somewhere designated as a high-risk environment. Similarly, GPS tracking could be used to increase monitoring capabilities such that, for example, parents could increase awareness of their teens' whereabouts, a common goal in family-based therapies or prevention programs. Another example under development is smartphone integration with wireless devices that measure physiological responses (e.g., indicators of stress or craving). Detection of specific responses would trigger an automatic communication with the phone that would prompt or deliver a therapeutic coping intervention (e.g., Boyer et al. 2010). These types of innovative uses of technology to enhance CBT/CRA interventions are only just beginning to be realized and tested.

Virtual reality (VR), i.e., computer-simulated experiences that utilize visual, auditory, tactile, or olfactory sensory features to facilitate active participation in simulated environments, offers another exciting possible method for augmenting the learning of behavioral coping responses to high-risk situations. VR can simulate realistic substance use environments and provide opportunities to practice skills consistent with successfully negotiating the risk situations without substance (Bordnick et al. 2011). Exposure therapies for specific phobias and posttraumatic stress disorder have effectively utilized VR to enhance outcomes (e.g., Gerardi et al. 2010; Meyerbroker and Emmelkamp 2010). Similar projects are under way in the substance abuse field that use VR to improve cue exposure therapies targeting reduction in cravings associated with specific environmental situations.

Last, video game platforms may offer another promising paradigm for supplementing CBT/CRA interventions (e.g., Raiff et al. 2012). Such games could provide a medium that includes modeling of coping skills via culture- and gender-relevant characters and environments and reinforcement of mastery and effective use of coping skills. The player would be faced with making decisions in various substance use or related situations that lead to "realistic" consequences. Advancing to higher levels or winning the game would require effective decision making and use of coping skills associated with refusal to use or responsible use of substances. Health behavior video games, including some that target prevention of substance abuse, are already a reality (Marsch et al. 2007a, b; Schinke et al. 2009).

60.2.3.1 Targeting Cognitive/Executive Function

Evidence has accumulated indicating that those with various substance use disorders compared with those without these problems, engage in more impulsive decision making whereby their choice behavior reflects desire for smaller more immediate reinforcers over larger delayed reinforcers (Bickel et al. 2011a). This putatively reflects the impulsive system of the brain dominating the executive system, a notion that has received increasing scientific support as an important component of the addiction process (Bechara 2005; Bickel et al. 2012). This theory has guided the development of neurocognitive remediation or executive function therapy that targets strengthening of executive function to increase self-control and reduce impulsive decision making. Computer-delivered programs offer such training through repeated reinforced practice of cognitive exercises requiring attentional focus, visual-spatial and verbal memory, abstract reasoning, and problem-solving skills. Initial studies demonstrated that cognitively impaired substance abusers showed improvements in cognitive performance and remained in treatment longer following such remediation training (Grohman and Fals-Stewart 2003; Grohman et al. 2006). A preliminary study with stimulant-dependent adults has demonstrated positive changes in delay discounting, a marker of impulsive decision making, following training focused on enhancing working memory (Bickel et al. 2011b). A second study of substance abuse patients showed improvements in measures of working memory, response inhibition, and decision making following completion of a systematic executive function training program (Alfonso et al. 2011). A third research report showed reductions in alcohol consumption among heavy drinkers when working memory was the only intervention (Houben et al. 2011). Another potential mechanism by which cognitive remediation may positively impact treatment outcomes is through improvement of the efficiency of cognitive behavioral therapies that require individuals to learn, remember, and apply specific skills in diverse situations (Pedrero-Perez et al. 2011).

60.2.3.2 Internet-Based Social Support

The ubiquitous ownership of cell phones, smartphones, and computers has made it possible to obtain social support for recovery from addictions through multiple mediums. Digital technology can provide almost immediate access to support, and provides and may increase utilization of support networks among those less likely to seek such assistance (e.g., socially anxious individuals, those living in remote geographic areas or without transportation). Applications might either enhance or substitute for traditional self-help groups or group therapies. Many self-help groups have now established live text and voice chat meetings through the Internet available most anytime. Such technology also allows individual or group interventions for substance use to include digital support networks through popular social networks (e.g., Facebook) or by establishing a unique network. One can envision many alternative therapeutic uses for such digital networks. They could greatly expand access to assistance with handling cravings or lapses, to opportunities to practice therapeutic skills, or to obtain ideas and information related to prosocial activities such as job opportunities or recreational events. Similarly, for those

whose family members are struggling with addiction, these networks would increase access to support, guidance, and skills training related to coping effectively with their child or spouse.

60.2.4 International Considerations

Although much of the research with technology-based computerized therapies for substance use disorders described above was conducted in the USA, the computer-delivered CBT-based intervention for comorbid cannabis and alcohol problems and depression was developed and evaluated by Kay-Lambkin and colleagues in Australia (Kay-Lambkin et al. 2009, 2011). We know of several additional ongoing evaluations of computerized interventions being conducted around the world. These include a Web-based self-help intervention, grounded in CBT and MET approaches to targeting cocaine use (called "Snow Control"), which is being studied in a randomized clinical trial in Switzerland (Schaub et al. 2011). Additionally, a study conducted in Amsterdam compared an online CBT/MET self-directed intervention targeting problematic alcohol use to an online CBT/MET intervention delivered via asynchronous chat with a therapist. Both showed greater effects on alcohol use than a wait-list control condition and generally showed comparable effects to one another (Blankers et al. 2011).

Perhaps the most frequent approach to leveraging technology in the delivery of health behavior interventions globally has been to deliver them via mobile devices. Due to increased globalization and the opening of economies, technology-based communication structures in many low- to middle-income countries have become increasingly strong in recent years. Over 90 % of individuals worldwide subscribe to mobile phone services, translating to nearly six billion worldwide mobile phone subscriptions (Union 2012). This rapid growth in access to mobile technologies has significant promise for bridging the digital information divide and reducing healthcare disparities that exist in many systems of care, including among vulnerable and underserved populations (Gibbons et al. 2011).

Mobile health approaches have been particularly helpful in settings that lack sufficient healthcare workers and financial resources and have high disease burden (Kayingo 2012). Although mobile devices have been applied to substance use disorders only to a limited extent in most countries, they have been applied extensively to the prevention and treatment of HIV, including among substance-abusing populations. Globally, much of this work has been conducted in India, South Africa, and Kenya (Deglise et al. 2012), and a number of mobile tools have been shown to be promising as part of HIV prevention interventions and in improving adherence to HIV treatment and viral load suppression among HIV-positive persons (Swendeman and Rotheram-Borus 2010; Horvath et al. 2012). Overall, the state of research in this arena suggests that mobile therapeutic tools offer promise to have a substantive impact on global healthcare broadly and may be similarly promising in targeting prevention, treatment, and recovery support for substance use disorders.

60.3 Conclusion

The brief review included in this chapter illustrates how the exploration of technology-delivered or technology-assisted therapies for substance use problems has been developing for some time, shows great promise, and is gathering momentum. The accumulation of data and knowledge has progressed to the extent that a "review of reviews" recently appeared in the literature and identified 9 meta-analytic and 13 qualitative reviews of technology-based interventions for substance use disorders (Litvin et al. 2013). This review concluded that "technology-based interventions for substance use problems are efficacious, but effect sizes are generally small to medium at best and treatment mechanisms remain largely unknown"; a conclusion that most would agree closely parallels the status of the majority of traditional therapist-delivered interventions.

Although research to date is promising, we have a long way to go to pass our Addiction Treatment Technology Test. Multiple studies have demonstrated that treatment models assisted by computer- or Web-based delivery of evidenced-based interventions (MET, CBT, CRA, CM) have the potential to improve access to care, reduce costs, and improve efficiency of treatment delivery. However, in order to advance the potential public health impact of this research, several areas warrant further investigation. Among these is the need for an expansion of research that embraces an implementation science framework in evaluating models for best integrating evidence-based technology-based innovations in diverse community settings, bringing value to all relevant stakeholders in a care setting, and promoting their sustained use. These models may include evaluation of technology-based therapeutic tools as supplements to standard care models, as tools that can replace a portion of "treatment as usual," or as stand-alone tools accessed outside of care settings. Results of such research offer the potential to generate knowledge regarding models for accelerating the process from research discovery in this arena to public health benefit.

A related area of inquiry that could greatly benefit the field is an expanded focus on economic analyses that parallel analyses of clinical effectiveness. An understanding of the cost-effectiveness and cost-benefit of technology-based interventions, and the conditions and deployment models under which they do/do not demonstrate cost-effectiveness and cost-benefit, is critical in efforts to scale up their deployment. Understanding optimal models of deployment may be particularly important in light of evolving healthcare systems (such as those evolving under the Affordable Care Act in the USA).

Further, another important area of future efforts is an increased research focus on the mechanisms of behavior change from technology-based interventions compared to traditionally delivered approaches. Given their "on-demand" availability and opportunities for personalization, technology-based interventions may impact the rate and nature by which health behavior change occurs. An increased understanding of the active ingredients and mediators of outcome from technology-based therapeutic tools can greatly enhance future efforts to optimize technology development efforts. This understanding could additionally aid the research field of

technology-based interventions to progress beyond direct adaptations of existing face-to-face interventions to better harness the dynamic potential of technology in collecting data about individuals in unprecedented ways and in real-time and in intervening at the exact moments when individuals may be maximally motivated and receptive.

The future of technology-delivered treatment in the addictions field will surely be substantial and important – a true advance. But we must keep that advance in its appropriate place within the field of addiction. As we noted above, to date, these technology-delivered treatments largely produce the same level of efficacy as traditional person-delivered treatments that they are based upon. From this, we can consider at least three possibilities. First, we could make a pessimistic assumption that treatment, regardless of delivery method, will always have small to medium effects; that is, we have wrought as much efficacy as can be wrought given this disorder. Second, we could offer an optimistic assumption that combining future innovative technological applications with existing treatments will produce more robust outcomes for more patients. And last, we could assume that we have not yet discovered all the elements or aspects of addiction that render it robust. We view the future optimistically and anticipate that continued research exploring novel and different aspects of addiction and its treatment will reveal novel interventions and will demonstrate that we can obtain a large effect size. Whatever those novel treatments may consist of, we think that their use will be incorporated into technological approaches being developed today. These technologies can clearly extend the reach of our interventions, which will contribute to improving the lives of those suffering from problems related to addiction.

Cultural Adaptation of Empirically-Validated Therapies for Treating Drug Dependence

61

Felipe González Castro and Manuel Barrera Jr.

Contents

Abstract

Efficacious drug abuse treatments (empirically validated treatments – EVTs) are those that have been designed by applying scientific theory and principles of effective drug abuse treatment. These EVTs are defined as efficacious when tested in randomized controlled trials that demonstrate that they "work" in promoting abstinence from drug use, in avoiding relapse, and in attaining targeted treatment outcomes. In principle, efficacious treatments should be implemented with fidelity in the delivery of the core elements necessary for

This chapter is based in part on presentations at the 2013 National Multicultural Symposium – Psychologists in Action: Implementing Best Practices to Reduce Health Disparities, January 18, 2013, Houston, TX and at the 34th Annual Meeting of the Society for Behavioral Medicine: Technology – The Excitement and the Evidence, March 20, 2013, San Francisco, CA.

effective treatment. By contrast, the need for local adaptations of these EVTs has emerged based on the considerable diversity in client needs that exists worldwide, given considerable variations in local cultural environments that exist within diverse communities worldwide. Issues of local adaptation are magnified when an EVT that is designed in one nation, such as the United States, is "exported" for use in another nation. The present chapter examines and analyzes issues in the local adaptation of EVTs to render them culturally relevant for treating members of local subcultural groups, while also maintaining the core elements that from scientific research must be delivered correctly to promote effective recovery from drug abuse and addiction. The Matrix Model is presented as an exemplar of an EVT that has been adapted for delivery within diverse communities worldwide. Also, stage models of common adaptation approaches and practices are examined. Finally, some practical approaches and recommendations are presented for conducting a local adaptation of an EVT within various nations or cultural communities.

61.1 Introduction

61.1.1 The Case for the Cultural Adaptation of Drug Abuse Treatments

Interest in the *adaptation* of model treatments – *evidence-based interventions* (EBIs) and *empirically validated therapies* (EVTs) – has increased in recent years (Carroll et al. 2011; Castro et al. 2010). This chapter examines issues, perspectives, and approaches in the cultural adaptation of original EBIs or EVTs, respectively, as examined within two research areas: (a) prevention interventions with adolescents and (b) drug abuse treatments with young adult and middle-aged clients.

Within the past decade, the strategy of adapting a validated model treatment, as opposed to its delivery with fidelity and thus without adjustment (Elliot and Mihalic 2004), has emerged as a significant and controversial approach. Some research investigators have argued that evidence-based interventions (EBIs) and empirically validated treatments (EVTs) (Carroll et al. 2011) should be disseminated widely to diverse client groups, and when implemented with high fidelity should work as designed, thus obviating any need for adaptation. By contrast, evidence from a study of school-based drug abuse prevention curricula (Ringwald et al. 2004) reveals that classroom teachers who administered manualized model prevention interventions frequently modified the original intervention because they saw significant limitations in the original model intervention. These teachers generally sought to modify the original EBI to make it more culturally relevant for their adolescent students. Similarly, among drug abuse counselors and therapists, fidelity in the delivery of original and validated EVTs has also been remarkably low (Carroll et al. 2011).

Regarding these efforts at local adaptation, teachers from schools populated by high percentages of racial/ethnic minority students were most active in making relevant adaptations. These adaptations focused on three major content areas: (a) adding content on preventing youth violence, (b) accommodating limited

English proficiency students, and (c) addressing issues relevant for racial and ethnic minority students (Ringwald et al. 2004). Although this example relates to substance use prevention interventions for adolescents within the United States, these adaptation issues parallel similar concerns in the adaptation of drug abuse treatments within the United States, as administered to underserved clients from major racial/ethnic minority populations – African Americans, Hispanics/Latinos, Asian Americans, and Native Americans.

61.1.2 Issues Involving Fidelity and Adaptation

Fidelity refers to the extent to which a treatment is delivered as originally developed and prescribed by the creators of that treatment and as implemented by the treatment's manualized procedures which have been validated within one or more randomized controlled trials (Flay et al. 2005). By contrast, the *adaptation* of a model treatment refers to modifications in one or more treatment components or activities with the aim of increasing treatment *relevance* and *effectiveness* for a specific subcultural group of clients (Castro et al. 2004). Such modifications often focus on treatment contents, activities, or forms of implementation as these neglect or conflict with the needs of a subcultural group of clients. Ideally, such adaptations will increase client engagement as well as the magnitude of treatment effects and thus the treatment's overall efficacy level.

In discussions on the relative merits of fidelity and adaptation, some research investigators have argued that original evidence-based treatment should *never* be adapted. They have argued that

> The Gold Standard is widespread adoption of model programs, implemented with fidelity, and sustained by routine funding sources within the community. The call for a negotiated balance and fidelity/adaptation has the potential for lowering this standard, encouraging and empowering local implementers to make questionable adaptations, and undermining the research community's commitment to fidelity. It could easily backfire and undermine public confidence and scientific claims that we have programs that work, if these programs prove effective when we take them to scale. (Elliot and Mihalic 2004, pp. 51–52)

In principle, each EBI and EVT should be broadly disseminated, thus making that treatment readily available to many communities and consumers. However, in practice, such broad-based dissemination and implementation has not been fully realized (Carroll et al. 2011). A general challenge involves the distinction between *adopting* an intervention or treatment "as is" and *adapting* that intervention with strategic adjustments to make it truly relevant and responsive to the needs of a local community and its consumers. Unfortunately, if a treatment lacks genuine *relevance* and *appeal* for local consumers, despite its efficacy rating, if local consumers dislike it and drop out, that treatment ultimately produces no benefits for these local consumers.

In the decade since these fidelity-adaptation controversies emerged, efforts to adapt model treatments have become "the rule rather than the exception" (Ringwald et al. 2004). One of several reasons for this may be that there exists no

"ideal" or entirely "universal" model treatment, a "one-size-fits-all," intervention that works well for everyone. Public health interventions that exhibit "universal" features typically consist of one-shot interventions, such as immunizations or seat belt use campaigns. By contrast, it becomes progressively more difficult to produce a "universal" and "one-size-fits-all" intervention, as an intervention increases in complexity, requiring several steps and a prolonged time frame to complete, e.g., an obesity reduction intervention. This difficulty also increases as a community exhibits greater diversity in its consumer populations and in the complexity of community needs and preferences.

The challenge of developing an entirely "universal" intervention increases exponentially when considering the expansive diversity of cultures that exist worldwide. For example, how can a single English-language drug abuse model treatment developed in the United States be implemented with complete fidelity, i.e., exactly as originally created and manualized within diverse countries such as Mexico, Spain, China, India, and Thailand? A more realistic scenario is that some form of *local adaptation* will be necessary, at very least involving a well-crafted linguistic translation, although it is likely that other cultural modifications will also be necessary.

61.1.2.1 Linguistic Translation of a Model Treatment

At the very least, *linguistic adaptations* are necessary when a model treatment originally developed in one language would be administered to people who speak a different language (Castro et al. 2004). By contrast, if a model treatment is grounded in scientifically established principles of human thought and behavior (Bandura 1986), these principles, as incorporated into an effective treatment, would be expected to generalize to a certain extent across many populations. In practice, the actual level of adaptation needed will depend on the extent of client-treatment non-fit as this treatment is administered initially within a new community setting or with a new cultural group.

61.1.2.2 Concerns over "Misadaptation"

Careful attention is needed to avoid making adaptation changes that actually lower the scientific standards of a model treatment, i.e., a misadaptation. "Misadaptation" occurs when making "a haphazard or inappropriate change in the prescribed procedures of a manualized model treatment" (Castro et al. 2010, p. 221). This can occur when program staff make arbitrary changes in a manualized model treatment, without a full understanding of that model treatment's core components and prescribed activities, as created by the developers of that model treatment. Clearly, misadaptation must be avoided, because it can erode treatment efficacy.

61.1.2.3 Issues from the Evidence-Based Movement

The *evidence-based movement* has emphasized the importance of creating and delivering empirically validated interventions and treatments (Norcross et al. 2006). Establishing that a treatment "works" is based on evidence from

clinical "best practices" and, better yet, from "empirical scientific research" regarding the treatment's efficacy or effectiveness (Flay et al. 2005), as established from one or more randomized controlled trials.

61.1.2.4 Concerns Expressed by Providers

Despite this scientific emphasis on evidence-based approaches, in the past, many treatment providers felt constrained by working with what they perceived to be overly prescriptive, restrictive, or culturally insensitive manualized treatments that they also judged to be unresponsive to the needs of racial/ethnic and other minority clients (Sue and Zane 2006). This dissatisfaction prompted ad hoc efforts by some service providers to modify or otherwise "informally adapt" a prescribed model treatment to address their clients' needs. As noted, such changes have been regarded by some treatment developers as entirely inappropriate and likely to erode the intervention's effectiveness (Elliott and Mihalic 2004).

61.1.2.5 Lessons Learned from the Clinical Trials Network

Regarding efficacious outcomes from drug abuse treatments, Carroll and collaborators summarized the lessons learned from 10 years of research from the NIDA Clinical Trials Network (Carroll et al. 2011). Regarding emergent issues that affect empirically validated therapies (EVTs) for drug abuse treatment, these investigators noted that (a) retention remains a major problem in substance abuse treatment and that promoting treatment retention is critical to treatment success; (b) EVTs are still not broadly implemented in practice and when implemented are often delivered with low fidelity; and (c) at the agency level, effort, support, and commitment are essential factors for adopting and sustaining an EVT given the costs of implementation, staff training, and supervision (Carroll et al. 2011). Given the importance of client retention, along with the problem of low utilization of EVTs, these issues should be addressed in the design of future EVTs to improve client retention by enhancing the treatment's cultural relevance as this can increase client engagement.

61.1.2.6 Cultural Considerations in Drug Abuse Treatment

In 1999, the National Institute on Drug Abuse published *NIDA's 13 Principles of Drug Addiction Treatment* (National Institute on Drug Abuse 1999). These principles are that (a) no single treatment is appropriate for all individuals; (b) treatment needs to be readily available, whereby delays in treatment availability can yield a loss of clients; (c) effective treatment attends to multiple needs, not just to drug use, and this includes attending to medical, psychological, social, vocational, legal, and other needs; (d) a continuous assessment and modification of a client's treatment plan is necessary to monitor changing needs and to respond accordingly; (e) remaining in treatment for an adequate period of time is crucial to treatment success – typically clients should remain in treatment for at least 3 months; (f) counseling and behavioral therapies are crucial components of treatment, as these can address treatment motivation, skill building, and problem solving; (g) medications are important components of treatment as they can reduce cravings, and this includes psychotropic medications for clients who need these;

(h) integrated treatment is needed for clients with psychiatric comorbidity; (i) medical detox is an important first step in treatment; and (j) treatment need not be voluntary to be effective, and engagement in such compulsory treatment is facilitated by familial, employment, legal, and other sanctions.

It is noteworthy that none of these 13 principles directly address issues of culture in the treatment of drug-dependent clients (Castro et al. 2007). A few years earlier, issues of culture and ethnicity were recognized as important for the complete and culturally sensitive treatment of many clients and primarily for those from racial/ethnic backgrounds (Ja and Aoki 1993; Terrell 1993). Terrell (1993) discussed several strategies for the design and implementation of efficacious alcohol and drug abuse treatments for racial/ethnic minority clients. These strategies include (a) assessing the client's immigration and acculturation experiences including their *acculturation stress*, as factors that can erode the protective effects of the client's traditional or native culture; (b) assessing a client's experiences with *discrimination*; and (c) developing *culturally responsive* treatment interventions (Terrell 1993). Today, the factors of race, ethnicity, gender, sexual orientation, and other cultural factors are considered important for a more complete treatment of diverse drug-dependent clients (Castro and Hernandez-Alarcon 2002; Castro et al. 2007).

Beyond these cultural issues, these 13 principles may be regarded as elements of drug abuse treatment that can operate as core treatment components. The multiplicity of these NIDA principles also underscores the complexities inherent in the delivery of a comprehensive drug abuse treatment. Such treatment also includes the need for ongoing monitoring of client progress and the need to make relevant adjustments that will optimize the treatment by tailoring it to the client's needs (Bernal et al. 2009).

61.2 Intervention Exemplar, Perspectives on Evidence, and International Considerations

61.2.1 Description of Approach

61.2.1.1 Exemplar of a Tested and Effective Drug Abuse Treatment Program

The Matrix Model is a manualized multicomponent model treatment. In its basic form, the Matrix Model consists of a 16-week program delivered in three sessions per week for a total of 48 sessions (Obert et al. 2000). The Matrix Model treatment includes (a) 12 family therapy sessions, (b) four social support group sessions, (c) four individual treatment sessions, and (d) a weekly breath alcohol testing and urine testing protocol. This treatment is nonjudgmental and nonconfrontational and includes positive reinforcement from therapists and peers for appropriate behavior change (Hillhouse et al. 2007; Rawson et al. 1995).

The Matrix Model was developed from the integration of empirically based interventions and "grassroots" clinical experiences (Rawson et. al. 1995).

This manualized treatment includes patient handouts and a patient workbook that introduce evidence-based recovery activities as developed from the integration of five theory-based treatment approaches: cognitive behavioral therapy (CBT), 12-step facilitation, motivational interviewing, contingency management, and family therapy (Obert et al. 2000). As developed from these five treatment approaches, the formal core components of the Matrix Model consist of (a) early recovery phase treatment activities, (b) relapse prevention, (c) social support groups, (d) family and conjoint sessions, (e) individual sessions, (f) urine testing, (g) relapse analysis, and (h) family education groups. The Matrix Model is guided by eight treatment principles which are conveyed to clients: (a) create explicit structure and expectations; (b) establish positive, collaborative relationship with the client; (c) teach information and cognitive behavioral concepts; (d) reinforce positive behavior change; (e) provide corrective feedback when necessary; (f) educate family regarding stimulant/drug abuse recovery; (g) introduce and encourage self-participation; and (h) use urinalysis to monitor drug use (Rawson et. al. 1995; J. Obert, 2 Apr 2013, personal communication).

61.2.1.2 Cultural Adaptation of the Matrix Modal

In principle, the cultural adaptation of the Matrix Model or any EVT begins by identifying problems in treatment implementation and also by identifying sources of client-treatment mismatches (non-fit) (Castro et al. 2004). This is followed by making strategic adaptations in treatment content, activities, or forms of delivery, as recommended by consumer feedback from key informants and stakeholders and as reviewed by a Cultural Advisory Committee. These adaptations would be accomplished (a) while seeking to maintain identified core treatment components (essential program activities); (b) increasing the cultural relevance of the treatment for local consumers (clients and subcultural groups); (c) increasing client motivation, engagement, and treatment involvement; (d) sustaining the efficacy of the treatment effect (i.e., maintaining the "effect size" on targeted outcomes); and (e) ideally increasing the treatment's "effect size" (Castro et al. 2010), that is, producing a greater and clinically significant magnitude of improvement on targeted outcome variables.

Moreover, effective cultural adaptation can ideally advance "beyond the black box," (Simpson 2004), meaning that these adaptations would introduce (a) a greater understanding of how cognitive behavioral theory or the treatment's logic model produces therapeutic improvements on targeted outcome variables and (b) greater knowledge of how cultural treatment factors improve the treatment's relevance for addressing client needs while also increasing the treatment's effect size.

Reducing Client-Treatment Mismatches

Conceptually, the greater the gap or *mismatch* between the core concepts and activities of the original model treatment, and the needs and preferences of a targeted group of clients, the greater the adaptive changes necessary to fit the needs of a targeted group of clients. For implementation in international venues, a relevant question is, "In what ways should an original EVT developed for

American drug-dependent clients be modified for application with specific groups of clients from another country?" In this regard, within the United States, certain "mainstream treatments" that were designed for middle-class White American clients were shown to be insensitive to the needs of many low-income African American and other racial/ethnic minority clients (Castro and Hernandez-Alarcon 2002; Sue and Zane 2006). This observation led to calls for *cultural sensitivity* in treatment development (Sue and Sue 1999) and also calls for greater *cultural competence* (Orlandi et al. 1992; Schwartz et al. 2010) among the counselors or therapists who would deliver these treatments. Such observations ultimately prompted the development of stage models for adapting such model treatments to better fit the needs of specific *subcultural groups* of clients (Barrera et al. 2011, 2013).

Need for Gender Sensitivity

As one historical example, in the past drug abuse treatments emerged primarily as treatments for drug-dependent male clients, inadvertently exhibiting insensitivity to the needs of many female drug-dependent clients (Greenfield et al. 2007). Such treatments did little to address certain critical issues that affect drug-dependent women, such as their victimization from domestic violence and abuse imposed by their partners, some of whom were also drug addicts. Thus, gender-sensitive programs were developed for application with drug-dependent women. Unfortunately, these treatments, when compared with conventional mixed-gender treatments, have *not* been shown via controlled randomized trials to be more effective in promoting recovery among drug-dependent women. Nonetheless, these gender-sensitive treatments have shown greater efficacy in addressing certain problems that are common among substance-abusing women (Greenfield et al. 2007).

61.2.2 Evidence to Support the Approach

61.2.2.1 Evidence Regarding the Effects of Core Components

In principle, intervention activities and procedures that constitute a treatment's "core components" are based on theory and on clinical procedures shown empirically to produce desired therapeutic effects. For example, and in principle, a treatment that utilizes principles from social cognitive theory (Bandura 1986) and cognitive behavioral procedures, e.g., contingency management, may exhibit near-universal effects on human behavior and thus would be generally applicable for treating clients from many parts of the world.

Given that the Matrix Model is based on social cognitive theory, as well as on principles from cognitive behavioral therapy (CBT) and family systems therapies, its major core components are (a) family sessions, (b) enhancing social supports, (c) individual treatment sessions, and (d) breathalyzer and urine testing. Thus, and in principle, within an adapted version of this model treatment, none of these core treatment components should be eliminated or modified. For example, the Matrix Model treatment might lose some of its treatment effectiveness if breathalyzer and urine testing were eliminated within a culturally adapted version of the original Matrix Model.

61.2.2.2 Evidence on the Need for Assessing Cultural Factors

A study in Belgium illustrates several core issues, as examined in an international setting, regarding the role of cultural factors in drug abuse treatment. That study conducted a qualitative analysis using in-depth interviews with drug treatment center staff and clients (Vandevelde et al. 2003). First, these investigators reported on problems emerging from the existing treatment system's client database, which did not collect data to distinguish the construct of "ethnicity" from "nationality." This omission led to a lack of information regarding ethnic issues, as these were conflated with very different issues that involve clients' nationality. From major ethnic themes involving ethnicity that emerged from these interviews, ethnic clients complained of a lack of cultural responsiveness in the drug abuse treatment that they received. Another theme involved cultural barriers in communication with the therapist. These barriers included problems in clients' ability to express themselves effectively in their own language, and this limitation became detrimental to progress in treatment. Other barriers included clients' perceptions that their own treatment needs conflicted with their therapist's Westernized world views. In summary, ethnic clients complained that the drug abuse treatment which they received lacked cultural relevance and responsiveness to their treatment needs.

Ironically, most of these clients and therapists recommended that developing a separate ethnic-specific treatment program would *not* be useful. Within the context of these complaints, these clients recommended that the conventional treatment program be retained yet also supplemented with attention to cultural factors and issues (Vandevelde et al. 2003). This outcome underscores the need to base drug abuse treatment on established scientific principles of recovery from addiction while also attending to issues of culture and local client needs. This case highlights the importance of integrating cultural sensitivity within an original drug treatment program, while also highlighting the importance of training culturally competent therapists. Such cultural issues can be addressed without replacing the treatment in its entirety, by adding one or more modules to the original treatment, to address specific cultural issues.

61.2.2.3 Evidence Regarding Engagement and Retention

As noted previously, in drug abuse treatment, several challenges exist regarding client engagement and retention (Carroll et al. 2011). One approach to increase treatment engagement and retention among youth and families is to reduce the total number of program sessions, e.g., from 12 to 8 sessions. However, some evidence indicates that a reduction in sessions can diminish program efficacy (Kumpfer et al. 2002), as clients may retain less essential knowledge and skills from this reduction in sessions.

Indices of Treatment Outcome

Based on research conducted with the Matrix Model, various indicators of client retention are as follows: (a) *engagement*, staying in treatment as assessed at the 2-week and 1-month observations; (b) *retention*, staying in treatment as measured by the number of weeks remaining in treatment, with a maximum of 16 weeks, and

also as measured by staying in treatment for 90 days or more versus less than 90 days; (c) *abstinence*, as indicated by the average number of drug-free urinalysis tests collected during treatment and the occurrence of three consecutive drug-free urine analyses during treatment; and (d) *completion*, the completion of the 16-week Matrix Model treatment with no more than two consecutive missed weeks of treatment versus non-completion of this 16-week program (Hillhouse et. al. 2007).

These indices of client participation are likely correlated, although each provides slightly different indicators of treatment outcomes. As one example, from the Matrix Model, significant predictors of abstinence following treatment from methamphetamine abuse were female gender, a high frequency of methamphetamine use at treatment entry (15 days or more of use), and the client's route of drug administration (e.g., injection drug use) (Hillhouse et al. 2007). Also, criteria on route of administration indicated that the more severe form of self-administration, e.g., injection versus snorting, was associated with lower rates of abstinence. Regarding gender differences, the reason why women exhibited greater difficulties in maintaining abstinence relative to men was unclear (Hillhouse et al. 2007).

61.2.3 International Considerations

61.2.3.1 General Considerations in Dissemination and Implementation

As an EVT (Shoptaw et al. 1994), a major Matrix Model treatment goal involves its broad dissemination to enhance the availability of EVT to help drug-dependent clients. The successful dissemination and implementation of evidence-based interventions (EBIs) and of empirically validated therapies (EVTs) offers great potential for increasing public health and well-being (Spoth et al. 2013). This pursuit, identified as "type 2 translation research," involves generating scientific evidence on best approaches for (a) building community and agency infrastructures to deliver EVTs and EBIs, (b) creating practitioner-scientist partnerships, and (c) establishing effective implementation procedures for adopting, implementing, and sustaining EBIs and EVTs within diverse community settings (Spoth et al. 2013).

As an exemplar of this pursuit, the Matrix Model has been translated into nine languages and disseminated to over 6,000 therapists or counselors in the United States and internationally, as taught by 320 key supervisors. These supervisors have conducted Matrix Model training in 21 countries and in all 50 of states of the United States, resulting in staff training conducted in over 2,500 treatment agencies (J. Obert, 2 Apr 2013, personal communication).

Based on challenges from Matrix Model dissemination efforts as conducted in Thailand, Mexico, and in other countries worldwide, the developers of the Matrix Model have drawn several observations to guide future dissemination and implementation efforts. First, despite the availability of a published Matrix Model treatment manual, this treatment cannot be delivered effectively from this manual alone; formal training of Matrix Model implementers is necessary. Second, at the organizational and community levels, agency and civic leaders must understand fundamental aspects of drug abuse treatment to provide appropriate support that

ensures correct treatment implementation and avoids administrative decisions that conflict with or that undermine Matrix Model principles and activities (J. Obert, 2 Apr 2013, personal communication). Third, dissemination efforts must be guided by a clear dissemination plan that is monitored for quality and professionalism in its implementation. As a result of prior difficulties encountered in initial dissemination efforts, the developers of the Matrix Model also designed a certification program to ensure quality in training of Matrix Model therapists and counselors. The aim is to implement this treatment with requisite fidelity and with treatment insights regarding fidelity of implementation and/or adaptation planning when encountering problems in the implementation of the Matrix Model (J. Obert, 2 Apr 2013, personal communication).

61.2.3.2 General Considerations in International Adaptations

The world is a diverse place in which cultural diversity is expressed in a multiplicity of spoken languages, variations in literacy levels, diversity of religious and cultural systems of beliefs, and a multiplicity of sociocultural attitudes, values, and norms as exhibited across nations and even within nation. Within this context, worldwide there exists a dynamic tension between the sociocultural forces of *modernization* and quests for change and *traditionalism* and quests for the preservation of tradition and a resistance to change (Shiraev and Levy 2010). Factors that promote modernism, such as international globalization, emphasize growth and standardization and operate as forces that tend to homogenize cultural practices. By contrast, factors that promote traditionalism and its indigenous perspectives (Ramirez 1999) tend to diversify whole populations into distinct subcultural groups, emphasizing the retention of unique cultural and local identities and lifeways. These broad cultural influences provide a systemic context against which to consider the cultural adaptation of EBIs and EVTs.

61.2.3.3 Stage Models of Adaptation and Applications Across Cultures

Within the past decade, several stage models have been developed to guide the cultural adaptation of prevention and treatment interventions (Barrera and Castro 2006; Domenech Rodrıguez and Wieling 2004; Kumpfer et al. 2008; McKleroy et al. 2006; Wingood and DiClemente 2008). Several of those models were developed for the adaptation of treatments developed initially for majority middle-class populations within the USA, as these original EBIs or EBTs could be modified for greater relevance as delivered to member of the major US subcultural groups, i.e., African Americans, Hispanics/Latinos, Asian Americans, and Native Americans. However, with few exceptions (Kumpfer et al. 2008; Wingood and DiClemente 2008), cultural adaptation models have *not* been developed for international applications in which EVTs and EBIs created in one country have been adapted culturally for use in another country.

Segmentation: Beyond "Country" as the Unit of Analysis

One important way to frame the approach to cultural adaptation is to think beyond "the country" as the units of analysis that are smaller and more culturally

homogeneous that the 'nation' as a whole. A more useful approach is to consider adaptation for a *local community* or *region* of a country, given the remarkable within-country heterogeneity that exists within most countries worldwide. In other words, sensibly adapting an original EVT "for Mexico" requires a more refined approach to adaptation, one that considers a *smaller unit of analysis* rather than an entire nation. Adaptation to a local region or to a local community is critically important. This more *microlevel* approach advances beyond an "ethnic gloss" (Trimble 1995) that occurs under a more *macro-level* of analysis, i.e., the nation, given that a macro approach often glosses over important within-country variations.

For example, in considering the cultural adaptation of the Matrix Model for use "in the country of Mexico," besides a translation from English to Spanish, this adaptation would also require variations for its use within large urban and lower- and middle-class environments, such as within Mexico City and Guadalajara. By contrast, a second modified and adapted version may be needed for use with residents from rural and indigenous communities, such as with residents from the Mexican states of Chiapas and Yucatan. For example, within indigenous Mexico, some local residents have very low literacy levels and may not communicate well in Spanish, with some not speaking Spanish as their preferred language. Thus, a linguistic adaptation of the Matrix Model to Spanish could render this adapted version only partially relevant when administered with an indigenous subcultural group from the region of Chiapas, Mexico. And such a linguistic adaptation alone would not address long-standing cultural traditions, thus also highlighting the need for a local or regional cultural adaptation. Some rural indigenous males from this region of Mexico may also have culturally based *macho* gender role norms and expectations that confer them with considerable male authority and privilege over their family and within their community. Such traditions and cultural practices must be addressed if this treatment is to engage such clients in culturally relevant activities and operate effectively with the male residents of this local community.

Approaches to International Adaptation

A recent article has presented an international model of intervention adaptations, an approach titled *Planned Intervention Adaptation* (PIA) (Sundell et al. 2013). The authors described PIA as a synthesis of several models that outline stages or conceptual frameworks for systematically adapting interventions for applications in new cultural contexts (Sundell et al. 2013). PIA consists of two broad phases that were inspired particularly by Resnicow and colleagues, who distinguished between the concepts of "deep structure" elements of an intervention from "surface structure" elements (Resnicow et al. 2000).

In reality, PIA is not fundamentally different than other cultural adaptation stage models (see Barrera et al. 2013). However, it does distinguish itself from others in the detail of its recommendations. For example, PIA specifies a time period for the initial adaptation stages and a sampling strategy for formative studies. Phase 1 of PIA consists roughly of a 1.5–2-year period when intervention developers and stakeholders (agency staff, potential consumers) agree to collaborate on five

preliminary steps that are summarized in a table and detailed in text (e.g., language translations, tests of translated materials, focus group checks on the cultural appropriateness of intervention materials and activities). These preliminary steps help to shape the adapted intervention.

In phase 2 of PIA, the authors recommend conducting a three-arm effectiveness study which would consist of (a) a minimally adapted intervention (solely surface structure changes such as language translation), (b) a fully adapted intervention (both surface and deep structure changes), and (c) a control condition. However, even for this recommendation, given the complexities in conducting *conceptually equivalent* linguistic translations, a linguistic translation itself may actually involve more than just surface changes. The PIA also recommended the inclusion of appropriate measures and data analytic procedures to identify possible mediators and moderators of intervention effects (Iacobucci 2008; MacKinnon 2008). Unfortunately, based on Sundell et al. (2013) article, it is not certain that the PIA framework actually has been used in the international adaptation of an original EVT intervention.

Undoubtedly, the best examples of international adaptations involve studies of the Strengthening Families Program (SFP), a family skills intervention for the prevention of youth substance abuse (Kumpfer et al. 2008). SFP was initially developed and tested in the United States and subsequently has been adapted for applications in Australia, Canada, Central America, Europe, South America, and Southeast Asia. The results of that work have been summarized with the following statement (Kumpfer et al. 2012, p. 176):

> Replications of SFP in non-experimental and quasi-experimental studies in about 17 countries and randomized control trials (RCTs) in nine countries (United States, Canada, Australia, UK, Sweden, Netherlands, Spain, Italy, and Thailand) with different cultural groups by independent evaluators have found SFP to be an effective program in reducing multiple risk factors for later alcohol and drug abuse, mental health problems and delinquency by increasing family strengths, children's social competencies and improving parent's parenting skills.

Kumpfer et al. (2012) detailed 10 steps that should be followed in creating an international adaptation of SFP and perhaps for other evidence-based programs (also see Kumpfer et al. 2008). Table 61.1 summarizes these ten steps. In Kumpfer et al. (2008), these steps were illustrated with examples from their extensive experience in many countries. This "must-read" article is filled with general guidance and best practices for those who are planning international adaptations of evidence-based interventions.

61.2.3.4 Conducting a Streamlined Cultural Adaptation: A Five-Stage Model

We recognize that many drug abuse treatment programs in the United States and also in various communities worldwide are delivered within medical centers and in a variety of community-based agencies, large and small. These professional settings often do not have the requisite research infrastructure (the program evaluation or

Table 61.1 Two systematic approaches to cultural adaptation

Step	Action (from Kumpfer et al. 2012)	Stage	Action
1	*Needs assessment* – collect needs assessment information from new or existing data to determine major family risk and protective factors for child developmental problems	1	*Information gathering* – review of the current drug treatment literature and a screening of client-treatment mismatches
2	*Literature review* – collect information from research literature or websites on appropriate family skills. Select the best program for age, ethnicity, and risk level of families (e.g., universal, selective, or indicated prevention approaches)		
3	*Cultural adaptation team* – create a cultural adaptation team including family members and the original program developer	2	*Preliminary adaptation design* – propose adapted modifications of specific mismatched content or activities for the original model treatment
4	*Linguistic translation* – translate into local language and do minor cultural adaptations		
5	*Initial implementation* – implement "as is" with minimal adaptation at first	3	*Preliminary adaptation test* – test this pilot adaptation to assess how well it works with clients from the targeted subcultural client group
6	*Implementation of initial changes* – have implementers from local culture make gradual changes based on what works (culturally appropriate language, stories, songs)		
7	*Ongoing cultural adaptations* – continuously make additional cultural adaptations and add to curriculum with the program developer's approval	4	*Adaptation refinement* – using client feedback from the prior stage, make adjustments on revisions to refine the emerging adapted model treatment
8	*Ongoing evaluation* – continuously conduct pre-and posttest evaluations on each family group to measure if the local cultural adaptations are making the program better or worse	5	*Cultural adaptation test* – as viable, conduct a small-scale or ideally a large-scale randomized controlled trial to formally assess the efficacy of the adapted model treatment, as compared with the original model treatment, and ideally also against a treatment-as-usual (TAU) control group
9	*Add or drop adaptations* – make adjustments to add or drop new cultural adaptations		
10	*Dissemination to similar groups* – disseminate the culturally adapted version to similar cultural groups if effective		

research staff, the funding and time, and other research or evaluation resources) to conduct a formalized and months-long randomized controlled clinical trial to test the efficacy of an EVT adaptation as described by Sundell and colleagues and by Kumpfer and colleagues.

61.2.3.5 A Practical Approach to the Cross-Cultural Adaptation of a Treatment Program

How then might a treatment center or community-based agency conduct a cost-effective, culturally responsive, and scientifically defensible cultural adaptation of an original EVT? Within such an abbreviated cultural adaptation effort, to avoid engaging in misadaptation, we encourage rigor in the application of scientific and community-based participatory research procedures (CBPR) (Minkler and Wallerstein 2003; Minkler et al. 2008). This abbreviated approach would aim to achieve, and perhaps enhance, certain targeted treatment outcomes: (a) treatment engagement, (b) retention in treatment, (c) abstinence from drug use, and (d) program completion (Hillhouse et al. 2007). And as noted, another goal is to avoid introducing iatrogenic effects as consequences of misadaptation.

61.2.3.6 General Strategy and Procedures for a Streamlined Intervention Adaptation

An initial assessment step in the cultural adaptation of an original EVT is to establish a Cultural Advisory Committee to identify and address cultural and other forms of local problems in treatment implementation and in client-treatment mismatches. Such culturally incongruous content or activities are characterized as elements of treatment that are found to be confusing, objectionable, or culturally offensive to members of a targeted subcultural client group. Under a community-based participatory research approach (CBPR), these forms of mismatch are identified by conducting *focus groups, key informant interviews,* and interviews with *stakeholders* and with clients who represent other clients who would be recipients of this treatment (Parasi et al. 2011). Also to be included are interviews with treatment staff and administrators who would deliver this treatment. The identification and assessment of cultural mismatches would reveal significant problems in the implementation of the original EVT, as well as approaches for correcting them. If not identified and addressed initially, such sources of cultural non-fit can alienate members of a targeted client group and induce them to drop out of treatment.

Castro et al. (2004) outlined three major dimensions of model treatment adaptation. These three major dimensions are as follows: (a) *cognitive information processing* characteristics, such as language and age/developmental or literacy levels; (b) *affective-motivational* characteristics, including gender, racial/ethnic identity and background, religious background, and socioeconomic status, as these factors can influence clients' comfort in accepting the EVT's messages and activities; and (c) *environmental* characteristics, including ecological aspects of the client's local community:

1. *Cognitive informational adaptation* involves changing program contents or activities that clients are unable to understand. In international adaptations, this would involve a linguistic translation to achieve equivalence in meaning (conceptual equivalence), and not in a word-for-word translation (Camfield and Ruta 2007; Geisinger 1994; Gonzalez et al. 1995).

This should also take into account the literacy level of members of the targeted subcultural group.

2. *Affective-motivational adaptation* involves modifications of program content or activities that can induce *cultural conflict* or that *prompt reactance* (behavioral resistance). An example might be a Westernized cultural approach that requires male clients to publically disclose their drug dependence or to discuss sexual issues in the presence of certain family members. Without understanding its possible cultural implications, that practice might be perceived by traditional culture males as culturally inappropriate, whereby they may feel stigmatized and resist participating in this otherwise important treatment activity. Conversely, as a culturally modest adaptation, eliminating a discussion of stimulant use as a trigger for sexual arousal and activity can undermine drug treatment, given the association between stimulant use and sexual activity, as this can trigger a relapse episode (J. Obert, 2 Apr 2013, personal communication). Thus, a discussion of benefits and liabilities from such adaptations is critical for making sound adaptation decisions that are both culturally sensitive and that also adhere to scientific principles of effective drug abuse treatment.
3. *Environmental adaptation* involves therapeutic changes in a client's family system, in the client's home neighborhood, and within the treatment agency, thus modifying local environment conditions to aid in the client's recovery. In this domain, two basic forms of adaptation consist of (a) modifying *program content* which relates to the environment and (b) modifying the *form of program delivery*. Modification of content would include shallow or deep structure changes in that content. Changes in form of delivery would involve presenting the same treatment content, although delivered with changes in (a) *characteristics of delivery personnel*, lay health workers rather than health educators; (b) *channel of delivery*, Internet delivery rather than a group session; or (c) *location of delivery*, improving access by delivering the program within a church setting rather than within a drug treatment center.

61.2.3.7 Five Basic Stages in a Local or Cultural Adaptation

In a version that parallels Kumpfer's ten-step approach to cultural adaptations, the cultural or local adaptation of an original drug abuse model treatment (an empirically validated therapy – an EVT) can be conducted via a basic five-stage process (Barrera et al. 2013). Ideally, this five-stage process is conducted formally under a randomized controlled trial. In the absence of that option, four of these five stages can be conducted using a community-based participatory research (CBPR) approach as overseen by a well-informed Cultural Adaptation Committee (CAC). Accordingly, this adaptation effort as conducted by a drug treatment agency would be conducted (a) with the aid and oversight of a Cultural Adaptation Committee and (b) by using CBPR procedures to facilitate input from key informants and stakeholders and a review of consumer feedback to attain culturally sensitive and also scientifically informed decisions on appropriate adaptations. The CBPR approach is a bidirectional approach that consists of a collective dialogue and group decision in adapting an original EVT protocol (Donovan et al. 2011).

Table 61.1 presents these five stages as described by Barrera and colleagues (2013). Based in this framework and process, these five stages are:

1. **Information gathering** – Review relevant drug treatment literature as background to identify implementation problems and sources of client-treatment mismatches, as linked to the three major dimensions of cultural adaptation assessment, along with proposed adaptive changes that consider (a) participant characteristics, (b) program delivery staff, and (c) administrative/community factors (see Castro et al. 2004).
2. **Preliminary adaptation design** – Integrate recommendations from the Cultural Adaptation Committee which is staffed by (a) various stakeholders, (b) community experts, (c) developers of the model treatment, and (d) former clients or representatives from the drug treatment program (treatment insiders) and, if needed, other important representatives from the local community or treatment center. Core intervention components would be preserved, unless there exists convincing evidence that one of these core components is detrimental to the well-being of clients from the targeted constituency.
3. **Preliminary adaptation tests** – Design and pilot test a preliminary adapted version of the original EVT to assess (a) the elimination of prior implementation difficulties, (b) the emergence of problems with content or activities, (c) client satisfaction with treatment elements, and (d) suggestions for improvement.
4. **Adaptation refinement** – Revise the adapted intervention. Then, if viable as a more formal adaptation activity, proceed to stage 5.
5. **The cultural adaptation trial –** Formally determine the efficacy of this adapted version by comparing it to a treatment-as-usual (TAU) control group and ideally to the original EVT. This adapted EVT's efficacy can be assessed as it influences identified psychological and health outcome variables, as well as the assessment of engagement indicators (e.g., client involvement, client attendance, completion of the treatment). Although seldom evaluated, within the cultural adaptation trial stage, intervention evaluators or research investigators should aim to assess the effects of the adapted EVT on specified mediators and moderators (Iacobucci 2008; MacKinnon 2008). For example, if a culturally adapted EVT adds a cultural pride component, a mediation analyses could determine whether the intervention was successful in enhancing cultural pride and then if this cultural pride enhancement exerts an effect in reducing drug use or in avoiding relapse. Similarly, moderator analyses could be conducted to determine if the culturally adapted EVT was differentially effective: (a) for men versus for women, (b) for clients high versus low in levels of acculturation, (c) among immigrants versus natives, or (d) for any other potential moderators of intervention efficacy (Barrera et al. 2012).

In addition, the adaptation team could utilize a rigorous mixed methods research design (Creswell et al. 2011), one that includes in-depth interviews with participants and interventionists, to conduct a more in-depth assessment of treatment outcomes and of the process involved in the implementation of this adapted EVT (Castro et al. 2014). This approach would allow a deep structure analysis of client and therapist commentaries on factors that (a) may operate as core treatment

components, (b) may operate as sources of problems within treatment, and (c) factors that worked very well and should be kept along with (d) client feedback for enhancing the content or delivery of treatment modes to aid in treatment revisions as incorporated into a future adaptation of this once-adapted EVT.

61.2.3.8 Some Observations/Recommendations for Adaptation of Drug Abuse EVTs

From this analysis of the cultural adaptation of EVTs and EBIs and their international considerations, we offer a few observations and recommendations.

Enhancing Client Engagement

Sufficient client engagement in treatment to promote client retention and treatment completion remains a pervasive problem that affects treatment efficacy and the benefits that can be derived from that treatment (Carroll et al. 2011). It is thus essential that newly developed, adapted, or refined EVTs and EBIs increase their capacity for client engagement.

Treatment Relevance and Fit

A treatment that is not designed with the needs of a specific subcultural group may exhibit insensitivity to that group's needs and preferences. Given that early drug abuse treatments emerged with a distinct male focus, it exhibited insensitivity to the needs of many drug-dependent women. That is, it lacked relevance and fit for many women, until it was recognized that the treatment of drug dependence also needed to consider the unique needs of women.

Importance of Cultural Factors

Recent studies have highlighted the importance of considering various cultural factors, such as gender, racial or ethnic identity, sexual orientation, and levels of acculturation as influences on recovery from drug dependence. Drug abuse treatments can be enhanced by incorporating a cultural sensitivity to these and other cultural factors to promote full recovery among diverse drug-dependent clients and to avoid relapse (Castro et al. 2007).

Increasing Cultural Relevance Without Reconstructing a Treatment

Increasing an existing EVTs cultural relevance need not involve a complete reconstruction of an existing EVT. Adding a relevant treatment module or culturally relevant content and activities may be sufficient to enhance treatment relevance and client-treatment fit.

Cultural Adaptation as a Systematic and Team Effort

The effective adaptation of an EBI or an EVT consists of a planned and systematic team effort, one that involves a scientist-provider partnership between the developers of the treatment and other stakeholders (Donovan et al. 2011). Organized agency structures are also needed and should be developed to conduct the most

rigorous treatment adaptation possible within the local community and also to sustain the delivery of that treatment with the requisite fidelity needed to produce efficacious treatment results.

Social Therapies and Treatment Settings

Gregory Bunt and Mahmood Nazar Mohamed

Social Therapies and Treatment Settings: An Introduction

62

Gregory Bunt and Mahmood Nazar Mohamed

Despite the advances in the neuroscience of addictive disorders, there is no indication that a biological cure for the disorder of addiction is at hand. To the contrary, the overwhelming consensus of experts in addictive disorders is that the disease of addiction is a bio-psycho-social-spiritual phenomenon. The recent definition of an addiction developed by a task force of the American Society of Addiction Medicine and adopted by the International Society of Addiction Medicine underscores this point.[1]

Over the decades since the original establishment of Alcoholics Anonymous and the introduction of opioid maintenance therapy, a diverse group of socially grounded treatment settings have been developed worldwide. Most have been framed so as to adapt to respective national settings where they operate. Furthermore, the cost-effectiveness of many of the social therapies described provides practical public access to treatment for addictive disorders; and this is essential for effective local, regional, and national responses to the addiction crisis.

In this section of the textbook, we consider approaches which can be grouped into several key areas. There were peer-led treatments largely falling into two domains: (1) those which are peer led but not formally imbedded in structured programs or funded by government agencies or subject to regulations and (2) those which are institutionally based and regulated by governments such as therapeutic communities.

Therapeutic communities emerging in the 1960s with Daytop Village, Phoenix House, Odyssey House, and Samaritan Village are multisite programs with Daytop in fact expanding internationally. These programs are based on the premise that transformation of pathological character traits can lead to a resolution of drug-seeking behavior. The noninstitutional peer-based programs exemplified by Alcoholics Anonymous and Narcotics Anonymous, both emerging from centers in the United States altogether with over 150,000 peer-led groups worldwide, are premised on peer support infused with spiritual renewal. Densingi in Japan is also peer led but does not emphasize spirituality to the same degree.

Two chapters related to service delivery illustrate the complexity of various treatment networks constituted of diverse approaches. The policy initiatives and technology-based approaches are described with an emphasis on specific examples of innovative service delivery. Additionally, strategies for drug abuse prevention in the workplace provide another example of the introduction of treatment methods into a broader social context.

Inevitably, the illness of addiction impacts on both the criminal justice system and the acute medical emergency services, and in recent years, there has been considerable progress in moving addiction treatment forward into settings outside of those directed specifically at treatment, i.e., prison settings; forensic applications as Drug Courts, or alternatives to incarceration; or legal civil sanctions. Additionally considerable sophistication has been introduced into the Emergency Medical Services for addicted patients.

We can learn a great deal indeed from examining the diversity of clinical approaches in differing cultural, regional, and national settings. Whether in the United States, Japan, Malaysia, Iceland, the United Arab Emirates, Vietnam, Lebanon, or any other nation delivering addiction treatment services worldwide, the diversity of options and opportunities for developing and advancing addiction services remains a vital challenge for the professionally trained addiction physician today.

Altogether, these diverse but carefully framed aspects of social therapies illustrate the many ways in which social support and structure, both in formal treatment settings and outside of them, have emerged since the twentieth century. The skill, wisdom, and knowledge with which addiction physicians apply these principles of social therapies and treatment settings for addictive disorders will have an enormous impact on the future of our field.

Therapeutic Communities for Addictions: Essential Elements, Cultural, and Current Issues

Abstract

The therapeutic community (TC) is a major treatment modality serving a wide spectrum of substance abuse clients worldwide. The weight of the research evidence developed over some 40 years demonstrates that the TC is an effective and cost-effective treatment particularly for substance abusers with serious social and psychological problems in addition to their drug abuse. This chapter provides an overview of the essential elements of the TC approach: its perspective, method, program model, and adaptation for special populations, settings, and different cultures.

TCs have been successfully modified for special populations of substance users including those with co-occurring disorders, adolescents, women with children, criminal justice clients in prisons, and community-based settings. TC programs have been implemented in Europe, Asia, Africa, Latin America, and the Middle East. And, despite ethnic, social-political, and religious differences, TCs have retained their essential elements and effectiveness across a variety of cultures.

Its evolution over some 50 years has surfaced key issues that challenge the TC to maintain the integrity of its unique social psychological approach – community as method. Several of these are briefly highlighted including funding, workforce, research, treatment fidelity, and the diversity of TC programs. In the current context, the TC is compelled to reassert its place and mission in human services – that of promoting recovery and right living.

63.1 Introduction

Drug-free residential programs for substance abuse appeared a decade later than did therapeutic communities (TCs) in psychiatric hospitals pioneered by Maxwell Jones and others in the United Kingdom. The term therapeutic community evolved in these hospital settings, although the two models arose independently.

The TC for substance abuse emerged in the late 1950s as a self-help alternative to existing conventional treatments. The originators were recovering alcoholic and drug-addicted individuals (Yablonsky 1965, 1989). Although its modern antecedents can be traced to Alcoholics Anonymous and Synanon, contemporary TCs for addictions are sophisticated human services institutions. Today, the label therapeutic community is generic, describing a variety of short- and long-term residential and nonresidential programs that serve a wide spectrum of substance

abuse clients. Although the TC approach has been adapted for different populations and settings, it is the perspective and method of the traditional long-term residential prototype for adult substance abusers that has documented effectiveness in rehabilitating substance-abusing individuals.

63.2 Essential Elements

63.2.1 The TC Perspective

The TC perspective or theory shapes its program model and its unique approach, community as method. The perspective consists of four interrelated views of the substance use disorder, the individual, recovery process, and healthy living.

63.2.1.1 View of Disorder

Drug abuse is viewed as a disorder of the whole person, affecting some or all areas of functioning. Cognitive and behavioral problems are often present, as are mood disturbances. Thinking may be unrealistic or disorganized; values may be confused, nonexistent, or antisocial. Frequently, the patient exhibits deficits in verbal, reading, writing, or marketable skills. Moral or even spiritual issues, whether expressed in existential or psychological terms, are apparent. Thus, the TC perspective considers the problem to be the individual, not the drug, and addiction is a symptom, not the essence of the disorder.

63.2.1.2 View of the Person

In TCs, individuals are distinguished along dimensions of psychological dysfunction and social deficits rather than according to drug use patterns. Regardless of differences in social background, drug preference, or psychological problems, most individuals admitted to TCs share clinical characteristics (Table 63.1). Whether they are antecedent or consequent to serious involvement with drugs, these characteristics are commonly observed to correlate with chemical dependency. More important, in TCs, a positive change in these characteristics is considered to be essential for stable recovery.

63.2.1.3 View of Recovery

In the TC perspective recovery extends beyond drug freedom, involving a change in lifestyle and in personal identity. The primary psychological goal is to change the negative patterns of behavior, thinking, and feeling that predispose the individual to drug use; the main social goal is to develop the skills, attitudes, and values of a responsible drug-free lifestyle.

In many TC residents, vocational and educational problems are marked; middle-class, mainstream values are either missing or not sought. Usually these residents emerge from a socially disadvantaged sector. Their recovery in the TC is better termed *habilitation*, the development of a socially productive, conventional

Table 63.1 Typical behavioral, cognitive, and emotional characteristics of substance abusers in therapeutic communities

Low tolerance for all forms of discomfort and delay of gratification
Problems with authority
Inability to manage feelings (particularly hostility/anger, guilt, and anxiety)
Poor impulse control (particularly sexual or aggressive impulses)
Poor judgment and reality testing concerning consequences of actions
Unrealistic self-appraisal regarding discrepancies between personal resources and aspirations
Prominence of lying, manipulation, and deception as coping behaviors
Personal and social irresponsibility (e.g., inconsistency or failures in meeting obligations)
Marked deficits in learning and in marketable and communication skills

lifestyle for the first time. Among individuals from more advantaged backgrounds, the term *rehabilitation* is more suitable, which emphasizes a return to a lifestyle previously lived, known, and perhaps rejected.

63.2.1.4 View of Right Living

TCs adhere to certain precepts and values that constitute a view of healthy personal and social living that guide and reinforce recovery. For example, community sanctions address antisocial behaviors and attitudes; the negative values of the street, jails, or negative peers; and irresponsible or exploitative sexual conduct. Positive values are emphasized as being essential to social learning and personal growth. These values include truth and honesty (in word and deed), a work ethic, self-reliance, earned rewards and achievement, personal accountability, responsible concern (being one's brother's or sister's keeper), social manners, and community involvement. The precepts of right living are constantly reinforced in various formal and informal ways (e.g., signs, seminars, in groups and community meetings).

63.2.2 The TC Approach: Community as Method

The TC approach can be summarized in the phrase "community as method" (De Leon 1997, 2000). A parallel concept – "community as doctor" – in the psychiatric or democratic TC was first coined by Rapoport (1960). Theoretical writings offer a definition of "community as method" as follows: the *purposive* use of the community to teach individuals to *use* the community to change themselves. The fundamental assumption underlying the TC approach is that individuals obtain maximum therapeutic and educational impact when they engage in and learn to use all of the activities, elements of the community as the tools for self-change. Thus, community as method means that the community itself provides a *context* of relationships and activities for social learning. Its membership establishes the *expectations* or standards of participation in community activities; it continually *assesses* how individuals are meeting these expectations and *responds* to them with strategies that promote continued participation.

63.2.3 TC Program Model

The key components of the program model are its social organization (structure), peer and staff roles, groups and individual counseling, community enhancement meetings, community management elements, and program stages. Each component reflects an understanding of the TC perspective and each is used to transmit community teachings, promote affiliation, and self-change.

63.2.3.1 Social Organization

The TC social organization is stratified with relatively few staff of the TC at the top complemented by resident peers at junior, intermediate, and senior levels. This peer level-to-community structure strengthens the patient's identification with a perceived ordered network of individuals. More important, it arranges relationships of mutual responsibility at various levels in the program.

The daily operation of the community itself is the task of the residents, who work together under staff supervision. The broad range of resident job assignments illustrates the extent of the self-help process. Residents perform all house services (e.g., cooking, cleaning, kitchen service, minor repair), serve as apprentices, run all departments, and conduct house meetings, certain seminars, and peer encounter groups.

The TC is managed by the staff, who monitor and evaluate patient status, supervise resident groups, assign and supervise resident jobs, and oversee house operations. The staff members conduct therapeutic groups (other than peer encounter groups), provide individual counseling, and organize social and recreational projects. They make decisions about resident status, e.g., discipline, promotion, transfers, discharges, furloughs, and treatment planning.

63.2.3.2 Peers as Role Models

Peers, serving as role models, and staff members, serving as role models and rational authorities, are the primary mediators of the recovery process. TC members who demonstrate the expected behaviors and reflect the values and teachings of the community are viewed as role models. TCs require multiple resident and staff role models in order to maintain the integrity of the community and ensure the spread of social learning effects.

63.2.3.3 Staff Members as Rational Authorities

Staff members foster the self-help learning process through performance of their managerial and clinical functions described above but also as role models and rational authorities. TC residents often have had difficulties with authorities who have not been trusted or who have been perceived as guides and teachers. Therefore, residents need a positive experience with an authority figure who is viewed as credible, supportive, corrective, and protective so that they may gain authority over themselves (personal autonomy). As rational authorities, staff members provide the reasons for their decisions and explain the meaning of consequences particularly in terms of recovery and personal growth.

63.2.3.4 Therapeutic Educational Activities (Groups and Individual Counseling)

Various forms of group process and individual counseling provide residents with opportunities to express feelings and resolve personal and social issues. They increase communication and interpersonal skills, bring about examination and confrontation of behavior and attitudes, and offer instruction in alternative modes of behavior. The main forms of group activity in the TC are peer-led encounter groups, staff-led therapy, and tutorial groups. Other groups that convene regularly or held as needed supplement the main groups. These vary in focus, format, and composition and include gender, ethnic, age-specific, or health theme groups. Additionally, cognitive-behavioral tutorials using manualized curricula are employed for targeted areas such as relapse prevention, criminal thinking, trauma and PTSD, etc.

One-to-one counseling balances the needs of the individual with those of the community. Peer exchange is ongoing and is the most consistent form of informal counseling in TCs. Staff counseling sessions may be regularly scheduled or conducted as needed. The focus of staff counseling is to address issues that may impede progress and to facilitate the patient's adjustment to and constructive use of the peer community. Counseling is also employed for the purpose of developing an individualized treatment plan.

63.2.3.5 Community Enhancement Activities (Meetings)

Community enhancement activities are the facility-wide meetings that convene daily. These include the morning meeting, the seminar, the house (evening) meeting, and a general meeting. Some of these are held almost daily while others are called when needed. These gatherings are necessary for building the spirit of community to which members are expected to participate actively. Though different in format, all meetings have the common objective of facilitating the individual's assimilation into the community. The purpose of the morning meeting is to instill a positive attitude in the community at the beginning of the day, motivate residents, create camaraderie, and strengthen unity. Seminars are community-wide teaching sessions led by peers or staff presenting topics that directly or indirectly relate to the TC perspective on recovery and right living. House meetings are coordinated by senior residents to transact community business. General meetings take place only when needed and are usually called so that negative behavior, attitudes, or incidents in the facility can be addressed. While these activities are often facilitated by senior residents, staff are available to oversee them. Community enhancement also occurs in a variety of nonscheduled, informal activities as well. These include activities related to rituals and traditions, celebrations (e.g., birthdays, graduations, phase changes, job changes), ceremonies (e.g., those relating to general and cultural holidays), and memorial observances for deceased residents, family members of residents, and staff members.

63.2.3.6 Community and Clinical Management Elements

Community and clinical management elements maintain the physical and psychological safety of the environment and ensure that resident life is orderly and productive.

Thus, they strengthen community as a context for social learning. The main elements that are staff managed, although with some input from the senior resident social hierarchy, are privileges, disciplinary sanctions, surveillance, and urine testing. However, peer confrontation in the form of verbal correctives, affirmations, and feedback (e.g., reactions, advice, information) are ongoing community management activities.

63.2.3.7 Program Stages and Phases

Recovery in the TC is a developmental process that can be understood as a passage through program stages of learning. The learning that occurs at each stage facilitates change at the next, and each change reflects movement toward the goal of recovery. Three major program stages characterize change in long-term residential TCs – *orientation-induction*, *primary treatment*, and *reentry* – and may include additional substages or phases. The original time frame for these stages was grounded in a planned duration of treatment ranging up to 24 months. Current stage and phase durations are shorter commensurate with decreased overall planned durations. Regardless of temporal changes completion of each stage is a celebrated event marking acknowledged programmatic and clinical progress.

Completion marks the end of active program involvement. Graduation itself, however, is an annual event conducted in the facility for individuals who have completed all program stages and have successfully spent some time outside the treatment facility. Thus, the TC experience facilitates a process of change that must continue throughout life; and what is gained in treatment are tools to guide the individual on a path of continued change. Completion, or graduation, therefore, is not an end but a beginning.

63.2.3.8 Aftercare

TCs have always acknowledged the patient's efforts to maintain sobriety and a positive lifestyle beyond graduation. Until recently, long-term TCs addressed key clinical and life adjustment issues of aftercare during the reentry stages of the 2-year program. As noted, funding pressures have resulted in shorter planned durations of residential treatment and the stages and phases therein. This has underscored the necessity for aftercare resources to address both primary treatment as well as reentry issues. Thus, many contemporary TCs offer post residential aftercare treatment and social services within their systems, such as intensive day treatment and step-down outpatient ambulatory treatment, or through linkages with outside agencies.

63.2.4 The Effectiveness of Therapeutic Communities

Over the past four decades, a considerable scientific knowledge base has developed with follow-up studies on thousands of individuals treated in TCs. The most extensive body of research bearing on the effectiveness of addiction TC programs has amassed from field outcome studies. These all employed similar longitudinal designs that follow admissions to TCs during treatment and 1–5 years (and in one study up to 12 years) after leaving the index treatment.

These studies show that TC admissions have poor profiles in terms of severity of substance use, social deviance, and psychological symptoms. The striking replications across studies leave little doubt as to the reliability of the main conclusion. Namely, there is a consistent relationship between retention in treatment and positive posttreatment outcomes in TCs. Replication studies overseas seem to follow the same trend. This conclusion is supported in the smaller number of controlled and comparative studies involving TC programs (for a recent review of the TC outcome literature in North America, see De Leon 2010).

Overall, the weight of the research evidence from multiple sources (multi-program field effectiveness studies, single-program controlled studies, meta-analytic statistical surveys, and cost-benefit studies) is compelling in supporting the hypothesis that the TC is an effective and cost-effective treatment for certain subgroups of substance abusers, particularly those with serious social and psychological problems in addition to their drug abuse.

63.2.5 Adaptations and Modifications of the TC for Special Populations and Settings

The traditional TC model described in this chapter is actually the prototype of a variety of TC-oriented programs. Today, the TC modality consists of a wider range of programs serving a diversity of patients who use a variety of drugs and present with complex social and psychological problems in addition to their chemical abuse. Client differences as well as clinical requirements and funding realities have encouraged the development of modified residential TC programs with shorter planned durations of stay (3, 6, and 12 months) as well as TC-oriented day treatment and outpatient ambulatory models. Having become overwhelmed with alcohol and drug abuse problems, correctional facilities, medical and mental hospitals, and community residences and shelters have implemented TC programs within their settings.

Most community-based traditional TCs have expanded their social services or have incorporated new interventions to address the needs of their diverse residents. These changes and additions include family services, primary health care specifically geared toward HIV-positive patients and individuals with AIDS, aftercare services particularly for special populations such as substance-abusing inmates leaving prison treatment, relapse prevention training, components of 12-step groups, mental health services, and other evidence-based practices (e.g., cognitive-behavioral therapy, motivational interviewing). Mostly, these modifications and additions enhance but do not substitute for the basic TC approach, community as method. Research literature documents the effectiveness and cost-effectiveness of modified TCs for special populations including homeless mentally ill chemical abusers, those in criminal justice settings, and adolescents (e.g., De Leon et al. 2000; Sacks et al. 2008; Wexler and Prendergast 2010; Jainchill et al. 2005; De Leon 1997).

63.2.6 TCs Worldwide

Over some five decades TC programs have been implemented worldwide. In Europe, the establishment of drug-free therapeutic communities was the main treatment response to the emerging heroin problems in the 1960s and 1970s. The original American TC model was adapted to the European culture and it integrated the long-standing local traditions and influences. Between 1968 and 1983, the TC approach spread rapidly across virtually all countries in Europe including the United Kingdom and subsequently to Asia, Africa, and Latin America. Globally, it is conservatively estimated that there are over 3,000 TCs operating in hospital, prison, juvenile centers, outpatient, and community-based settings.

63.2.7 TC Outcome Research Worldwide

The North American research literature is the most extensive and has been briefly cited above. There is a modest but developing research literature on TCs worldwide particularly of European programs. The main conclusion from recent reviews of the European outcome studies may be briefly summarized.

"Length of stay in treatment and participation in subsequent aftercare were consistent predictors of recovery status. The authors conclude that TCs can promote change regarding various outcome categories. Since recovering addicts often cycle between abstinence and relapse, a continuing care approach is advisable, including assessment of multiple and subjective outcome indicators" (Vanderplasschen et al. 2013). Similar conclusions are obtained in outcome studies of TC programs in Peru and Thailand (Johnson et al. 2007, 2008), Australia, (Pitts and Yates 2010).

Although treatment process studies are few, emerging research has supported hypotheses concerning the generality of the perspective, model, and method of TC. Utilizing a common assessment instrument (the Survey of Essential Elements Questionnaire SEEQ; Melnick and De Leon 1999), these studies emphasize that differences exist between standard and modified TCs in essential elements within cultures but that the similarities in elements outweigh the differences across cultures (Dye et al. 2009; Goethels et al. 2011; Johnson et al. 2007, 2008).

63.2.8 Cultural Adaptations of the TC

Given the complexity of the TC as a social psychological approach, it is understandable that its implementation has been influenced by cultural context. Even within North America, for example, TC programs have adapted to ethnic diversity factors (De Leon et al. 1993). The adaptation of the TC to cultural diversity or context factors is still greater at the global level.

Beyond the above studies supporting the generality of the essential elements, there has been relatively little empirical research that focuses on cultural influences in the adaptation of the TC. However, a considerable descriptive literature of TCs in different cultures has unfolded over some four decades. Some reports can be found in scientific journals but most are contained in the published conference proceedings of international and regional TC associations, e.g., the World Federation of Therapeutic Communities (WFTC), the European Federation of Therapeutic Communities (EFTC), the Australasian Therapeutic Communities Association (ATCA), the Latin American Federation of Therapeutic Communities, and the Asian Federation of Therapeutic Communities.

These writings, along with the few empirical studies and the years of observations by trainers, consultants, and others, have indentified various cultural context influences that are embedded in TC programs (see some examples in Table 63.2). It is beyond the purview of this chapter to discuss these in detail, but several working conclusions are offered concerning the TCs adaptation to cultural influences.

First, the TC perspective (i.e., views of the whole person disorder, recovery, and right living) and its approach (community as method) can be preserved and integrated within diverse cultures. Second, empirical research is needed to abstract a more complete list of cultural influences and to assess their impact on outcomes. Finally, across all cultures, maintaining *fidelity* of practice is necessary to assure the optimal effectiveness of the TC approach, a general issue which is briefly discussed in the last section of this chapter.

63.2.9 Issues and Challenges to the TC

The evolution of the contemporary therapeutic community (TC) for addictions over the past 45 years may be characterized as a movement from the marginal to the mainstream of substance abuse treatment and human services. Currently TCs serve a wide diversity of clients and problems; they have reshaped staffing composition, reduced the planned duration of residential treatment, reset its treatment goals, and, to a considerable extent, modified the approach itself. These evolutionary changes have surfaced key issues that challenge the TC to maintain the integrity of its unique approach. Several of these are briefly highlighted: funding, workforce, research, treatment fidelity, and the diversity of TCs. Though interrelated, these issues are discussed separately.

63.2.10 Funding and Planned Duration of Treatment

Issue: The success of the TC approach has been demonstrated primarily for residential programs with planned durations of treatment of at least 9–12 months. In recent years, however, fiscal support has been steadily decreasing for long-term treatment in general and for residential treatment in particular. Thus, for the large

Table 63.2 Some examples of cultural elements shaping the unique TC characteristics in different cultures

Gender. In cultures where there are strict norms regarding the mixing of the sexes, there are separate TCs for men and women. The segregation is not driven by clinical rationale intended to better meet the unique needs of a particular gender but more for moral and reasons of propriety.
Religion. In most Eastern TCs, religion and religious practices are integrated into the TC structure. Those who belong to minority religions are encouraged to practice their faith. Major religious holidays are observed and program activities are tailored around celebrations of such holidays. Even dietary practices are observed.
Social organization. The traditional hierarchical structure of the TC is highly compatible with the formal and often rigid social structure in most conservative cultures. The TC hierarchical structure lends clarity which is consistent with the formal social structures of most of these societies. The delineation and lack of ambiguity of job positions and social status in the community promotes social harmony. It also defines the social roles of and expectations from the community members.
Role of the recovering addict as therapist. In most Oriental or Eastern cultures, academic credentials are preferred over experiential training. The contributions of the "recovering" person as therapist are not greatly appreciated, unless the person has a college degree in addition to personal experience. It requires a paradigm shift to consider, for example, a recovering addict or a recovered mentally ill person become therapists themselves.
Time orientation or temporal perception. Eastern culture has a fluid perception of time in contrast to Western society's highly structured time perception, "on time" versus "in time" orientation. Time orientation or how and when activities are implemented has implications in terms of operational efficiency and outcomes. The result-oriented and purpose-driven structure and schedule of the TC compel timeliness in order to comply with the demands and expectations of supporting and maintaining the community. Timeliness is observed across the board out of necessity, transcending cultural temporal perception.
The professional as TC staff. Many TCs outside the United States were founded by professionals who employed the services of TC-recovered ex-addicts as clinical staff along with professional staff. Working as a team, the combination creates a very progressive TC by exploiting the unique contributions of each.
Family. The importance of the family and their role in treatment in various cultures are evident in the popularity of family associations (Perfas 2012). Some TCs, such as in the case of Indonesia, were conceived by parents who originally sent their children to a Malaysian TC for treatment. In due time, they initiated a TC movement in their own country. Malaysian and Chinese TCs consider family and religion (spirituality) to be central to treatment (Bunt et al. 2010).

majority of TCs that depend upon public funding, planned duration of treatment has been reduced often *below the threshold* of time needed to yield positive outcomes. This adjustment to funding pressures potentially undermines the viability of the TC as a cost-effective modality in the health-care system.

63.2.11 Workforce

Issue: The expansion of the TC to serve special populations in special settings has resulted in a number of problems in the recruitment, retention, and development of experienced staff. General problems include low salaries, limited career goals, and difficult working conditions. However, a specific workforce issue arises from the

diversity of staff in TCs. The increased number of traditional professional staff from mental health and social services has posed a special challenge to the TC. Based on their education and training, traditional professional staff utilize concepts, vernacular, and methods that often counter or subvert the fundamental mutual self-help features of the TC. Moreover, most professionals and ex-addict paraprofessionals who work in TCs do not undergo rigorous and supervised training on the TC model and its practice.

63.2.12 Research

Issue: Despite decades of therapeutic community (TC) outcome research, some critics have questioned whether the TC is an evidence-based treatment for addictions. Given the relative lack of randomized, double-blind control trials, it is concluded that the effectiveness of the TC has not been "proven." Such conclusions contain serious implications for the acceptance and future development of the TC.

A new research agenda should build on the existing knowledge base that documents the contribution of the TC as a major health and human services modality. This agenda should include studies that demonstrate (a) *health and social benefits* (e.g., reduction in drug/alcohol use and social deviancy and increase in employment, education, and overall psychological well-being); (b) *cost-benefits* of both long-term TCs and shorter-term residential programs for specific subgroups of substance abusers; and (c) *collateral benefits* which refers to the *prevention* of trans-generational drug use, HIV, STDs, as well as family breakdown among treatment successes.

63.2.13 Treatment Fidelity

Issue: Understandably, TCs have pursued financial solvency by expanding to serve a wide variety of populations, e.g., mental health, homeless, corrections, juvenile justice, and child care. Contracts have obligated TCs to meet regulations of community, state, and federal agencies and often to incorporate practices based upon different professional views of treatment.

This expansion outward of the TC, however, has been at the expense of *inward* refinement of the approach itself. It is one thing to modify and adapt the TC for special populations, settings, and shorter durations of treatment. It is quite another to ignore the development of the TC's unique approach, *community as method*. Thus, if the TC is to retain its unique identity within mainstream human services, it must address the complex issue of treatment *fidelity*.

TC effectiveness and fidelity of treatment are closely related. High-fidelity treatment produces better outcomes (Dye et al. 2009). The key strategies needed to assure high-fidelity TCs are staff training based upon critical elements, teaching curricula grounded in a uniform definition of community as method, and appropriate training models that integrate didactic and experiential learning.

Table 63.3 Classification of TC programs

Standard TC programs. These are guided by the TC perspective, retain essential components of the program model, and utilize community as method as the primary approach. They are mainly housed in residential settings, with longer planned durations of treatments, serving the more severe substance abusers (primarily client driven).
Modified TC programs. These are guided by the TC perspective, incorporate essential components of the model, but adapt community as method for special populations (e.g., co-occurring disorders, criminal justice substance abusers, juveniles) and settings (hospitals, shelters, prisons). Key adaptations are more staff directed, greater emphasis on individual differences, moderated intensity of group process, and a more flexible program structure. Additionally, these programs incorporate strategies and services which have proven useful in addressing particular problems and special populations, including pharmacotherapy (e.g., methadone, buprenorphine, psychotropic medications) as well as varieties of counseling and family therapy (client and staff driven).
TC-oriented programs. These *are not* guided by the TC perspective and do not adhere to community as method. Typically, these serve less severe clients in short-term residential or day treatment settings and are eclectic in their approach. They select elements of the TC (e.g., community meetings, peer support group, etc.) but mainly utilize services and practices that are not specific to the TC (primarily staff driven).

63.2.14 Diversity of TC Programs

Issue: The TC approach and model has been successfully adapted and modified for various populations and settings. However, within the wide diversity of programs that represent themselves as TCs, many do not actually implement the TC approach that has proven successful. This often results in variable treatment outcomes and fosters misperceptions of the therapeutic community as an effective evidence-based approach. The credibility of the TC modality in health and human services will require classification of the diversity of programs as well as the development of standards of quality assurance.

63.2.15 Classification of TC Programs

The range of TC programs for substance abuse and related problems can be organized into three broad categories. These are based upon the extent to which a program is guided by the TC perspective (whole person, recovery, and right living), adheres to the approach (community as method), and retains essential components of the program model (see Table 63.3).

Thus, not all programs that label themselves as therapeutic communities are actually TCs. Clarification of differences in programs, the clients they serve, the goals of treatment, and the fidelity of the particular treatment strategies utilized, is necessary to preserve the integrity of the TC approach.

Finally, TCs worldwide are also undergoing many of the evolutionary changes described above, including modifications for special populations and particularly adapting to fiscal pressures to reduce time in residential treatment. A notable development is the rapprochement between the addiction TC and the psychiatric TC pioneered by Maxwell Jones that has been prominent in Europe. Both of

these TC approaches share many of the common elements of community as method to treat populations with both substance use and personality disorder. Nevertheless, maintaining uniformity and fidelity of the TC approach in light of these changes remains a challenge.

63.3 Conclusion

Arguably, the therapeutic community for addictions (TC) is the first formal treatment approach that is explicitly *recovery oriented*. Surely, AA and similar mutual self-help approaches facilitate recovery but these represent themselves as support, not treatment. Pharmacological approaches, notably, methadone maintenance, have as their treatment goal the reduction or elimination of illicit opiate use; and behavioral approaches, such as cognitive-behavioral therapy (CBT), contingency contracting, and motivational enhancement (MET), focus upon reduction, and not necessarily abstinence and recovery, in targeted drug use. In the TC perspective, however, the primary goal of treatment is *recovery* which is broadly defined as changes in lifestyles and identities.

Thus, in the current context of substance abuse policy and issues (e.g., various treatment options, harm reduction strategies, the economic pressures on health care), the overarching challenge of the TC is to reassert its unique place and mission – that of promoting recovery and right living.

Spiritual Aspects of the Twelve Step-Method in Addiction Treatment

64

Marc Galanter

Contents

Abstract

This chapter is directed at defining the nature of spirituality and its relationship to empirical research and clinical practice. A preliminary understanding of the spiritual experience can be achieved on the basis of diverse theoretical and empirically grounded sources, which will be delineated. Furthermore, the impact of spirituality on addiction in different cultural and clinical settings is explicated by illustrations of its application with regard to Alcoholics Anonymous.

64.1 Introduction

64.1.1 AA as a Spiritual Recovery Movement

How does spirituality relate to recovery from addiction? There is a parallel between the way attitudes are transformed in intensely zealous groups and the way the denial

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment: International Perspectives*, DOI 10.1007/978-88-470-5322-9_53,

of illness and the self-defeating behaviors of alcoholics and drug addicts may be reversed through induction into Twelve-Step groups like AA.

Members of the lay public may conclude that certain healthcare issues are inadequately addressed by the medical community, particularly when doctors are not sufficiently attentive to the emotional burden that an illness produces. When mutually supportive groups of laymen coalesce to implement a response to this perceived deficit, they may form a spiritual recovery movement (Galanter 1997), one premised on achieving remission based on beliefs independent of evidence-based medicine. Such movements may ascribe their effectiveness to higher metaphysical or nonmaterial forces and claim to offer relief from illness.

AA can be considered as a highly successful example of a spiritual recovery movement, as such movements have three primary characteristics. They (a) claim to provide relief from disease, (b) operate outside the modalities of established empirical medicine, and (c) ascribe their effectiveness to higher metaphysical powers. The appeal of such movements in the contemporary period is due in part to the fact that physicians tend not to attend the spiritual or emotional concerns of their patients (Galanter 2005).

Clearly, the attitudes and behavioral norms that AA espouses are much more in conformity with the values of the larger culture than those of zealous religious sects. The expectation of avoiding drunkenness in AA, normative in our culture, illustrates this. People who are highly distressed over the consequences of their addiction are therefore candidates to respond to the strong ideologic orientation of AA toward recovery and are operantly reinforced by the relief produced by affiliation with the group's ideology and behavioral norms, all related to abstinence and a spiritually grounded lifestyle. Significantly, AA generates distress in its members by pressing them to give up their addictive behaviors, but the distress associated with this conflict is relieved if they sustain affiliation and cleave to the group.

64.2 Spiritual Aspects

64.2.1 Spirituality as a Psychological Construct

Two empirically grounded perspectives have played a material role in framing how we conceptualize recovery. One derived from a model of psychopathology modeled on the work of Emil Kraeplin (1902). He framed an approach that now characterizes the contemporary medical model for mental disorders, categorizing disease entities diagnosed on the basis of explicit and discrete symptoms. This approach is evident in the development of criteria for substance use disorders employed in recent editions of the symptom-based Diagnostic and Statistical Manual of Mental Disorders (American Psychiatric Association 2000). From this perspective, a state of remission, colloquially called recovery in rehabilitation circles, can take place with the resolution of the specific symptoms listed as diagnostic criteria. A second perspective on recovery derives from behavioral psychology, whose model of stimulus-response sequences has led to the ordering of experience around discrete

phenomena that can be observed by a researcher or clinician. From this perspective, recovery can also be defined in terms of observable, measurable responses to substance use, lending credence to recovery as a process defined in behavioral terms.

Both perspectives are well suited to the study of psychopathology and have lent the addiction field approaches to studying addiction as a disorder, one that is compatible with research approaches employing experimental controls that are used in the physical and biological sciences. Both have therefore had heuristic value in promoting a research field that has yielded many advances in addiction treatment. There is a third perspective, however, that is defined on the basis of addicts' reports of their own subjective experience. These experiences are not directly observable by the clinician but are available only as reported through the prism of the person's own introspection and reflection. This model is more difficult to subject to measurement, but instruments are being developed that can be applied for its study, as will be discussed below. This approach is inherent in the spiritually oriented psychology of Carl Jung (1978), who had a direct influence on Bill W's framing of the Alcoholics Anonymous ethos (Cheever 2004). William James (1929), often described as the father of American psychology, also discussed mental phenomena in terms of subjectively experienced mystical or spiritual experience. (In fact, he wrote that "the drunken consciousness is one bit of the mystic consciousness" [p. 378].) The need for spiritual redemption was vital in the writings of Viktor Frankl, who wrote *Man's Search for Meaning* (1984), and has recently been espoused with regard to psychotherapy by William Miller (1999).

This third perspective is related to the model of spiritually grounded recovery we will discuss here, insofar as it emphasizes the achievement of meaningful or positive experiences, rather than a focus on observable, dysfunctional behaviors. Research on this third approach would typically rely on self-report scales, such as those which can be facilitated by development of instruments like the Life Engagement Test (Scheier et al. 2006); the General Well-Being Schedule (Dupuy 1972); or our own Spiritual Self-Rating Scale (Galanter et al. 2007). We will consider its role in AA, models for how it takes place, and ways it can be measured. In this respect, recovery can be understood as a process whereby an abstinent addicted person is moving toward a positive adaptation in life. This movement can take place with varying degrees of success, depending on the person's own innate capacities and the circumstances in which they find themselves.

64.2.2 Spirituality and Religious Experience

The relative role of spiritual experience in the Twelve-Step recovery process has been investigated from a variety of perspectives, generally in relation to patients' experience in AA. Kelly et al. (2009) reviewed studies that applied mediational tests to ascertain how AA achieves beneficial outcomes and found little support for a role of AA's specific spiritual mechanisms. In fact, with regard to religiosity, Tonigan et al. (2002) found that, although atheists were less likely to attend

AA meetings, those who did join derived equal benefit as did spiritually focused individuals. On the other hand, in one study on persons recovering from cocaine dependence (Flynn et al. 2003), respondents attributed their positive outcomes to religion and spirituality. Additionally, Zemore (2007) followed up a large sample of substance abusers 1 year after inpatient treatment and found that increases in spirituality contributed to the increment in total abstinence associated with Twelve-Step involvement.

Our own experience, as well, is compatible with these findings, as we have found in multiple settings (Galanter et al. 2012, in press a, b) that spirituality is integral to recovery in Twelve-Step groups. This was particularly evident among long-term members.

64.2.3 Spiritually Grounded Recovery in AA

The AA "program of recovery" is mentioned in numerous places in the Big Book, *Alcoholics Anonymous* (Alcoholics Anonymous World Services 1955), and is associated there with terms such as "spiritual experience" and "spiritual awakening" and with working AA's Twelve Steps. Four of the steps include the word God, which is qualified "as we understood Him." Some clarity is lent to this latter phrase in the Big Book where it is pointed out that "with few exceptions, our members find that they have tapped an unsuspected inner resource which they presently identify with their own conception of a Power greater than themselves" (p. 569–570). Flexibility on the issue of theistic belief is also made clear in one chapter that addresses any alcoholic person "who feels he is an atheist or agnostic," encouraging their membership as well. The text points out for these members that even "We Agnostics. . .had to face the fact that we must find a spiritual basis for life" (p. 44) in order to achieve recovery, implying therein the fellowship's distinction between spirituality and theistic religion.

This issue of theistic connotation, however, is as yet resolved relative to the judicial system, where the application of AA is sometimes constrained because of potential church/state conflicts. It is open to question, however, whether the theistic connotations of AA can be modified without vitiating the program's effectiveness. In this relation, it should be noted that in a 5-year follow-up of recovering cocaine-dependent patients, the strength derived from religion and spirituality significantly distinguished between those who had a highly favorable outcome from those who did not (Flynn et al. 2003). Additionally, attendance at religious services distinguished significantly between criminal justice clients referred for substance abuse treatment who had a positive outcome and those who did not (Brown et al. 2004).

Spirituality among long-term members is likely instrumental in sustaining the integrity of the fellowship itself. The prominence of spiritually committed long-term members at meetings, and their availability to serve in the sponsorship role creates readily available models for earnestly held sobriety. They serve as role models for believing commitment to the Twelve-Step spiritual ethos to help

newcomers achieve stabilization in membership. Nonetheless, some people attending NA meetings may find it hard to identify with the spiritual orientation of long-term members.

In the clinical context, recovery is based on a person's behavioral and physiologic status, which can be assessed by recourse to criteria employed in the DSM. Some of these criteria are also embodied in the Addiction Severity Index (McLellan et al. 1992), which is employed widely in research to evaluate recovery. These items can be assessed relatively easily, as they are premised on observable behavior or delineated by symptomatology described by patient, family member, or clinician.

A spiritually grounded definition of recovery, however, can be useful as well. Such a concept relates to the importance of non-demographic subject factors, originally proposed as "quality-of-life" issues (Campbell et al. 1976) – among which spirituality can be considered. In this context, a series of suitable criteria for "diagnosing" addiction (a more apt term than "substance dependence") could be developed. They could then be used to assess the spiritual aspect of recovery associated with the Twelve-Step experience. Resolution of these issues could be considered as important to the spiritual aspect of recovery from addiction. A series of criteria could include items such as:

- Loss of sense of purpose due to excessive substance use
- A feeling of inadequate social support because of one's addiction
- Continued use of a substance while experiencing moral qualms over its consumption
- Loss of the will to resist temptation when the substance is available

Another aspect of the DSM format can be considered as well. The manual stipulates "course specifiers" of remission such as "on agonist therapy" and "in a controlled environment." These are included because they are explanatory to the clinician. To them could be added "fully engaged in a program of Twelve-Step recovery," which would be equally explanatory to many clinicians.

But are spiritually grounded criteria measurable? In recent years, methodologies have been developed and validated that could be used to assess outcome based on such subjectively experienced criteria. They employ a systematic approach to measurement and can be used to describe spiritually related states:

A. **Affective state:**
   (i) A sense of well-being, measured by the General Well-Being Schedule (Dupuy 1973) (which we employed) or the Subjective Happiness Scale (Lyubomirsky and Lepper 1999).
   (ii) Contentment with one's life circumstances, measured by the Satisfaction with Life Scale (Diener et al. 1999).
   (iii) Positive affect, assessed with the Positive and Negative Affect Schedule (Watson et al. 1988), dealing with both variables as separate dimensions, rather than bipolar ends of the same scale.
   (iv) Feelings of support, employing a Scale for Perceived Social Support (Cohen et al. 1985).

B. **Existential variables:** Meaningfulness in one's life: assessed by the Purpose in Life Test (Crumbaugh and Maholick 1969).

C. **Flow**: The experience associated with engaging one's highest strengths and talents to meet achievable challenges, as measured by Experience Sampling (Csikszentmihalyi and Larson 1987) or the Flow Scale (Mayers 1978).
D. **Spirituality:** The Spirituality Self-Rating Scale, which we developed and applied to both substance-abusing and non-substance-abusing populations (Galanter et al. 2007), as well as other such scales. By means of our own scale, we were able to distinguish different populations of substance abusers' level of spiritual orientation from the of non-substance populations.
E. **Personality assessment**: The Classification of Strengths (Peterson and Seligman 2004), a series of characteristics based on categories of moral excellence drawn from observations across different cultures.
F. **AA involvement:** Measures of the degree of affiliation and commitment to the AA fellowship (Humphreys et al. 1998).

A methodology for defining recovery based on measurements like these may not have the same appeal to biomedically oriented clinicians as does the conventional symptom-based approach, as these measurements are based on self-report of the person's subjective state. Furthermore, the enthusiasm of newfound recovery may yield a Hawthorne effect. The biomedical format currently applied in diagnosis derives from the school of Kraeplin and subsequent investigators like those who developed the Feighner criteria (Feighner et al. 1972) in the 1970s and then in the ensuing DSM system. Spiritual variables, however, have a lineage as well, from William James, Carl Jung, and Bill W.

64.2.4 AA in the Professional Context

The spiritually oriented Twelve-Step approach has been integrated into professional treatment in some settings where it serves as the overriding philosophy of an entire program or, in others, where it is one aspect of a multimodal eclectic approach. The Minnesota Model for treatment, typically located in an isolated institutional setting, is characterized by an intensive inpatient stay during which a primary goal of treatment is to acculturate patients to acceptance of the philosophy of AA and to continue with AA attendance after discharge (Cook 1988). Although a variety of exercises are included during the stay, this approach has been criticized as dogmatic because of its sole reliance on the Twelve-Step approach. The outcome of this model, however, has been shown to yield positive results in a survey of patients discharged from one such setting (Hazelden, in Center City, MN) (Stinchfield and Owen 1998), but randomization of patients treated in Minnesota Model facilities with those treated by means of an alternative approach is needed.

A more eclectic option is illustrated in the integration of Twelve-Step groups into a general psychiatric facility for the treatment of patients dually diagnosed for major mental illness and substance abuse. The importance of spirituality in such a highly compromised population was evidenced in our studies (Galanter et al. 2007) in which such patients ranked spiritual issues like belief in God and

inner peace higher than tangible benefits like social service support and outpatient treatment. One inherent advantage of this format is that it benefits from the introduction of an inspirational approach to patients who, as Goffman has pointed out (1963), have become "degraded" by stigmatization due to their psychiatric disorders.

In summary, spirituality is a matter of personal meaning that is widely accepted. It is also central to the recovery process from addiction for many AA members. The fellowship of AA, in fact, can be considered a movement developed in relation to people's spiritual needs. Although spirituality is subjectively experienced, it can be assessed systematically in given individuals by employing currently available empirical techniques. By such means, an important aspect of addiction recovery can be defined and studied.

Contents

Abstract

Japan has rapidly developed in the economic field following World War II. Simultaneously, alcohol and drug dependence have been serious problems for several decades. To deal with such problems, indigenous self-help and mutual-help organizations for alcohol and drug dependence have been founded and developed.

Danshukai is the most widely spread organization of self-help and mutual help for alcohol dependence throughout Japan. Its early activities were inspired by AA (Alcoholics Anonymous) and have been translated into the Japanese context. The membership of Danshukai has reached double the number of AA participants in Japan but has gradually tapered off in recent years. The consistent slogan of Danshukai is "one-day abstinence," which means that the members promise themselves that they will not drink alcohol on that day.

The DARC (Drug Addiction Rehabilitation Center) system was developed originally in Japan. DARC was formed as a rehabilitation facility with a community of drug-dependent associates in Tokyo. Such communities have been formed in many cities in Japan. The activities of DARC not only have

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment: International Perspectives*, DOI 10.1007/978-88-470-5322-9_54,

extended to the rehabilitation for drug dependence but also encompass the approach to various drug addiction problems, such as consultation for and education in drug problems.

65.1 Introduction

Alcohol and drug misuse have created social, medical, and economic problems for several decades in Japan. Both formal and informal interventions for these problems have been conducted. Many facilities have developed systems to meet the therapeutic needs associated with alcohol and other drug misuse.

Japan has a particular language, culture, and tradition. In earlier eras, the Japanese were gifted at translating various cultures from China or Western countries into the Japanese context. These trends have been inherited by modern Japanese society and systems. Rehabilitation programs and organizations aimed at treating alcohol and drug addiction in Western countries have been modified to suit the Japanese context. Particular mutual aid support groups for alcohol and drug addiction also spread throughout Japan. Here, we introduce these distinctive mutual-help organizations in Japan.

65.2 Support Groups

65.2.1 Danshukai

In Japan, there are currently two major self-help groups for alcohol-dependent individuals. The first is AA (Alcoholics Anonymous), which was introduced from the United States. The second is the Japan Sobriety Association "Danshukai," which is an indigenous and distinctive organization in Japan.

Danshukai was founded in the city of Kochi in November 1958 and has spread throughout Japan since 1965. Its early activities were inspired by AA and have been translated into the Japanese context. The number of members reached approximately 10,000 individuals at the beginning of the 2000s, which was double the number of AA participants in Japan. However, the number of Danshukai participants reached a plateau and has gradually tapered off in recent years, partly because the number of medical institutions treating alcohol dependence has increased and an extended medical support system has been developed for alcohol-dependent patients. In April 2012, the number of Danshukai members decreased to 8,500 (Zendanren 2013). The members belong to one of the 556 nationwide community-level "Danshukai." Most cities and towns have one or more of these community-level Danshukai. Therefore, knowledge of Danshukai for alcohol-dependent individuals has spread widely among the general public, although the precise roles and activities are not necessarily known.

Instead of the 12 steps of AA, Danshukai has 7 principles (Zendanren 2012):

1. We should confess that we are helpless against alcohol and that we could not do anything by ourselves.

2. We should attend regular meetings and speak about ourselves honestly.
3. We should remember our past experiences and failures that have been caused by alcohol. We should gain insight about ourselves by listening to other members' experiences.
4. We should respect others' personalities and realize that we can remain abstinent through our connections and trust in the group.
5. We should try to reform ourselves and create a new life.
6. We should provide compensation to our family and to those whom we have troubled.
7. We should speak about our pleasure in remaining abstinent to others suffering from alcohol harm.

AA emphasizes the need for a "higher power" to recover from failures caused by alcohol. Many Japanese cannot easily accept religious concepts based on Christianity, since many Japanese believe in polytheism. Therefore, Danshukai does not underscore the importance of religious power, but instead emphasizes the mutual help and unity provided by the group and the importance of compensation for the members' family. The concept of Danshukai is more familiar to Japanese people. This is one of the primary reasons that Danshukai activities have spread throughout Japan.

Danshukai has several original characteristics, compared with AA (Higuchi and Kono 1994). Danshukai has been incorporated and administrated by fees from members and external financial assistance. The activities of Danshukai have been supported by the Health Care Authorities in each district. Danshukai has a strict hierarchy system from the community level to the national level. Daily activities are at the center of each community-level Danshukai, which consists of several members to dozens of members. These community-level Danshukai belong to a prefectural Danshukai that in turn belongs to the All-Japan Federation. Danshukai at each level elect a president and executives, and they independently administer each community group and hold meetings (Table 65.1).

While AA meetings are strictly anonymous, Danshukai demand that participants introduce their names to the community. Danshukai members believe that exposing oneself, including one's name, one's family, and one's private life, is essential to recovering from alcohol dependence. The attendance of family members is also encouraged, because Danshukai consider spouses to play a major role in the continued abstinence of alcohol-dependent individuals. The attendance of couples facilitates communication, resulting in the recovery of family relationships. These philosophies of Danshukai are familiar to middle-aged and elderly men, especially in the rural areas. There were 3,800 family members (primarily wives) participating in Danshukai in 2012.

On the other hand, alcohol-dependent women and adolescents are inclined to resist the philosophy of Danshukai. The number of female members was about 800 in 2012. Only 160 Danshukai members had enrolled while they were in their teens or 20s. In 2012, only 47 Danshukai members were in their 20s, and none of the members were in their teens. The decrease in membership has become one of the greatest problems faced by Danshukai. Their philosophy and system must adapt to

Table 65.1 Comparison between Danshukai and Alcoholics Anonymous in Japan

Characteristics	Danshukai	Alcoholics Anonymous
Members	Approximately 8,500	Approximately 4,700
Basic policies	Attendance at regular meeting	Attendance of meetings
	"One-day abstinence"	Twelve steps and twelve traditions
Spirituality	The unity and solidarity in the community are emphasized	A "higher power" that is greater than the individual is respected
Anonymity	Non-anonymity	Anonymity
Family	Families are encouraged to attend meetings	Al-Anon are held for family members
Establishment	Founded in Kochi city in November 1958	Founded in Tokyo in March 1975
Activity	Activities have expanded nationwide. Support has been obtained from Health Care Authorities	Activities have spread to peoples of various social levels, but are still limited to large cities
Organization	Danshukai is incorporated and is operated as an organization, forming a hierarchical system	AA has a flat organizational structure
		Local committees are formed by representatives of each group
Financial base	Fees from members	Contributions by members
	Financial assistance and donations from external sources	Sale of publications
		No financial assistance or donations from external sources are accepted
Office	Federation of Japan Sobriety Association, Tokyo	AA Japan General Service Office (JSO), Tokyo

meet the needs of the times. Danshukai has started activities to increase the number of members. They have held meetings for alcohol-dependent women only. Recently, they have received alcohol-dependent adolescents with multiple problems, such as drug dependence or eating disorders. Moreover, Danshukai meetings have been frequently held in the afternoon for retired members or unemployed members who are free during the daytime. Those who have physical disabilities or gait disturbances can also easily attend the daytime meetings (Wake 2013).

One of the most important tasks of members is to attend regular meetings. Meetings are usually informal and almost all are open (i.e., available to anyone). Members talk about their stories caused by drinking. While feature discussions are sometimes held, general discussions account for most of the meeting time. The core regulation of the meetings is "just speaking and listening." The members talk about their present condition or problems with alcohol in turn, and others must not interrupt their speech. Other members, except for the speaker, just listen. In principle, they are not allowed to criticize or encourage, even if the speakers confess their re-drinking or complain of their circumstances. Just talking about one's self and just listening to other members' speech lead to a sense of relief and an awareness that they have similar alcohol problems. Members can share the recognition that the troubles caused by alcohol are not unique to themselves, helping them to realize that they are not alone. Members can begin to help each other,

because they are companions who have undergone similar catastrophes. The sense of solidarity and responsibility is a motivating power to prevent members from drinking. AA members are encouraged to find an experienced individual, called a sponsor, who can help them to understand and follow the AA program. Although Danshukai members do not have such a sponsor, they receive mutual help as well as advice and support from other members as needed.

Regular meetings are held once every day, once a week, or once a month. The frequency of meetings is arbitrarily decided by each community-level Danshukai. A member is able to join a meeting held by another community apart from their home-affiliated community. Therefore, members in urban areas can easily attend meetings held in different spots. Members who have just started abstinence or who are continuing to drink are recommended to take part in meetings more frequently to avoid drinking. Through the meetings, members are able to recover their sensitivity and develop social skills.

The other important task is to maintain "one-day abstinence," which is a consistent slogan of Danshukai. Although abstinence should be maintained as long as possible, it is very difficult for alcohol-dependent individuals to achieve such a goal. To maintain abstinence, members pledge "one-day abstinence," which means that they will not drink alcohol on that day. Maintaining "one-day abstinence" can result in lifetime abstinence. Today, Danshukai members are trying to maintain abstinence by pledging "one-day abstinence."

Little evidence of the efficacy of Danshukai is available. Since participation in Danshukai meetings is voluntary and is not randomly allocated, a controlled study is very difficult to do. Two opposing self-selection biases may exist: (1) participants in Danshukai might have sufficient motivation to change their drinking habits, and (2) participants in Danshukai might have severe and refractory alcohol problems.

A longitudinal follow-up study of 133 alcohol-dependent Danshukai members was previously conducted in a rural area in Japan (Doi 1987). The ratio of newcomers who attended more than three meetings was 45.6 % during a 10-year period. More than half the members dropped out after participating in the meetings only once or twice. Twenty-five of the 133 participants who attended more than three meetings remained abstinent for over 2 years. The ratios of attendance and abstinence were relatively high, compared to another longitudinal follow-up study of AA meetings (Pagano et al. 2013), partly because medical staff played a role in the study. Eighteen of the 133 attendants died during the 10-year period.

65.2.2 DARC (Drug Addiction Rehabilitation Center)

In Japan, drug dependence is also a serious problem, in addition to alcohol dependence. Amphetamines and methamphetamines have been the most widely used illegal drugs. Recently, the use of new strong composite types of illicit compounds, which are comprised of various ingredients such as cocaine, heroin, marijuana, and so on, has begun to spread among young people in urban areas. Benzodiazepines are popular among various generations, especially among

individuals with serious anxiety and depressive moods. Actually, drug dependence has long been a problem in Japan, dating back to the 1950s.

DARC is an acronym for "Drug Addiction Rehabilitation Center." DARC consists of rehabilitation facilities for drug-dependent individuals (Tokyo DARC Support Center 2010). DARC members can use the facilities to recover from drug dependence over the course of several months to years. Members are able to receive physical, mental, and social support from DARC while they learn to live without drugs.

DARC was founded in 1985 by a drug-dependent patient. The patient provided an old house in Tokyo and formed a community with other drug-dependent associates (Kondo 2000). They started a rehabilitation program for drug dependence in their community. The program was a modification of the 12 steps of AA and emphasized group meetings. The goal of the program is not only to stop drug use but to recover their human nature, such as expressions of sympathy, kindness, and honesty. As of 2013, about 50 communities exist around Japan. The activities of DARC are independently practiced in each community. This diversity of activities among each community is an outstanding characteristic of DARC.

Member candidates of DARC are introduced through many pathways including lawyers, police officers, welfare, psychiatric hospitals, public health centers, and so on. Some members voluntarily enter DARC on their own. In many cases, they are brought to DARC by their families. About 90 % of the members have experienced medical care for a drug-related problem. About 70 % have been arrested prior to participating in DARC. Members in their 20s or 30s account for 80 % of DARC members. Usually, 12–13 years since their first drug use have elapsed at the time of a member's first DARC meeting (Nishimura 2004).

DARC members must generally live jointly with other members in a community house for 3 months to over 1 year and complete the residential program. They can then attend DARC meetings after they have left the community house. Members must pay a fee every month. The activities of DARC are administered using the membership fees. Since anonymity must be maintained within the community, DARC members use nicknames when speaking with each other. All members have an equal status in DARC and are free from social positions.

The only rule of DARC is regular participation in the meetings. Members are obliged to participate in morning meetings, afternoon meetings, and evening NA (Narcotics Anonymous) meetings. DARC is strongly connected to NA. Members are recommended to continue attending NA meetings after the completion of the DARC program. DARC does not necessarily force its members not to use drugs, but it encourages them to cultivate their independence and responsibility.

Even if members encounter problems, such as the reuse of drugs, they must participate in the meetings and tell their problems to the other members honestly. In their relationships with other members, they can share their distress, loneliness, and emptiness that resulted in their drug use or that were caused by drug use. They are also able to acquire the ability to communicate with others and to experience alternative lifestyles without drug use through the DARC program. The slogan of DARC members is "just for today," which means not using drugs today and doing their best today. Today without drugs will certainly lead to a clean future.

Table 65.2 Role and activities of DARC

Social	1. Nongovernmental organization
	2. Enlightenment of general public regarding drug problems
	3. Reduction of social and economic losses
Medical	1. Community for the treatment of drug dependence
	2. Awareness regarding the necessity of rehabilitation for individuals with drug dependence
	3. Information center for drug problems
	4. Primary care for drug dependence
	5. Training of counselors for mutual help
Judicial	1. Diversion from restraint to rehabilitation for drug dependence
	2. Support of defense for crimes caused by drug use
	3. Care program after release from prison
Welfare	1. Transition support for employment or schooling
	2. Consultation for drug problems
	3. Cooperation with the public administration
Educational	1. Education of risk for drug use to students
	2. Instruction regarding coping with drug problems to teachers or school staffs

Many members drop out of the program and return to a drug-dependent lifestyle. However, any member can resume the DARC program whenever they decide to stop drug use once again. DARC does not exclude those who slip into the reuse of drugs. Less than 1 % of the members have never resumed drug use after taking part in DARC. However, 30–35 % of members continue to attend NA meetings, even if they resume drug use several times along the way (Kondo 2000). Some members can become staff members who manage the DARC program after the completion of staff training. The staff and program members are equal and support each other to prevent drug reuse.

DARC also addresses various addiction problems. Therefore, the role of DARC has extended into various fields (Table 65.2). Members have spoken about their experiences with drug use in schools to prevent young people from using drugs. DARC has trained some members to be addiction counselors who can sympathize with people who cannot help being addicted to drugs. Through such campaigns, the activities of DARC have become known among medical, judicial, and educational staffs. The outlook of DARC emphasizing rehabilitation has spread, and DARC activities are expected to expand throughout Japan so that many people who suffer from drug dependence can participate in rehabilitation programs to recover, instead of being isolated in prisons or hospitals. Such interventions are critical for those who are afflicted with drug abuse.

Addiction Recovery in Services and Policy: An International Overview

66

Alexandre Laudet and David Best

Contents

Abstract

This chapter provides an overview of the sweeping changes occurring in the addiction field in the United States and abroad, with special emphasis on the growing focus on recovery as the goal of services and the guiding vision of drug policy. "Recovery" goes well beyond substance use patterns to encompass improved functioning in life areas impaired by active substance use, as well as improved overall quality of life. Because research shows that substance use disorders are often chronic, recovery is

conceptualized as a process that unfolds over time and requires a continuing care approach. We describe emerging service models including Recovery-Oriented Systems of Care (ROSC) and peer-driven recovery supports and review the implications of this new orientation for service providers and evaluation research. We conclude with some recommendations on strategies that medical professionals can use to promote recovery among substance-using patients.

Recovery • Peer support • Addiction • Treatment

66.1 Introduction

As healthcare is changing on a number of fronts, healthcare professionals are grappling with new systems and care models while continuing to diagnose and treat human conditions that are, in many cases, as old as the human race. Substance use, abuse, and dependence is likely one such condition. However, the way society views it has changed over time – from moral failing or crime to chronic brain disease (McLellan et al. 2000). Parallel with these changes come changes in how addiction is addressed by systems and healthcare providers. In this chapter, we describe and discuss the increasingly popular "recovery" orientation to substance use problems: a model where the desired outcome goes beyond changes in substance use to a broader notion of improved personal functioning and quality of life. After describing the model and corresponding services, we end with a brief discussion of consequences of this new orientation for healthcare professionals.

66.2 Recovery Becoming Guiding Vision of a Substance Use Services and Policy

Treatment systems addressing substance use disorders (SUDs) and the federal agencies regulating them (e.g., in the United States, SAMHSA – the Substance Abuse and Mental Health Services Administration) have begun to effect a shift in their emphasis, with recovery becoming the guiding framework. There are two key, empirically based elements to this paradigmatic shift: the reconceptualization of SUD as chronic disorders and the broadening of what "recovery" means. First, research in the past decade has suggested that addiction is best conceptualized as a chronic disorder on par with other chronic conditions such as diabetes, asthma, or hypertension (McLellan et al. 2000). However, unlike these other conditions, treatment for substance use disorders (SUDs) has historically been delivered and evaluated using an acute care model: intense episodes of care during which a person, often in crisis, is assessed, treated, and released – ideally "cured" – all in a relatively short time (Dennis and Scott 2007). Growing evidence for long addiction and treatment "careers" consisting of multiple cycles of intensive and

costly treatment episodes (Dennis et al. 2005) followed by return to active addiction (Scott et al. 2005) has led to the conclusion that the acute care model is ill suited to address SUD as a chronic condition (Hser et al. 1997; McLellan et al. 2005a; O'Brien and McLellan 1996). Noting the disappointing outcomes of the current system and the many similarities between SUD and other chronic illnesses, the Institute of Medicine and leading addiction researchers have called for SUD treatment to shift from the acute care model to one of recovery management akin to the chronic care model used in the treatment of other chronic conditions (Dennis and Scott 2007; Humphreys 2006; Institute of Medicine 2005; McKay 2005; McLellan et al. 2000; Miller 2007; White et al. 2002, 2005b). A continuum of care model consistent with chronic disease is also aligned with the experience of persons in recovery who overwhelmingly describe recovery as "a process" vs. "an end point" (Laudet 2007).

The second element of the paradigmatic shift to a recovery orientation is rooted in the growing recognition that recovery goes well beyond making changes in one's substance use patterns (see next section). McLellan and colleagues may have put it best where stating: "typically, the immediate goal of reducing alcohol and drug use is necessary but rarely sufficient for the achievement of the longer-term goals of improved personal health and social function and reduced threats to public health and safety – i.e., recovery" (McLellan et al. 2005b, p. 448). Thus, the emerging recovery-oriented model of care provides a continuum of service and support designed to promote and sustain improvements in substance use (abstinence or significant reductions) and psychosocial functioning. This recovery framework reconciles a public health response to chronic care with a strength- and community-based focus that places the individual at the heart of their own recovery journey and emphasizes personal empowerment and individual ownership of the definition of and pathway to recovery. Promoting recovery requires giving individuals the tools and strategies to develop "capital," a strength-based approach that has gained prominence in both psychology (Seligman 2003) and criminology (Ronel and Elisha 2011) and is embodied in the addiction field by the construct of "recovery capital" (Granfield and Cloud 2001).

The emerging emphasis on recovery in addiction services is paralleled by a similar shift at the federal policy level. In the United States, the President's National Drug Control Strategy emphasizes the importance of promoting recovery, regardless of pathway (Office of National Drug Control Policy 2011) and calls for the expansion of recovery support services across community-based settings. The White House Office of National Drug Control Policy (ONDCP, the so-called drug tsar office) has also begun several interagency initiatives that emphasize the centrality of the recovery orientation to addressing SUDs, the need for recovery support services, and the importance of eliminating legal barriers to recovery (e.g., restrictions on housing and student loans for persons with a drug-related criminal history). For example, ONDCP is working in the US Department of Education that adopted the goal of providing a continuum of recovery supports at all levels in academic settings (Dickard et al. 2011). ONDCP has created a Recovery Branch to coordinate these efforts and engage federal partners, state

and local governments, membership and advocacy organizations, service providers, and other stakeholders in the design and development of policies, systems, services, communication campaigns, and other activities that support long-term recovery (Office of National Drug Control Policy 2011).

The growing emphasis on recovery-supportive services and policy unfolding in the United States is also observed in other countries. The United Kingdom is undergoing its own system transformation at the service and policy levels (Best 2012; United Kingdom Drug Policy Commission Consensus Group 2007). The UK Home Office that oversees most drug and alcohol policy in England and Wales has endorsed recovery as a goal of treatment services (HM Government 2010). That has been seen as a core component of the government "personalization" agenda, although the impetus for change has arisen in part from a dissatisfaction with the effectiveness of drug treatment in England and Wales (Easton 2008; McKeganey 2010). This shift in the United Kingdom followed an earlier change in Scotland, whose government's "Road to Recovery" (Scottish Government 2008) is a blueprint to system transformation. The origins of SUD recovery orientation were different in Scotland from England, with the policy document citing the success of the mental health recovery movement in Scotland, in particular its coordinating organization, the Scottish Recovery Network (Scottish Government 2008). In England, the policy shifts reflect the unique recovery context – i.e., the mounting critique of a treatment system predicated on low-intensity treatments (Best 2012) and a dissatisfaction with the prevailing treatment system and philosophy. In both countries, this was combined with a growing awareness of the burgeoning US recovery movement and a baseline of recovery activity in mutual aid and therapeutic communities to drive practice and policy change.

Most recently, seeds of transformation are also being planted in the Australian state of Victoria where the second author (DB) is spearheading a growing number of recovery initiatives including the promotion of policy change, the challenge of stigma through recovery walks and other events, and the development of a -university-based teaching and research program on recovery (Recovery Academy Australia 2012). This has resulted in a state-level reform road map (Victorian Department of Health 2012) where the principles of recovery are prominent and will drive the restructuring of the treatment system.

66.3 What Does "Recovery" Mean?

The term "recovery" has been ubiquitous in the substance abuse field for half a century if not longer but, until recently, had remained undefined. Researchers typically operationalized the term in studies by measuring short-term abstinence (typically a year or less), some from a single substance (e.g., alcohol) and others from all substances (for a discussion, see Laudet 2007). The field began to delve into the meaning of "recovery" in 2005 when the Center for Substance Abuse Treatment (CSAT), a division of the Substance Abuse and Mental Health Services Administration (SAMHSA), convened a panel of experts representing a number of key stakeholder

groups (Center for Substance Abuse Treatment 2006). The following year, the Betty Ford Center convened a smaller panel of experts and stakeholders that published the first consensus definition of "recovery" as "voluntarily maintained lifestyle composed characterized by sobriety, personal health, and citizenship" (Belleau et al. 2007, p. 221). Other definitions have since been formulated, but all share the premise that SUD recovery goes well beyond the reduction of/desistance from substance use and extends to improved functioning in key life areas typically impaired but active use. Stated differently, one can regard recovery as currently conceptualized as non-problematic substance use (or total abstinence) *plus* improved functioning in such areas as physical and mental health, employment, economic, family, and social life, to name only a few. Central to this new model is that recovery is a dynamic and individual process whereby the combination of factors defining recovery is individually determined and may well change over time as recovery progresses.

66.4 What Does Adopting a Recovery Orientation Mean for Addiction Treatment Services?

Broadly stated, the two elements of the paradigmatic shift discussed above mean that SUD services need to be expanded in time, in philosophy, and in scope. In terms of time, SUDs have thus far been addressed using intensive, short-term episodes of professionally delivered services in in- and/or outpatient settings. While the effectiveness of treatment has received support (Waldron and Turner 2008; Weisner et al. 2003b), the rate of return to active use following treatment, even among those who had achieved abstinence (the goal of treatment in the United States), is high (Dennis et al. 2005; Laudet et al. 2007; McLellan et al. 2005a). This typically leads to treatment reentry (be it in the community or in jail settings) as well as to numerous costs to the individual, to his/her community, and to society. On the other hand, there is evidence that participation in ongoing recovery support – typically 12-step fellowship meetings such as Alcoholics Anonymous, often the only available community-based recovery support resource until very recently but also less structured forms of community engagement and activities – is associated with decreased rates of return to active substance use (Fiorentine and Hillhouse 2000; Kyrouz et al. 2002; Laudet et al. 2007; Tonigan 2008) and with utilization of costly services (Humphreys and Moos 2001, 1996). Taken in a broader context, the empirically demonstrated usefulness of mutual aid recovery support groups emphasizes the importance of peer and most notably the critical role on ongoing support to sustaining recovery (see later section).

In terms of scope, a recovery orientation requires the provision of comprehensive services designed to address needs in all life areas that are typically impaired during active addiction and where improvements are considered an inherent part of recovery – e.g., physical and mental health, employment, economic, family, and social life (see preceding section). Services addressing these issues have thus far often been referred to as "ancillary" in status or "aftercare" in the timing of delivery in spite of their importance to clients, and their evidences impact on the transition to

stable recovery (Laudet et al. 2009; Laudet and White 2010). One study illustrating the importance of non-addiction-related services to treatment clients interviewed individuals who had left treatment before completion – in that study, 60 % of the cohort has left before completion, a finding on par with the national average (Substance Abuse and Mental Health Services Administration Office of Applied Studies Treatment Episode Data Set (TEDS) 2005, 2008). We asked clients why they left the program and whether they felt there was anything the program could have done differently to keep them engaged in services longer (Laudet et al. 2009). Answers fell into one of three broad categories, none of which mentioned addiction treatment services: need for social services (54.2 % – job training, help with housing, childcare, stable housing), need for more supportive staff (25.8 % – e.g., encouraging, trusting, and caring), and need for greater schedule flexibility to accommodate other responsibilities, including work (20 %). These findings are consistent with that of another study we conducted examining current challenges and life priorities in a sample of 356 community-based persons in abstinent recovery from severe polysubstance dependence (Laudet and White 2010). Participants' responses were examined as a function of how long they had been abstinent: under 6 months (28 %), 6–18 months (26 %), 18–36 months (20 %), and over 3 years (26 %). Across these stages, working on one's recovery (e.g., staying sober, "making recovery a priority") was consistently cited as the top priority (cited by 34–49 % across stages); notably, employment was the second most frequently mentioned priority at all stages, cited by the same percentage of persons abstinent over 3 years as working on one's recovery (34.1 % each). Taken together, findings from these studies underline the importance of services designed to foster improvement in non-addiction functioning among both individuals in treatment and those at various stages of the recovery process.

The comprehensive recovery-oriented service model is significantly different from the currently prevalent model where services focus, by necessity, on substance use-related issues and are delivered by trained addiction professionals. Note that delivering a comprehensive recovery-promoting approach does not require that all services be delivered in a single setting, nor does it signify the approaching disappearance of "addiction treatment" as practiced today. In the next section, we summarize prevalent models of recovery support services.

66.5 What Do Recovery-Oriented Addiction Services Systems Look Like?

As clinicians and researchers have come to recognize the chronic nature of SUD, they have developed and evaluated a growing menu of interventions designed to help clients sustain and build on their treatment gains – i.e., relapse prevention. Perhaps the most prevalent form of aftercare consists of *a stepped down course of services typically following intensive inpatient* or residential treatment (McKay 2001, 2009; McKay et al. 2009); in spite of its established existence and intuitive appeal, few clients access these resources and the evidence for the effectiveness of the approach

remains limited (Godley et al. 2007; McKay 2001). In the past decade, clinicians have also started to capitalize on health technology such as telephone-based continuing care (McKay et al. 2005), and several large treatment agencies are developing proprietary web-based online recovery maintenance and support programs for clients to use after they leave service; one example is Hazelden's MORE.[1]

66.6 Recovery-Oriented Systems of Care

In the United States, the shift to a recovery orientation in SUD services has been primarily spearheaded by the Substance Abuse and Mental Health Services Administration (SAMHSA). SAMHSA is advancing the Recovery-Oriented Systems of Care (ROSC) model that constitutes an organizing framework for recovery support services. A key premise underlying recovery supports is that addiction is typically a chronic rather than acute condition. While a chronic condition cannot be "cured," the symptoms can be arrested and the condition managed. The need for this new model was perhaps stated most explicitly by Dr. Clark, a SAMHSA official: "Recovery is more than abstinence from alcohol and drugs; it's about building a full, meaningful, and productive life in the community. Our treatment systems must reflect and help people achieve this broader understanding of recovery" (Clark 2008b, p. 2). As described in SAMHSA materials,[2] ROSC's goals are to intervene early with individuals with SUDs, to support sustained SUD recovery, and to improve the health and wellness of SUD-affected individuals and families. Consistent with the multidimensional and developmental nature of recovery discussed earlier in this chapter, the ROSC model proposes a multisystem, person-centered continuum of care in which a comprehensive menu of coordinated services and supports is tailored to individuals' recovery stage, needs, and chosen recovery pathway (Clark 2008a, b). Services and supports are provided in a comprehensive array of recovery-related domains including education and job training, housing, childcare, transportation to treatment and work, case management, spiritual support, as well as SUD-focused services – e.g., relapse prevention, recovery support, SUD education for family members, peer-to-peer services and coaching, self-help, and support groups (Kaplan 2008; Sheedy and Whitter 2009).

Services are intended to address the multitude of life areas adversely affected by active substance use and to respond to clients' changing needs across their life span. ROSC is responsive to calls from the Institute of Medicine and leading addiction researchers for a shift in SUD treatment from the acute care model to one more akin to the model used in other chronic conditions (Humphreys and Tucker 2002; Institute of Medicine 2005; McLellan et al. 2000; White et al. 2005a). From a systems perspective, this means that the case management and care coordination function of services is conferred a more prominent role in treatment design and delivery.

[1] http://www.hazelden.org/web/public/more_demo.page

[2] http://partnersforrecovery.samhsa.gov/rosc.html

Key principles guiding the recovery orientation include primacy of participation; promoting access and engagement; ensuring continuity of care; employing strength-based assessment; offering individualized recovery planning; functioning as a recovery guide; community mapping, development, and inclusion; and identifying and addressing barriers to recovery (Kirk 2008, 2010; Tondora and Davidson 2006).

Implementing ROSC nationwide in the United States will require transformative changes in agencies that address SUD directly as well as within those serving the population through other avenues (e.g., mental health and social service agencies). This has implications for the training and evaluation of staff and service managers and those responsible for commissioning and evaluating treatment services. The Affordable Care Act's expansion of Medicaid and the creation of health insurance exchanges give states added resources to make these changes. At this writing, ROSC is gradually taking hold as more states and cities are implementing components of the model (Evans 2007; Kaplan 2008; Kirk 2008). Still, the ROSC model is still in its infancy at the level of field implementation and, at this writing, has not been formally evaluated. There is, however, emerging evidence supporting its potential usefulness. Statewide data from Connecticut – the first to begin implementing a true ROSC in 1999 (Kirk 2010) – provide early support for the effectiveness and cost-effectiveness of the approach: this includes a 24 % decrease in expenses, 25 % decrease in annual cost per client, 46 % increase in number of people served statewide, 62 % decrease of acute care, 40 % increase in outpatient care, and 14 % lower cost with recovery support. Internationally, untested belief that a recovery-oriented approach is prohibitively expensive has been a significant barrier to implementation and one that needs to be tested with adequate effectiveness and cost-effectiveness evaluations and health economic research.

66.7 Individual Recovery Support Services Elements

In addition to the emerging system-level recovery orientation embodied by ROSC, the field is also witnessing the development of a growing menu of recovery support services (RSS) described in a number of recent articles and monographs that also review the emerging science supporting the approach (Kaplan 2008; Laudet and Humphreys 2013; Sheedy and Whitter 2009; White 2008, 2009). Unlike professionally delivered aftercare (see earlier), peer-based RSS are not solely conceptualized to be delivered after treatment but can also be provided in addition to or even in lieu of professional services. This is important as there are a number of barriers to SUD treatment that include wait lists, finances, stigma, and ambivalence about seeking professional help (Appel et al. 2004; Cunningham et al. 1993; Laudet et al. 2009; Zemore et al. 2009).

At least two aspects of RSS are unique. First, RSS are often delivered by peers, individuals who have experiential knowledge (Borkman 1999) and work as volunteers or as paid service workers (Kaplan 2008) to assist others in initiating and maintaining recovery and enhancing their quality of life (White 2009).

Other healthcare fields have capitalized on peers to promote symptom management in the context of chronic conditions (e.g., asthma, cancer, psychiatric illness, and diabetes – Greenfield et al. 2008; Kyrouz et al. 2002). A randomized clinical trial using a prospective design with repeated measurements documented the effectiveness of adding a peer-based component to clinical treatment in reducing substance use (Rowe et al. 2007) among clients dually diagnosed with a mental health and a substance use disorder, and peers have also proven effective at designing and disseminating mutual help-related public service announcements to increase involvement in mutual aid/self-help groups for a range of chronic problems, including SUD (Humphreys et al. 2004). The use of peers is intuitively appealing and empirically demonstrated to be useful in the addiction field as well. Research has shown that social support, particularly from other individuals in recovery, predicts successful substance use outcomes (Humphreys et al. 1999, 1997; Weisner et al. 2003a). Many individuals in recovery report that being in the company of peers is helpful (Granfield and Cloud 2001; Laudet et al. 2002; Margolis et al. 2000; Nealon-Woods et al. 1995). In Glasgow, Scotland, one study found that the two strongest predictors of positive quality of life in recovery were spending time with other people in recovery and engagement in meaningful activities – including working, training, volunteering, and involvement in community groups (Best et al. 2011).

The second unique aspect of peer-based RSS is that they can be delivered in a broad range of community-based settings – e.g., recovery community centers, faith-based institutions, jails and prisons, health and social service centers, and addiction and mental health treatment agencies (Faces and Voices of Recovery 2010). This is important not only because it increases the accessibility of recovery support literally (i.e., to persons who may not have the means of transportation to go to a treatment program) but also more figuratively by removing some of the stigma and ambivalence that are sometimes attached to "seeking help" in a traditional healthcare or SUD treatment setting.

One type of peer-based recovery support service that is increasingly being implemented in the United States is peer recovery coaching: a peer mentors the individual seeking recovery (e.g., assists in setting recovery goals and a recovery plan, serves as role model in recovery). This aims to help the individual connect to recovery-supportive resources needed to restructure life (e.g., professional/nonprofessional services including housing and employment) and serving as an advocate and liaison to formal and informal community supports, resources, and recovery-supporting activities. While no formal evaluation of peer recovery coaching has been conducted to date, a clinical trial of an integrated case management including using peer coaches to help integrate SUD treatment and child welfare services for parents in substance-involved families enhanced access to treatment and resulted in increased family reunification rates compared to standard care (Ryan et al. 2006). Moreover, reports compiled in the context of broader recovery-oriented efforts have provided emerging evidence for the benefit of peer coaching (Mangrum 2008).

There are a handful of other models of peer-based recovery support that we only briefly describe here as they are more fully discussed in a recent review

article (A. Laudet and Humphreys 2013). One model is the sober residence, a home that offers mutual help-oriented, financially self-sustaining, self-governed, democratic communal-living environments where individuals in recovery can reside for as long as they choose after inpatient treatment or incarceration, during outpatient treatment or as an alternative to treatment (Polcin 2009). The most prevalent model of sober residences is Oxford House (OH) with 1,300 houses in the United States (Jason and Ferrari 2010). The benefits of the model in terms of substance use and related domains (e.g., employment, criminal involvement) have been extensively documented in prospective peer-reviewed studies across subpopulations (Alvarez et al. 2006; Jason et al. 2001, 2009; Majer et al. 2002, 2011; Millar et al. 2011), as has been its cost-effectiveness (Lo Sasso et al. 2012; Olson et al. 2006). Most recent and perhaps most innovative is the campus-based Collegiate Recovery Program (CRP) model that is emerging nationwide. The high prevalence of substance use on college campus can jeopardize recovery for young people at a time of their development where fitting in with peers is central to their identity; for some, that may lead to foregoing or postponing college in the absence of a readily available sober network (Baker and Harris 2010; Botzet et al. 2007; Harris et al. 2008; Laitman and Lederman 2007; Smock et al. 2011; U.S. Department of Education Higher Education Center for Alcohol and Other Drug Abuse and Violence Prevention 2010; Woodford 2001). The CRC developed to meet the needs of college students with a history of SUD who have successfully remitted from the disorder and seek to pursue educational goals. Central elements of the CRC model include a peer-driven approach informed by 12-step tenets and services such as drug-free housing, on-site peer support, and counseling provided by a small staff, as well as opportunities for sober recreational activities, relapse prevention, and life skills workshops. Little documentation is currently available about specific CRC services across programs, but it is believed that the breadth of service varies (Bell et al. 2009). Common to all are on-site 12-step and other recovery support meetings, a campus-based location where students can meet and spend time with sober peers; some offer sober housing and peer academic support. All function with minimal professional staff as the emphasis is clearly peer driven. The model seems consistent with the continuing care paradigm within a "recovery management" system that experts recommend (Godley et al. 2002). CRCs are also responsive to calls for appropriate campus-based infrastructure to support recovering students (Misch 2009), with recent shifts in drug (Office of National Drug Control Policy 2010) and with the US Department of Education's goal of ensuring a continuity of care from high school to college to postgraduation (Dickard et al. 2011). The model is growing in popularity nationwide: in the past decade, growing concerns about substance use on campus and federal agencies' focus on building a community-based continuum of care system for youths have fueled a fivefold increase in the number of CRPs, from four in 2000 to 32 in 19 states today. No formal evaluation has been conducted yet, but site-specific reports document

encouraging outcomes – low relapse rates, above school average GPAs, graduation rates, and perceived helpfulness (Baker et al. 2011; Bell et al. 2009; Cleveland et al. 2007; Harris et al. 2008). The first author is currently conducting an NIH-funded survey of all CRC programs and student participants nationwide to learn more about the breadth of services offered and the characteristics and needs of students served; that knowledge will inform a subsequent large-scale evaluation of the model. In the same vein as CRCs though professionally rather than peer delivered are recovery high schools (Moberg and Finch 2008) that typically function as charter schools in a public school system and serve students who recently left SUD treatment. This model is currently undergoing systematic evaluation.

The three initiatives discussed above – around education, housing, and peer activities – are all consistent with three core tenets of recovery-oriented services: a care coordination across a range of service sectors requiring case management skills and "outward-looking" specialist treatment services, an increased role for peers and a recognition of the validity of "expertise by experience," and a continuity of care model that acknowledges the need for integrating acute services with those targeting longer-term changes in well-being and social integration. This grassroots or "bottom-up" approach represents a drastic departure from the current SUD service model. Moreover and importantly, it is accessible to individuals who have reservations about the mutual aid movement (12 steps in particular) and is consistent with an asset-based community development model (Kretzmann 1993) and with the public health model to addictions that is gathering momentum in the United Kingdom and elsewhere in Europe.

Overall, a growing menu of professionally and peer-delivered recovery support services is being developed and implemented, with the professionally driven efforts being spearheaded (in the United States) by federal funding agencies, principally SAMHSA. None of the peer-driven strategies have been formally evaluated though state-level data report encouraging outcomes. These findings are of course preliminary; the approaches need to be systematically evaluated, and the stability of the documented improvements over time remains to be determined.

66.8 What Can Medical Professionals Do to Promote Recovery Among Substance-Using Patients?

Given the prevalence of substance use disorders and how frequently medical and substance use disorders co-occur, medical professionals routinely come into contact with patients who are or were abusers of/dependent drugs and/or alcohol. This section briefly outlines suggestions for medical professionals to promote the initiation and maintenance of recovery from substance use disorders.

Addressing active substance use in primary care as Screening, Brief Intervention, and Referral to Treatment (SBIRT)[3] is increasingly being implemented and evaluated. The rationale behind SBIRT is simple yet effective: identifying (screening) a substance use problem early reduces the risk that it will progress to clinical levels (in this case, chronic SUD); this secondary prevention approach (preventing disease progression) is accomplished either through a brief intervention delivered by the professional conducting the screening, immediately following detection of a problem, or through referral to specialty care (i.e., SUD treatment) when the severity of the identify problem warrants it. There is a growing body of evidence for the effectiveness of SBIRT across populations (adults, youths, veterans) and across settings – e.g., primary care and emergency departments (Agerwala and McCance-Katz 2012; Gonzales et al. 2012; Gryczynski et al. 2011; Lotfipour et al. 2013; Madras et al. 2009; Mitchell et al. 2013; Murphy et al. 2013; Young et al. 2012). The effectiveness of brief intervention has long been established, with the largest trial being conducted by the World Health Organization (WHO): 1,661 heavy drinkers in 8 countries were randomly assigned to a control condition (no intervention) or to one of two forms of brief intervention to reduce drinking. At a 6-month follow-up, participants receiving either of the two brief interventions showed significant reductions in drinking outcomes compared with the control group (WHO Brief Intervention Study Group 1996). Implementing SBIRT in primary care is especially critical in view of the fact that studies of SUD treatment clients show that two decade or more pass between first and last uses (Dennis et al. 2005). Fewer than 10 % of individuals needing SUD treatment seek it in a given year (Kessler et al. 1996; Wang et al. 2005), about a third in their lifetime (Compton et al. 2007; Hasin et al. 2007). Therefore, it is critical to capitalize on opportunities to address substance use problems early, and primary care settings (as well as emergency departments) represent very promising venues to achieve that goal. Addressing substance use in primary care is also essential because substance use can complicate the course of other diseases and jeopardize adherence to and outcome of treatment (Braithwaite et al. 2007; Oyugi et al. 2007; Watson et al. 2007). In addition to promoting the initiation of recovery through such strategies as SBIRT, healthcare professionals are also in a position to help support recovery *maintenance*. Continued screening for substance use in patients with former SUD is desirable to detect any relapse early – as is currently routinely done for mental health problems during office visits. Moreover, active addiction has numerous negative consequences for many major organs and systems (e.g., liver, heart, and lungs) as well as the potential for undiagnosed infectious disease (e.g., HIV/AIDS and Hep C); years of active addiction often result in neglected self-care, increasing the odds that any developing medical condition progresses unaddressed. Therefore, because individuals with an SUD history have lower access to health services (Samet et al. 2007), they may be at enhanced risk for developing chronic

[3] http://www.samhsa.gov/prevention/sbirt/SBIRTwhitepaper.pdf

conditions; it is important that healthcare professionals educate themselves about the consequences of active addiction and screen patients with a history of SUD for conditions frequently associated with an addiction history. Studies have documented the high rate of co-occurring chronic medical (and mental health) conditions among persons with a history of SUD, both of which complicate also the attainment of recovery outcomes such as seeking employment A cross-national trial of brief interventions (Laudet 2012). Overall, the evidence suggests that substance use (be it active or past) interacts dynamically with physical health, enhancing the need for healthcare professionals to engage patients in an honest, nonjudgmental dialogue about their current and past substance use.

Finally, though a full discussion is beyond the scope of this chapter, the treatment of acute and chronic pain for patients in recovery from an SUD is a growing area of research and of practice for healthcare professionals, discussed in details in several recent book chapters and articles (Brown et al. 2012; Cruciani et al. 2008; Miotto et al. 2012; Portenoy et al. 2005).

66.9 Conclusion

The emerging recovery orientation builds on a growing addiction science and an evidence base that shows the effectiveness of a range of treatment interventions. It also represents a paradigmatic shift in the way SUD recovery is conceptualized and how recovery services are delivered both at the individual and at the systemic level. Recovery is an organizing concept that promotes empowerment and choice within a change model based on a chronic disorder with unpredictable rates of relapse necessitating a service model that integrates acute interventions with holistic, comprehensive care coordination and community engagement. Recovery services approaches are consistent with the needs of the recovery community as documented in a handful of studies summarized here and have a burgeoning evidence base around peer support, around recovery housing, and around long-term transitions to training and employment. Healthcare professionals in all sectors should become familiar with the breadth and growing availability of recovery services and supports in their communities as these resources supplement and for some may replace traditional SUD treatment. Doing so will allow providers to have a larger menu of options to discuss with and offer patients, with the ultimate goal of reducing the duration and impact of active substance use and SUD, and giving patients the resources necessary to improve their overall health and functioning.

Abstract

This chapter summarizes the growing body of research demonstrating that science-based information and communication technologies (e.g., delivered via the web and/or on mobile devices) offer great promise in targeting the full spectrum of substance use disorders, ranging from assessment and prevention to treatment and recovery support. This chapter provides a summary of the growing scientific literature showing that these tools (when they are well developed and in close collaboration with the target audience) may be engaging to the target

audience and effective in a number of models of deployment. The chapter additionally reviews the potential public health impact of this approach when integrated into various models of care targeting substance use disorders. Overall, these tools offer great promise for changing models of service delivery targeting substance use disorders (as well as other areas of behavioral health) to increase quality and reach of care while containing costs in a wide array of settings and countries. Finally, the chapter reviews best practice models for implementation of technology-based care approaches and research needs and opportunities.

67.1 Introduction

67.1.1 The Promise of Technology

A growing body of research suggests that science-based information and communication technologies (e.g., delivered via the web and/or on mobile devices) offer great promise in targeting the full spectrum of substance use disorders, ranging from assessment and prevention to treatment and recovery support. These tools may be accessed in a wide array of settings, such as when individuals move about their daily lives, in the privacy of their own homes, in specialty addiction treatment programs, or in primary care settings. And they can enable a broad reach of effective assessment and intervention tools that can be accessed on demand and at low cost.

In the assessment arena, these tools may help individuals and their providers better understand if they meet the criteria for problematic substance use and/or understand how their substance use relates to normative data from a broader community (e.g., persons of the same gender and in the same generation). These tools may also help individuals monitor their own substance use and better understand patterns in their use (e.g., how often they use in a given period of time, how their use may be related to other aspects of their lives such as mood, exposure to specific peer groups, and/or specific settings). Additionally, using technology-based assessment tools generally leads to more accurate reporting of sensitive behavior (e.g., risky substance use, risky sexual behavior) relative to more traditional, person-delivered assessment.

Technology-based applications in the area of substance abuse prevention may be designed to teach protective factors and reduce risk factors for substance use and other risk behavior among children and adolescents (e.g., via interactive multimedia games). They may also focus on the prevention of substance-related harms (e.g., in college/young adult populations, among an HIV-positive community).

The application of technology to treatment may include an array of behavior therapy interventions, including tools for interactive skills training, self-management, and goal setting/tracking to foster change in problematic substance use and achieve functional outcomes (e.g., get a degree, get a job, improve an interpersonal relationship, be a better parent). Additionally, behavioral self-monitoring/assessment tools may be linked to interventions and can be designed

to trigger personalized interventions depending on an individual's needs and preferences (e.g., when one may be at risk for relapse). The advancement of mobile and web-based technologies now allows for ongoing, real-time recovery support beyond the boundaries of traditional recovery models.

Technology also allows for tailoring of user experiences based on a variety of individual factors (e.g., level of severity of use, co-occurring mental health problems). With technology, interventions can also be tailored over time (e.g., adaptive interventions that can change based on progress a person is making in reaching intended goals).

67.2 Applications of Technology

67.2.1 The Scientific Support

A growing scientific literature is showing that these tools (when they are well developed and in close collaboration with the target audience) may be engaging to the target audience and effective in a number of models of deployment. When provided as an adjunct to a traditional model of care, these tools may enhance the quality, reach, and outcomes of care (e.g., enhance outcomes in substance abuse treatment and/or HIV prevention) (Carroll et al. 2008; Marsch et al. 2011). When compared to science-based interventions delivered by highly trained educators/clinicians, some data suggest these tools may be of comparable effectiveness (Budney et al. 2011; Kay-Lambkin et al. 2009). These findings underscore the scope of effects that can be achieved with a technology-based model of intervention delivery. Additionally, technology-based tools may enhance treatment outcomes and allow for greater capacity for service delivery if they are provided in a model where they replace a portion of traditional models of care (e.g., a substance abuse treatment program can care for more clients if a portion of intervention delivery is provided via a technology-based system of care). Further, a number of scientific studies have supported the effectiveness of a direct-to-consumer model. There is additionally evidence that these tools may be cost-effective (Olmstead et al. 2010).

[For a comprehensive review of the state of scientific research developing and evaluating technology-based therapeutic tools targeting behavioral health, refer to ▶ Chap. 60, "Computerized Therapies: Towards an Addiction Treatment Technology Test" by Budney and colleagues in this same volume].

67.2.2 The Opportunity for Public Health Impact

As highlighted from the research described above, technology-based assessment, prevention, and behavior change intervention tools may be clinically useful when integrated into various models of care targeting substance use disorders. Overall, these tools offer great promise for changing models of service delivery targeting substance use disorders (as well as other areas of behavioral health) to increase quality and reach of care while containing costs.

The utility of technology-based therapeutic tools for substance use and other behavioral health care may become even more pronounced in the USA, given evolving models of health care (under the Affordable Care Act of 2010) which will expand federal insurance coverage for the first time to an estimated 32 million individuals who are currently uninsured. It is expected that many of the uninsured who will receive insurance for the first time are individuals that are poor and unemployed, with disproportionately high mental health and substance use problems (Substance Abuse and Mental Health Services Administration 2010). Technology may be useful as part of an integrated model of care as the current health-care workforce seeks to embrace this large influx of new clients.

Technology-based therapeutic tools may also be useful to the majority of persons with substance use disorders who are not engaged in traditional models of care for their problematic substance use. For example, in the USA, about one in ten Americans are estimated to be diagnosable with one or more types of substance use disorders, and the majority of these individuals (about 90 %) are not engaged in substance abuse treatment. Technology offers a mechanism for providing access to effective interventions for these persons who are not in care and may, in some cases, serve as a conduit to more formal models of care for substance use.

Substance use and mental health disorders are also highly prevalent among persons with chronic physical health conditions and greatly reduce the effective management of chronic illness. Co-occurring chronic illness and behavioral health problems have been associated with lower quality of life, poorer response to treatment, worse medical and psychiatric outcomes, higher mortality, and higher costs of care (Cimpean and Drake 2011). Leveraging technology in the integration of behavioral health and physical health disorders offers great promise in overall health-care management.

67.2.3 Opportunities for Developing Countries

The potential for emerging technologies, particularly mobile technologies, to change the face of health research and health-care delivery in developing countries is enormous given the high penetration of these technologies in these countries. In addition, many factors constrain health system performance in developing countries. Infrastructure is limited, and hospital resources are concentrated in urban areas. Incidence of disease and its impact on people's livelihoods and economic productivity is high. In many areas, there is also a severe shortage of health-care workers (in some areas one to every 250,000 patients) (Scheffler et al. 2009), and workers are difficult to recruit and retain, especially in rural areas. Supervisory and care management systems are often lacking or weak.

The burgeoning growth of cellular infrastructure in developing countries has considerable prospects for reaching and following individuals who were previously unreachable. Technology-based therapeutic tools can reach broad population bases with targeted care, including treatment, augments to clinical care, and self-management tools. For example, there is growing evidence that automated

medication and treatment reminders improve medication adherence and health among individuals living with HIV (Lester et al. 2009). Mobile technologies can also broaden access to education and training of health-care professionals via easily accessible online learning. The resource sharing capacities of cloud computing can be harnessed to improve health system management, workflow, and communication between providers in the service of care coordination (Kahn et al. 2010).

67.2.4 Research Needs and Opportunities

The rapid emergence of innovative technologies such as wireless and mobile devices has introduced exciting opportunities for researchers and providers alike. We are now in a reality in which wearable sensors that measure physiological metrics such as heart rate, skin conductance, and accelerometry can be feasibly worn naturalistically in daily living. Current technologies allow us to harness the existing sensor systems of mobile devices, such as global positioning systems (GPS), accelerometry, and microphones to collect valuable information about individuals' location, motion, and voice. These physiological, geographic, movement, and sound metrics can now be readily coupled with real-time mobile ecological momentary assessment surveys to produce continuous streams of data on an individual's physiology and psychology (attitudes, symptoms, cognitions, and emotions), with the potential to yield new insights into the factors that lead to substance use and mental illness. The potential to use these convergent sources of data to identify precursor signatures of substance use behaviors will ultimately allow for delivery of in-the-moment interventions when individuals need it the most. Advances in mobile health, or mHealth, have the potential to change when, where, and how health care is provided.

Yet, while the implications of mHealth for delivery of care for substance use and co-occurring disorders are tremendous, the development of technologies, such as wearable and physical sensors and the myriad of health "apps," has far outpaced the science needed to understand their benefits, risks, and impact on health outcomes. The empirical support for emerging technologies, such as sensors, as potential tools for care of substance use disorders and other behavioral health issues is in its infancy. There is much basic research to be done to better understand how, and if, these emergent technologies can feasibly and effectively be harnessed to impact substance use disorders and associated behaviors.

67.2.5 Best Practice Models for Implementation of Technology-Based Care Approaches

Despite a growing evidence base and enthusiasm for the potential of technology-based therapeutic tools to broaden and enhance care delivery, adoption has been slow. There is much research to be done to understand best practice strategies for disseminating evidence-based technologies to consumers and integrating

these technology-based approaches into systems of care. One main advantage of technology-based care approaches is the ability to reach broad consumer populations across time and setting. As such, it is critically important to understand individual and organizational characteristics associated with readiness to implement technology-based approaches to care delivery across diverse settings, including direct-to-consumer venues, schools and other community-based organizations, criminal justice, and health-care organizations.

Existing models of organizational readiness to adopt innovations, grounded in the diffusion of innovations theoretical framework (Rogers 1995), can guide dissemination and implementation research on adoption of technology-based therapeutic approaches. Extant research has identified a number of factors that influence the adoption process, including general organizational perceived need for change and a climate marked by clarity of mission, stable and supportive leadership, staff cohesion and cooperation, open communication, and adaptability and openness for embracing innovations and change (Greenhalgh et al. 2004; Rogers 1995). There is solid evidence supporting the importance of organizational readiness for promoting successful implementation and sustained adoption of treatment innovations within behavioral health-care settings, but little is known about the readiness of these care settings to implement technology-based therapeutic approaches. In a recent survey study of administrators and clinical directors at community behavioral health-care settings in the USA, organization readiness to use technology-based initiatives was associated with both internal (e.g., clients, staff, supervisors/managers) and external (e.g., funding sources, reimbursement policies) pressures for change, perceived readiness to meet demands of health-care reform, current use of technology in some capacity in the care setting, and low concerns about privacy with the use of technology (Lord et al. 2013).

Future implementation science research focused on technology-delivery therapeutic tools for substance use and co-occurring behavioral health issues could include implementation demonstration trials that focus on optimization of implementation outcomes as a necessary first step in producing better client outcomes (Proctor et al. 2011). These implementation outcomes include *end-user acceptance and satisfaction* with the technology (i.e., how did stakeholders like the technology), *feasibility* of implementation with specific stakeholders (i.e., did stakeholders use the technology as intended), *fidelity* of implementation (i.e., did stakeholders use the technology as intended), *penetration* of the technology among stakeholders (i.e., what proportion of stakeholders used the technology, for how often, and what components), *likelihood of adoption* (i.e., would stakeholders use the technology in the future), and *cost* of implementation (i.e., how did use of technology impact staff time/resources/costs?). Such implementation research should also include assessment of characteristics of the intervention, external and internal organization influences, individual stakeholder groups, and the implementation process itself that are associated with positive implementation outcomes (Damschroder et al. 2009).

While addressing implementation challenges associated with the use of technology-based therapeutic solutions, researchers should aim to identify barriers and solutions associated with issues of privacy, confidentiality, regulatory control,

human subjects' protection, and accessibility (e.g., interoperability among carriers) with the use of these tools. From a practical perspective, effective dissemination and implementation of technology-based care delivery approaches can benefit from effective marketing strategies to promote buy-in of leadership and key opinion leaders through emphasis on value of the technology for each stakeholder group, accessible and comprehensive training procedures for all stakeholders to foster self-efficacy and motivation to use the technology, and ongoing technical assistance to support integration of the technology solution within an organization culture.

Romans were known to recommend both public and private asylums for those addicted to alcohol. In the early nineteenth century in the United States, Dr. Benjamin Rush (1746–1813) is often credited with one of the first proposals to treat the disease of intemperance with medical care and residential treatment. He has been called the "father of American psychiatry" and wrote what became the first American medical textbook. Other American physicians followed suit with similar recommendations in the mid-nineteenth century including Eli Todd, Samuel Woodward, and Joseph Turner.

Rush's interest in chemical dependency issues seems to have arisen from his own family experience. His father's alcoholic drinking contributed to his parents' divorce. His mother was later remarried to a distiller who abused her. On a professional level as physician-general of the Continental Army, Rush was struck by the problems created by inebriation in the Army. In 1777 his essay condemning the use of distilled liquor was distributed to all soldiers. In his 1782 newspaper article "Against spirituous liquors," Rush recommended that farmers stop providing laborers with daily allocations of liquor. In 1784 he published a 36-page pamphlet, An Enquiry into the Effects of Spirituous Liquors on the Body, and Their Influence Upon the Happiness of Society.

Rush first promoted the chronicity and progression of alcoholism as a medical ailment, opening the door to addiction to alcohol as a treatable condition. He attributed this progression to a "disease of will" and recognized the frequent familial expression of alcoholism. Although his ideas were not readily accepted by the general public at the time, his writings and teaching of scores of young physicians at the Philadelphia School of Medicine laid the foundations for the temperance movement which followed. Working independently, Rush's international contemporary in England, Dr. Thomas Trotter, wrote, "Essay, Medical, Philosophical and Chemical, on Drunkenness," also attributing to alcoholism the status of a medical illness. The "disease concept" of alcoholism as a medical malady was born.

68.2 Residential Programs

68.2.1 Beginnings of Inpatient Residential Treatment

Prior to the development of specialized alcohol and addiction treatment facilities, those suffering from these ailments often found their way to jails, charitable homes, workhouses, and lunatic asylums. None particularly welcomed the alcoholic or addict and none provided specific treatment for their rehabilitation or cure. Lacking the availability of treatment, many so afflicted simply hid their addictions throughout their entire lives.

Rush was fully cognizant of these challenges in treating alcoholism, so in 1810 he recommended the establishment of a "Sober House" for the confinement and rehabilitation of confirmed alcoholics. Confinement would be determined by "evidence of drunkenness, neglect of business, and ill-treatment of family members" (White). Religious and moral instruction would constitute treatment in this setting

and a judicially appointed committee determined discharge following adequate rehabilitation. As hospitals were scarce at the time and drunkards were viewed as morally ineligible for admission, along with unwed mothers and those suffering from venereal disease, "Sober Houses" may have seemed like a reasonable choice.

Alcohol-related problems also led to the birth of a series of personal recovery movements in the United States in the 1800s. The Washingtonian movement is perhaps the most well known but others included the Sons of Temperance, Good Templars, Good Samaritans, Osgood's Reformed Drinkers Club, Reynold's Red Ribbon Reform Club, Francis Murphy's Blue Ribbon Reform Club, Business Men's Moderation Society, and many others. These involved thousands to hundreds of thousands of reformed alcoholics and supporters, but all seemed to follow the same course of widespread appeal and growth followed by eventual demise. However, in aggregate they laid the groundwork for the rise of residential inebriate homes and asylums which was to follow.

In 1840, R. Grinrod proposed the establishment of inebriate asylums:

> Let the experiment be fairly tried; let an institution be founded; let the means of cure be provided; let the principles on which it is to be founded be extensively promulgated and I doubt not, all intelligent people will be satisfied of its feasibility. . .. At the head of this institution place a physician of zeal, medical skill and enlarged benevolence; let the principle of total abstinence be rigorously adopted and enforced. . ..let the appropriate medication be afforded; let the mind be soothed. . ..let the certainty of success be clearly delineated to the mind of the sufferer. . .. Let good nutrition be enjoined while the prostration of strength and energy continue. . ..this course, rigorously adopted and pursued, will restore none out of ten in all cases. (White)

Finally, in the later nineteenth century specific institutions for the treatment of addiction began to spring up. By 1870 six such inebriate asylums were in operation. Their managers soon got together to create the American Association for the Cure of Inebriates. The association included 32 members by 1878 and more than 100 institution members by 1902. Some of the first members included the Washingtonian Homes in Boston and Chicago, the New York State Inebriate Asylum, the Pennsylvania Sanitarium for Inebriates, the Kings County Inebriates' Home, and Walnut Lodge.

Many different monikers were attached to these sorts of institutions: inebriate asylums, inebriate homes, inebriate colonies, inebriate farms, lodging homes, reformatories, retreats, and sanitaria. Some provided room and board with minimal additional treatment. Others provided a sober place to stay while the residents attended temperance movement meetings. Some were established as medical facilities both privately and publically funded. Public funding, unfortunately, was often inconsistent. The goal of all of these institutions was the treatment of the alcohol dependence, although other chemical addictions were treated as well. Brooklyn Home for Habitues, founded by Dr. Jansen B. Mattison in 1891, was one of the first to focus exclusively on nonalcohol chemical addiction.

Medical treatment was often quite variable at this time with physicians caring for various medical problems and assisting in ambulatory detoxification. Some patients visited the physician 3–4 times a day while living at home or staying in a hotel.

More consistent treatment recommendations began to appear. The establishment of three tiers of continuum of care medical facilities was recommended by Dr. T.D. Crothers:

Level 1: Voluntary or involuntary residential stays of up to 1 year for acute cases of inebriety

Level 2: Residential stays of 1–3 years for chronic cases of inebriety

Level 3: Farm colonies or workhouses for incurable inebriates who could be forced to adhere to "military habits of life and work, and kept in the best conditions of forced healthy living" (Crothers 1893)

Generally, the first step of residential treatment was detoxification. Some recommended the "cold turkey" approach. Others supplemented this phase with a wide variety of medications including "whisky, beer, sherry, chloral hydrate, strychnine, atropine, coca, cannabis indica, atropine, hyoscyamus, belladonna, quinine, iron and placebos" (White). Physical restoration of the patient usually followed detoxification. Methods included treatment of medical issues, "rest, Turkish baths, massage, phototherapy (exposure to sunlight), electrotherapy (electrical stimulation), nourishing meals and vitamin supplements, high fluid intake, exercise, and lots of fresh air" (White). Spiritual or religious experience was thought to be necessary. Religious instruction, exposure to religious leaders, prayer, and Bible readings were all applied. Social support and exposure to similarly challenged individuals were believed to be helpful as well. Work and recreation were thought to be beneficial. Exposure to music, self-reflection, and moral suasion were all thought to benefit the recovering patient. Very little modern style counseling was provided but patients were encouraged to partake in acts of service. Finally various forms of aversion therapy were also applied.

Funding for the early addiction treatment programs came from a variety of sources: families, government grants, alcohol taxes, charitable donations, selling of patient-produced products, patient labor, and the patients themselves. Government funding was often sought but, as today, this source always carried the risk that approved funding streams could be diverted to other more socially desirable projects or needs. Even many of the privately funded programs often tried to provide a "charity" bed or two (White).

Some felt that the moral and practical responsibility to provide this care should that of the public sector. It was even suggested that funding be provided by a tax on the sale of alcoholic beverages.

On the basis of a report submitted by Dr. Charles Hewitt of the Minnesota Board of Health in 1873, the Minnesota legislature approved a law establishing a special saloon tax. The monies collected were slated for use in creating and operating a "treatment center for inebriates." Opposition at the time was able to derail this funding stream and funnel the money for general psychiatric care. But in 1907 the legislature created a two percent liquor tax with similar goals in mind. These funds were to be dedicated to the treatment of inebriates and Willmar State Hospital was born. Funding dried up in 1920 and alcoholism treatment responsibilities reverted back to various psychiatric facilities for the next 30 years.

From the earliest days, conflicts arose between the administrators of the inebriate treatment institutions and the administrators of the psychiatric institutions. Inebriate patients were categorically excluded from the state psychiatric institutions. Where to place patients suffering from a combination of inebriety and psychiatric illness became a bone of contention.

Psychiatric asylums often admitted their inability to deal effectively with inebriates and even judged them contrary to the welfare of their psychiatric patients. In addition, there were conflicts inherent in using the psychiatric treatments of the time. Whisky and opium were liberally used as psychiatric medications at that time and drinking and drug problems were apparently not uncommon among the psychiatric hospitals' staff (Geller and Harris 1994).

As early as 1875, Dr. Henry Bowditch in Massachusetts began to advocate for patient-helpers in the inebriate home treatment model. In addition to those former patients who were required to "work off" the cost of their treatment, Dr. Bowditch believed that recovering inebriates who possessed the education and intelligence had a moral duty to help those less fortunate patients. Some contributed in the clinical setting and others in the administrative or maintenance areas. Paid jobs for these individuals soon evolved and at times the line between patient and paid staff was muddled.

Wives and family members were often viewed as a nuisance by treatment staff. All too often the patients' spouses either interfered with treatment or acceded to the patients' wishes and pulled them out of treatment prematurely. The results, of course, were inevitable. Aftercare was spotty or nonexistent by the standards of today. Following residential treatment, the patient was often placed in the home of nondrinking friends. Involvement with a religious or fraternal temperance organization was encouraged.

In 1870, the American Association for the Cure of Inebriates was founded in New York City by a group of physicians, lay people, and inebriate asylums. The American Association for the Study and Cure of Inebriety statement of principles and purpose included the following (Crothers 1893):

- Intemperance is a disease.
- It is curable in the same sense that other diseases are.
- Its primary cause is a constitutional susceptibility to the alcoholic impression.
- This constitutional tendency may be inherited or acquired.

The statement further recommended that scientifically based residential treatment replaces the penal approach in fashion at the time for the treatment of addiction. The association also lobbied for state financial support for residential treatment and for laws which would mandate residential treatment for those suffering from inebriety. They were concerned with the spread of quack addiction cures and sought stronger regulation of addiction treatment medications, physicians, and institutions. Not everyone agreed with this approach; some even recommended that those suffering from the "hereditary weakness" of alcoholism be allowed to die, thereby cleansing society forever of alcoholism (Crothers 1893).

During this period the idea of individualized treatment was further developed. Treatment philosophies fell within two broad arenas. Asylums viewed the goal of recovery as physical regeneration resulting from the scientific treatments provided. Washingtonian homes understood recovery as a moral regeneration resulting from healthy, courteous, and respectful environment. Many questions were posed, some perhaps still unanswered. Should treatment be physical or moral? Should facilities be large or small? Should coercion be used or should treatment be purely voluntary? Superimposed on all this was the question of length of stay. Hopeful cases were treated for 6 months or less while more advanced cases of addiction were thought to require a minimum of 1–5 years of treatment. Mandated treatment was experimented with in some areas but the public looked disparagingly at these practices due to the conflict of interest apparent in this model.

Residential treatment came to a conceptual fork in the road at the end of this period. The young specialty of psychiatry described addiction as a symptom of a subconscious emotional pathology. Another view evolved that substance abuse reflected a willful misbehavior which must be criminally punished to be corrected. However, more so than by any other criteria, it appears that patients were segregated by social class and financial means. Those with social standing and financial means were treated by psychiatrists in private sanitaria. Those who lacked these assets were more likely treated in publicly funded asylums or made their way into the criminal justice system. These nineteenth-century ideas survive today and still influence the treatment of addiction. Well-to-do prescription addicts with good medical insurance are often said to be "chronic pain patients" suffering from "pseudo addiction," while those without financial means are more likely to be punished for their addiction within the criminal justice system or redirected to publicly funded methadone maintenance programs.

68.2.2 Residential Treatment in the Early Twentieth Century

A number of addiction "cures" appeared in the nineteenth century, including the Neal Institutes, the Oppenheimer Institutes, the Empire Institutes, the Gatlin Institutes, the Hagey Cure, and the Leyfield Cure. Arguably the most well-known was Leslie Keeley's Double Chloride of Gold Cure. More than a half million alcoholics and addicts took the Keeley Cure between 1880 and 1920. The heart of the cure was four injections a day of Keeley's secret Double Chloride of Gold formulation. In addition to rest, nutrition, and psychological support, graduated reduced doses of opium were used to detoxify opium addicts. At its peak there were more than 100 Keeley Institutes and the Keeley Cure was used in other institutions and sent out by mail order as well. Aftercare support was provided by the Keeley League, initially called the Bi-Chloride of Gold Club, boasting 30,000 members and 370 chapters across the United States.

Controversies swirled about the Keeley Institute and many critics surfaced over the years. Among the many criticisms was that the injections contained no gold and

were, in fact, merely placebo concoctions designed to keep the patients in residential treatment for 4 weeks. Leslie Keeley went to his grave without ever revealing the secret formula for his highly touted cure. The Keeley empire began to decline with the death of Leslie Keeley in 1900 but continued in operation for many years thereafter. In the 1940s, Alcoholics Anonymous arranged a loose affiliation with Keeley, and AA meetings were sometimes organized at Keeley facilities. The last patients were admitted to the original Keeley facility in Dwight, Illinois, in 1966.

Notwithstanding the many critics of Dr. Keeley's concoctions and marketing techniques, the Keeley phenomenon did advance the evolution of addiction treatment in many positive ways. First, Dr. Keeley's aggressive marketing campaigns helped to educate the public about the disease nature of alcoholism and addiction and its potentially successful treatment. Second, through this public education process, the stigma of alcoholism and addiction was reduced. Third, regardless of the actual physiological effects of the Double Chloride of Gold concoction, many addiction recoveries were initiated through its use. Fourth, many of those were attracted to treatment by the public's awareness of the large number of successfully treated patients coming out of the Keeley Institutes. Fifth, while the focus of the Keeley Institutes was residential treatment, the widespread mutual help network established by the Keeley League bridged the gap between the Washingtonians and the inception of Alcoholics Anonymous in 1935. Sixth, the Keeley philosophy of hiring recovered alcoholics and addicts laid the groundwork for many of the treatment philosophies of today. Seventh, more recovered physicians were employed by the Keeley Institutes than by any treatment provider either before or since. Eighth, the Keeley philosophy promoted an enthusiasm for sobriety for recovering patients, replacing the pall of punishment seen in some institutions of the day. And lastly, many permanent recoveries resulted from the healing environment established and promoted by the Keeley system of medically supervised detoxification, mutual support among residential patients, graduated renewal of both emotional and physical health, and engagement of patients in early sobriety in the miracle and magic of recovery.

As the twentieth century drew near, optimism reigned among those who envisioned the upcoming widespread availability of residential treatment for addictive disorders. Unfortunately, political and economic forces of the day were not aligned with the enthusiasm of treatment center founders. A look at the early decades of the twentieth century revealed a dramatic decline in residential treatment in the United States. For example, the Southern California State Asylum was founded but was neither opened nor built. Others were opened briefly but soon closed or were used for other purposes. Even the institutions that remained open experienced a tenuous existence (White). Crothers noted that only 30 of the first 50 inebriate asylums remained open and that many of those remaining drifted from their scientific orientation.

The Scientific Temperance Federation studied prohibition's effect on residential treatment in 1922. Of the 275 residential treatment facilities identified prior to prohibition, they were able to collect information on only 184. Of those, only 51 were still open for business. Most had closed their doors or redefined their

mission due to lack of admissions. Their research revealed only 27 dedicated residential inebriate treatment facilities nationwide (Stoddard 1922).

Inebriate asylum	Facilities at peak	Facilities in 1922
Gatlin Institute	5	0
Neal Institute	62	2
Keeley Institute	100	12

Even those that remained open experienced a dramatic drop in admissions. For instance, between 1919 and 1921 male admissions to the Chicago Washingtonian Home dropped from 1,114 to 171 (Stoddard 1922).

Residential treatment for addiction all but disappeared. Facilities were either closed altogether or became prisons, private hospitals, or asylums for the insane. The only remaining treatment centers were very expensive private hospitals or public insane asylums. Professional interest in the treatment of addiction withered and the American Medical Association for the Study of Alcohol and Other Narcotics dissolved in the 1920s (Cherrington 1925).

White identifies eight external and internal causative factors to explain the rapid decline in residential inebriate treatment: economic forces, social and political forces, poorly developed clinical technology, patient selectivity, modality/environmental bias, conflict within the field and with allied fields, ethical abuse, and the problem of leadership succession (White 1998). A brief expansion of each of these factors follows:

- Economic forces: The failure of government to provide structure or support to residential addiction treatment funding left the movement to the whim of the capricious economic marketplace.
- Social and political forces: The attitudinal trend toward criminalization of addiction disorders marginalized and ultimately almost eliminated residential addiction treatment.
- Poorly developed clinical technology: The scientific foundations of residential addiction treatment never gained the respect of either the scientific community or the public at large.
- Patient selectivity: While publicly funded establishments were often burdened with disruptive court-mandated clients, private institutions became adept at accepting only those wealthiest clients with a high probability of success, often engendering public scorn through this process.
- Modality/environment bias: While residential treatment costs more than outpatient treatment, at the same time it self-selects for those later-stage patients who have burned through their resources and thus restricted their ability to afford the treatment they need.
- Conflict within the field and with allied fields: Conflicts within individual institutions, within the field of addiction treatment, and between the field of addiction and that of mental health treatment created an environment in which sustained growth became impossible.

- Ethical abuses: Perhaps even more striking than the abuses themselves, which were significant, was the treatment professionals' refusal to recognize the concerns and complaints of the patients.
- The problem of leadership succession: The visionary and often charismatic founders of the residential treatment movement seemed particularly inept at recruiting and training the new generation of leaders in the field, and many residential addiction treatment programs simply died with their founders.

Over the course of the residential chemical dependency treatments, however, the inebriate homes and asylums did make substantial contributions. These contributions included support for those suffering from chemical dependence, the first professional medicalization of drug and alcohol excess consumption, biological explanations of drug dependence, and recommendations for physical treatment methods. Discussions of the biology and heredity of inebriety helped move treatment from moral instruction to medical treatment. And doctors who treated drunks began to gain legitimacy as physicians who attended to legitimate patients suffering from a real disease.

68.2.3 Residential Treatment in the Mid-Late Twentieth Century

The year 1935 marked considerable advancements in the treatment of addiction in the United States. First it observed the meeting of an alcoholic New York stockbroker and an alcoholic Akron, Ohio, physician which culminated in the founding of Alcoholics Anonymous (AA). And it commemorated the opening of the first federally supported residential drug treatment center called the Addiction Research Center (ARC) in Lexington, Kentucky. Researchers at ARC spearheaded the study of addiction as a disease in a residential setting, and their work continues today at the National Institute of Drug Abuse in Baltimore, Maryland (White 1998). 1935 was also noteworthy for the founding of residential addiction treatment based on Pavlovian aversive therapy. Seattle businessman Charles Shadel's quest for a solution for his own alcoholism had brought him to Dr. Walter Voegtlin, a gastroenterologist who had just created a treatment for alcoholism based on the use of nausea as a conditioned reflex. Shadel was so impressed with the successful results that he first provided treatment services in his own home and then bought another house to institutionally treat patients and soon thereafter a second institution in Portland. In short, patients were carefully screened for motivation to stop drinking altogether. They were admitted and provided with as much alcohol as they wanted to drink, coupled with injections of emetine to induce vomiting. These treatments were repeated every other day for 10 days and then repeated regularly following discharge for the next year. As with other aversion therapy treatment centers, patients were provided with other detoxification medications, counseling, improved nutrition, sympathetic staff, and a generally supportive environment. The Shadel hospitals were later purchased by Schick Laboratories and operated under the name of Schick-Shadel in Texas and California. A subset of the original Shadel system was later operated under the name Raleigh Hills and franchised into ten states and 21 separate hospitals.

The period between 1948 and 1950 saw the development of the "Minnesota Model" developing from the influence of three separate institutions: Pioneer Hospital, Hazelden, and Willmar State Hospital. This model went on to influence alcoholism and addiction treatment for the next 65 years, and there seems to be no indication that this influence will diminish into the foreseeable future.

In the late 1940s, the welfare department of the city of Minneapolis, Minnesota, became increasingly aware of the rising successes of those residents who became engaged in the fledgling Alcoholics Anonymous. Funding was identified and a new treatment facility was created under the direction of a local sober member of AA. Named Pioneer House, the new treatment program was described as neo-Washingtonian. Patients were given a copy of Alcoholics Anonymous (The Big Book) and Twelve Steps and Twelve Traditions upon admission and the treatment philosophy was based on flexibility and spirituality.

As Pioneer House was just getting underway, Hazelden began to come together as a "sanitorium for curable alcoholics of the professional class" (White). Again, the treatment philosophy was to be founded in AA and the early staff was led by a sober AA alcoholic. Detoxification was generally "cold turkey" but medications were prescribed at times for severe situations. Treatment consisted of lectures, mutual support, improved nutrition, and occasional recreational activities. The facility had four requirements of their patients:

1. "Practice responsible behavior."
2. "Attend the lectures on the Steps."
3. "Associate and talk with the other patients."
4. "Make their beds."

With the exception of only minor creative flexibility in those earliest days, the treatment was simply pure AA.

The 28-day inpatient, abstinence-based, program of treatment was initially developed over a period of 3 years, from 1952 to 1955, by junior clinicians at Willmar State Hospital in Minnesota. Their work would evolve to become known as the Minnesota Model of addiction treatment, which arose from the co-integration of a state hospital program and a nonprofit AA recovery program. The Minnesota Model gained widespread acceptance in the 1970s and became the standard for rehabilitation treatment through the 1970s and 1980s.

As described by William White, there were several components that contributed to the "Minnesota Model" formula (White):

- Alcoholism is an involuntary, primary disease that is describable and diagnosable.
- Alcoholism is a chronic and progressive disease; Barring intervention, the signs and symptoms of alcoholism self-accelerate.
- Alcoholism is not curable, but the disease may be arrested.
- The nature of the alcoholic's initial motivation for treatment – its presence or absence – is not a predictor of treatment.
- The treatment of alcoholism includes physical, psychological, social, and spiritual dimensions.
- The successful treatment of alcoholism requires an environment in which the alcoholic is treated with dignity and respect.

- Alcoholics and addicts are vulnerable to the abuse of a wide spectrum of mood-altering drugs. This whole cluster of mood-altering drugs can be addressed through treatment that defines the problem as one of chemical dependency.
- Chemical dependency is best treated by close, less-formal relationships with their clients and whose activities are integrated within an individualized treatment plan developed for each client.

The founders of the Minnesota Model describe their program stemming from two key principles: (A) respect for individual patients/clients and their families and (B) recovery is possible with the help of a Higher Power and the fellowship of AA (Anderson et al. 1999). Further key elements of the Minnesota Model include the following seven elements: "(1) the integration of professional staff with trained recovering alcoholics; (2) the focus on the disease concept and our link to the 12-step fellowships; (3) the dedication to family involvement; (4) the insistence on abstinence from the use of all addicting drugs (for example, people addicted to alcohol were not considered clean and sober if they used marijuana or cocaine and vice versa); (5) the emphasis on patient and family education; (6) an individualized treatment plan; and (7) a continuum of care integrating sustained aftercare into all treatment plans" (Anderson et al. 1999).

Twenty-eight-day programs typically begin after a patient has undergone medically managed withdrawal from any alcohol, sedative, or opioids they may have been taking. The most effective treatment for alcoholism includes an orientation to AA, an expectation of "step work," groups that combine confrontation and support, lectures, one-to-one counseling, and the creation of a dynamic "learning environment." Based on a 12-step model of spiritual awakening, patients are educated about the disease model of addiction, relapse prevention, and the 12 steps of Alcoholics Anonymous (or Narcotics Anonymous) through didactic sessions. Small group therapy sessions are typically the core of treatment, where patients are encouraged to share their stories and present assignments related to their recovery. In its current iteration, these treatment modalities are often augmented with individual therapy sessions, specialty groups, fitness programs, mindfulness exercises, acupuncture, and a myriad of other approaches.

The most viable, ongoing, sobriety-based support structure for clients following treatment is AA.

In recent years the Minnesota Model has at times endured criticism for being too rigid, but in the early years, the treatment model was quite flexible. Outcome studies seemed good for the time and others soon began to follow this model. According to William White, the reasons for the spread of the Minnesota Model are as follows (White):

- The AA network
- Professional conferences, particularly the Yale-Rutgers Summer Schools
- The educational campaign of the National Council on Alcoholism
- Former clients
- Internship and training programs
- Visitors to Willmar and Hazelden
- Former staff of Willmar and Hazelden

By 1960 the Unites States was home to approximately 200 alcoholism treatment centers, some of longstanding presence and others founded within the preceding 2 decades. Some of the long established programs included the Washingtonian Homes, the Keeley Institute, the Keswick Colony, the Menninger Foundation, the Shadel Sanitarium, and the Blythewood Sanitarium. Some of the newer residential treatment facilities included Mrs. Pink's Place, the Bridge House, Beech Hill Farms, Alina Lodge, Portal House, Brighton Hospital for Alcoholism, the Georgian Clinic and Rehabilitation Center for Alcoholism, the Salvation Army, and the Chit Chat Foundation.

In the 1970s, Minnesota Model proponents were successful in some jurisdictions at requiring insurance payers to include 28-day inpatient stays for substance use disorders as a requirement to sell insurance. The late 1980s and early 1990s saw the emergence of managed care, which sought to aggressively control costs through limiting benefits for behavioral health treatments and particularly substance use disorder treatment.

In 1986, President Reagan signed an executive order mandating the federal Drug-Free Workplace program and the Anti-Drug Abuse Act passed, authorizing $4 billion to support law enforcement approaches to fight drugs. The very next year, 1987, saw the United States launch its War on Drugs, signaling a shift away from treatment and toward law enforcement and incarceration approaches to manage drug and alcohol problems.

These led to changes in payer approaches that effectively eliminated 28-day inpatient treatment programs as first-line insurance-financed treatment for substance use disorders (White 1998). The burden of paying for these programs shifted to state Medicaid programs, and by the mid-1990s, many 28-day free-standing centers had closed. Hospital-based treatment units, once focused entirely on the treatment of substance use disorders, consolidated with other forms of psychiatric treatment under the umbrella of mental health or behavioral health. Additionally, programs began to focus services on partial hospital or intensive outpatient levels of care (White 1998).

Despite these changes, 28-day residential inpatient programs remain colloquially synonymous with the term "rehab." Many well-known addiction treatment centers continue to maintain treatment programs organized in the 28-day residential model of treatment, typically on an out-of-pocket fee basis. In contrast, for indigent patients, there remain residential or inpatient 28-day programs for those program meeting criteria for this level of care. These programs are typically funded by state Medicaid programs in combination with local fundraising.

68.2.4 Halfway House Movement

Halfway houses were in no way restricted to addiction and alcoholism treatment but did find significant application in that regard. Throughout history various cultures have utilized the halfway house concept. For well over a hundred years almshouses

and "country farms" had been established places where alcoholics could be sent to sober up. "Temperance hotels" and "lodging rooms" were used similarly. Beginning in the 1930s, however, it appears that after sober Alcoholics Anonymous members began to take in newcomers to establish their own sober foundation, the halfway house concept really began to take hold. Some appeared to focus on alcoholics who might be on their way into a more structured treatment facility. Others seemed to be organized in a way to help alcoholics who were on their way from a structured treatment environment on their way back to society.

While halfway houses differed widely, there were some general commonalities: structured living, peer support, and lifestyle reconstruction (White). Earl Rubington noted "four structured principles" (White):

- Small size
- Simple rules
- Reduction of status differences between residents and staff
- Informality

In 1974 the International Halfway House Association boasted 1,300 members.

In 1975 the Oxford House model arose as an interesting subset of the halfway house concept. Newly sober congressional attorney Paul Malloy was about to be evicted from the halfway house in which he lived. Rather than go back to the street, he and the other residents got together and created the first resident-administered Oxford model halfway house. They took the concept of recovering staff perhaps one step further. Oxford House has no staff whatsoever, only recovering alcoholics and addicts. Average length of stay is 15 months but residents can actually stay indefinitely. All the residents are expected to hold down a job as well as do their share of the chores. Officers are democratically elected in each house. Every new resident is interviewed and must be voted in by the current residents. Relapses are dealt with by a vote of the residents of each house, usually with immediate eviction. Sobriety is of paramount importance, and if a resident is not willing to maintain their own sobriety, they must find another place to live. Within 15 years there were over 200 homes and by 2013 Oxford House could boast 1,600+ homes around the country, each one run by the residents who supported their own house with their own contributions.

The middle of the twentieth century saw other experiments in residential treatment. Teen Challenge was founded in 1961 by the clergy of the Assembly of God Church and operated 40 residential programs around the country.

68.2.5 Therapeutic Communities

The concept of the therapeutic community (TC) first appeared in the Dead Sea Scrolls at Qumron with discussions of the rules of community. Adherents to this concept were expected to follow the ways of the community and live righteously and healthfully. Similar ideas were applied in the inebriate asylums of the nineteenth century and further developed by Dr. Maxwell Jones in the 1950s. The first broad application of the "community as treatment" was developed as

Synanon evolved out of Alcoholics Anonymous by Charles Dederich on the Santa Monica beachfront in the late 1950s. It began as a 2-year residential treatment program but shifted focus toward a place of self-discovery through an alternative lifestyle, moving it away from drug and alcohol treatment into a quest for utopia through the Church of Synanon (Batiste and Yablonsky 1979).

Daytop Village was founded in New York City in 1962 by an order of the Kings County Supreme Court of New York. Despite the cost of long-term housing and board, costs were kept down by the almost exclusive use of former addicts as both the clinical and administrative staff. Under the astute leadership of Msgr. William O'Brien, Daytop grew into a multi-facility, multistate long-term residential treatment program primarily focused on addiction treatment and following the therapeutic community model. Daytop, Phoenix House, and other similar programs proved highly successful with the very difficult population of addicted criminal offenders.

The most comprehensive evaluation of the therapeutic community model has been done by George DeLeon in his book *The Therapeutic Community*. Despite the positive outcome studies, several documenting success rates well above 90 %, many are still critical of this proven modality.

Most of the therapeutic communities of the late twentieth and early twenty-first centuries relied heavily on government support for their existence (Delancey Street in San Francisco being a stark exception). While they enjoyed high rates of long-term success (no drug and alcohol use and no criminality) at very low relative cost, the governmental funders first in Europe and then in the United States saw them as the geese laying golden eggs. Over time, more and more nonclinical demands were placed on the therapeutic communities while their funding was whittled away year after year. Demands were made to include educational components, health care, and psychiatric management. Government agencies which were unable to deal effectively with the severely mentally ill and otherwise mentally handicapped began to require that the therapeutic communities accept all that were referred their way. The programs were required to hire state licensed personnel, often without the clinical skills of the traditional ex-addict staff who were the key to the dramatic success of the early therapeutic communities. Often these clinical demands were not balanced with commensurate funding, further aggravating the situation. In fact, government agencies frequently pressured therapeutic communities to continually decrease their length of stay, abbreviating the residents' clinical exposure to the point that the programs began to become ineffective.

One shift in the approach of punishing addicts came with the passing of California Proposition 36 into state law, which is also referred to as the Substance Abuse and Crime Prevention Act of 2000, wherein qualified convicts of nonviolent drug possession charges were placed on probation and referred to identified drug treatment programs in the community instead of fulfilling a traditional sentence in jail or on probation without treatment. Treatment programs included residential treatments and aftercare services for approximately 12–18 months (Longshore et al. 2005). The law went into effect on July 1, 2001. Within the first 4 years, there was a 71 % drop in drug use in the nearly 48,000 people that completed treatment (Anderson et al. 1999).

The Greenhouse Program at Bellevue Hospital was a novel approach to the treatment of dually diagnosed persons in a modified TC. It was a peer-led program, with hired staff, based on the structure of TCs for "singly diagnosed substance-dependent patients." It was located in one section of the Bellevue Homeless Shelter in New York City. The first 100 patients had a 33 % completion rate (which is similar to that of Prop 36) and all were abstinent for the duration of their time in the program. Despite this success and over a decade of building a community that patients returned to even after completion of the program, funding was eventually cut leading to the dissolution of the program (Westreich et al. 1996).

Another bright spot is a residential treatment program founded in San Francisco by Mimi Silbert in 1971. Delancey Street describes itself as a "residential self-help organization for former substance abusers, ex-convicts, homeless and others who have hit bottom" and avoids the term therapeutic community (Delancy Street Foundation. http://www.delancystreetfoundation.org/wwa.php). But there are some similarities with the traditional TC of the 1960s. A strong emphasis is placed on the "total learning center" approach, encouraging "financial self-sufficiency and teaching residents self-reliance and life skills." There is no clinical staff; the entire program is resident-run. Average length of stay is 3–4 years and the minimum residential commitment is 2 years. Delancey Street currently boasts five residential facilities with 1,200 total residential beds. While Delancey Street does accept donations of goods (beds, building supplies, etc.), they do not accept any government funding whatsoever, and never have. They do run a variety of enterprises including restaurant, café, digital print shop, moving and trucking business, and several other businesses. In this day of diminishing public funding, this model may be the best alternative for many who suffer from the disease of addiction.

68.3 Conclusion

Despite a history beginning several centuries ago, the future of residential care in the treatment of substance use disorders remains uncertain. During the 1970s, there was an expansion of residential treatment centers particularly with the advent of the Minnesota Model. However, this eventually contracted due to a lack of support and recognition. The overall decline of such programs has left a huge treatment void in Europe, and the United States seems not to be learning from their experience. It is worrisome to consider the defunding of public treatment programs, drying up of insurance funding as health care becomes nationalized, and the fact that private programs are becoming exorbitantly expensive for the common man. Sadly, we may be seeing the next pendulum swing away from addiction treatment and back toward incarceration and this at a time when the world's economies are least able to squander resources on such wasteful and unsuccessful practices. The future of addiction treatment worldwide may well be correlated with appreciating that access to residential treatment is the key in the continuity of care of persons with addiction.

Strategies of Drug Prevention in the Workplace: An International Perspective of Drug Testing and Employee Assistance Programs (EAPs)

69

David E. Smith and Leigh Dickerson Davidson

Contents

Abstract

Drug testing in the workplace is not universal and is regulated by various governmental agencies at the federal, state, and municipal levels, as well as by various industries. Safety-sensitive occupations are typically targeted, and various industries and agencies have differing drug testing protocols. In the United States, drug testing is highly structured, and much of it falls under the purview of a Presidential Executive Order issued in 1986 and subsequent legislation, establishing a drug-free workplace. A medical review officer (MRO) resolves questionable false-negative and false-positive tests. In European Union countries, drug testing is much less uniform, as attitudes to workplace drug problems are quite variable with no standard approach. While illicit drug use spurred widespread drug testing in the United States, legitimately prescribed medications that may impact safety in the workplace are a growing issue that has not yet been fully addressed. Many companies establish employee assistance programs (EAPs), which are designed to help businesses address productivity issues by providing various services to behaviorally affected employees to alleviate and

resolve issues, including substance abuse, with their job performance. It is easier to evaluate the effectiveness of the US method, due to its structure, than to assess the varied European approach.

69.1 Introduction

Drug testing to promote workplace safety by preventing (or at least reducing) employee drug use is regulated by various governmental agencies and at the federal, state, and municipal levels. Employers' insurance companies may require drug testing programs. Different protocols exist for various industries and agencies, although certain elements are constant. Some companies require testing of every employee, others require preemployment testing, and still others require testing for employees holding safety-sensitive positions. Most require testing for drug and alcohol use following accidents. The consequences of verifiable illicit drug use in the workplace range from some form of disciplinary action to referral for treatment to termination of employment.

69.2 Drug Prevention in the Workplace

The modern era of drug use prevention – other than alcohol – in the workplace began in the 1980s in the United States with the establishment of the Drug-Free Federal Workplace Program (Executive Order 12564 1986), which paralleled

the drug epidemic permeating industrial settings in the United States and contributed to a number of highly publicized major, multiple-fatality accidents, in which several of the workers involved tested positive for marijuana. As a result, the US Federal Government issued Executive Order # 12564 in September of 1986:

> The Federal Government, as the largest employer in the nation, can and should show the way towards achieving drug-free workplaces through a program designed to offer drug users a helping hand and, at the same time, demonstrating to drug users and potential drug users that drugs will not be tolerated in the Federal workplace . . ..

The executive order mandated that most of the federal agencies under the purview of the Executive Department require their employees to refrain from the use of illicit drugs, that the agencies implement and develop employee assistance programs, and that they implement drug testing programs and procedures. The focus of the drug-free workplace was to eliminate illicit drug use such as heroin, cocaine, amphetamine, marijuana, and 1-(1-phenylcyclohexyl)piperidine (PCP), known as the "NIDA-5" ("NIDA" being the National Institute on Drug Abuse). However, because alcohol was and is the primary drug problem in industry in both the United States and worldwide, the Omnibus Transportation Employee Testing Act of 1991 included alcohol. As determined by the Division of Workplace Programs of the Substance Abuse and Mental Health Services Administration (SAMHSA) in the United States, the majority of current illicit drug users are employees, as full-time workers constitute about two-thirds of the adult population (unemployed individuals have a higher rate of substance use behaviors and disorders) (Larson et al. 2007).

While illicit drugs were the main impetus for the establishment of the drug-free workplace regulation in the 1980s in the United States, legitimately prescribed medications, primarily opiates, are a growing issue that has not yet been fully addressed.

The components of a comprehensive Drug-Free Workplace Program in the United States include a formal written policy, an employee assistance program, supervisor training, employee education, and methods for detecting illicit drug users (i.e., drug testing). Not all companies in the United States have comprehensive workplace programs.

In addition, US legislation established the designation of "medical review officer" (MRO) for the evaluation of questionable drug test results. Organizations such as the American Society of Addiction Medicine (ASAM) offer regularly scheduled courses to provide clinical training in the review and analysis of drug test results and certification of qualified MROs (ASAM 2005/2009).

Many companies internationally have established employee assistance programs (EAPs), which are designed to help businesses address productivity issues by providing various services to behaviorally affected employees to alleviate and resolve issues interfering with their job performance (Office of Disability Employment Policy 2009). The Employee Assistance Professionals Association lists several national and regional EAP associations and organizations at www.EAPASSN.org.

69.2.1 Drug Testing in the US Workplace

Workplace drug testing in the United States is highly structured and intended to foster workplace safety standards. Tests are generally administered in a nonmedical setting, where body fluids, most commonly urine, are collected and analyzed, passing through a rigorous and well-documented "chain of custody" process (ASAM 2002/2012). The frequency, type, and drugs tested for typically depend on the industry and various governmental regulatory bodies involved. Companies and organizations with US government contracts must be compliant with governmental regulations regarding drug use in the workplace.

Drug testing is most common in settings where employees perform hazardous tasks such as operating heavy equipment and where they could place other persons at risk, as in transporting passengers or performing medical and surgical procedures, in the operation of nuclear power facilities, and in public safety positions such as police and fire. Each branch of the military has a program for drug testing of its service members.

Several types of drug testing exist: applicant, accident/unsafe practice, reasonable suspicion, follow-up to treatment, random, and voluntary. Many employers require drug testing of potential employees; all require drug testing of employees involved in accidents (accident/unsafe practice). Drug testing may also be ordered if an employee's performance is impaired (reasonable suspicion) and/or the employee has been observed using alcohol and/or other proscribed substances.

Follow-up drug testing is often instituted as part of an individual's plan for recovery after intensive treatment. Ideally the tests are random. Voluntary tests might be characterized by an individual desiring to know his own level of substance levels, perhaps in anticipation of an employer test.

Interpreting drug test results is more nuanced than a simple "positive" or "negative" if a valid result is to be obtained. Individuals may test positive if they are taking a prescribed pain reliever, for example. They may test negative if a test is compromised or adulterated either intentionally or inadvertently. For this reason, it is advisable that a qualified medical review officer (MRO) be available to certify the results obtained. It must be noted that while MRO protocols, supplies, and equipment are quite rigorous to prevent adulteration of samples, the Internet and human initiative offer an ever-growing fount of information for bypassing the procedures. Medically prescribed drugs and dental procedures can skew results, and the new synthetic drugs that are continually emerging typically do not even show up in the standard assays (ASAM 2002/2012).

Use of a drug is not associated with impairment and risk of accident. Therefore, in the United States, the focus has been on total drug use prevention, rather than impairment and accident risk.

Random drug testing is mandated by many regulatory agencies to more accurately gauge whether the employees they are regulating are using illicit substances. Employee identifications are usually generated in a random fashion, and the employee must report for a drug test typically within 24 h at a location determined by the employer. A specimen is collected and, depending on the technology

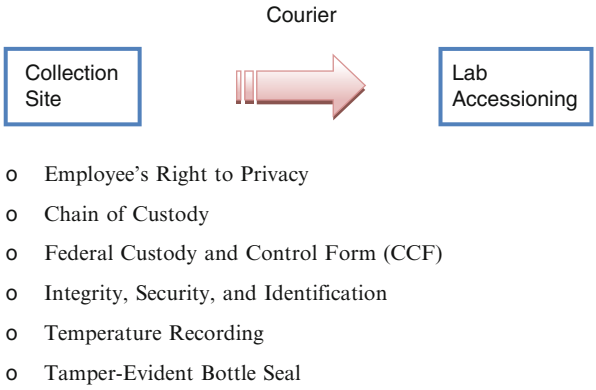

Fig. 69.1 Components of specimen collection

available, is either analyzed digitally on site immediately or shipped via overnight express to a centralized laboratory. Samples are usually "split" in the event of a need to reanalyze, e.g., if a sample is positive and the employee protests the result. At this point the MRO would become involved and order a retest of the split specimen to validate the results of the original test.

The specimen collected, often urine, but possibly other bodily fluids such as blood or hair, follows a rigorously controlled path to control for and balance various concerns such as the employee's right to privacy and the possibility of tampering (Fig. 69.1).

Employees testing positive are often relieved of duty until positive drug test results are resolved by the MRO. The specimen may have been collected incorrectly, subjected to shipping delays, or otherwise mishandled. Employees may also be using over-the-counter (OTC) or prescribed medications that can alter results. Depending on the sensitivity of the tests being used, foodstuffs, e.g., poppy seeds, may also generate a false positive. For this reason, workplace testing in the United States has established cutoff levels for opiates well above the levels triggered by poppy seeds, and for marijuana, well above the levels of passive inhalation ("second-hand smoke"). The test, however, is geared to established drugs. There are many designer drugs such as the synthetic stimulants, e.g., "bath salts," and synthetic cannabinoids, e.g., "spice," designed to create a high for the individual but not registering on the NIDA-5 tests.

Upon resolution of the questionable test results by the MRO, the employer is notified of the validated results. The employer then takes appropriate action as specified by the regulatory agency – ranging from return to work to referral to treatment to termination of employment.

Drug testing is crucial for effective identification, intervention, and monitoring in the workplace. A drug test is a medical test, although it may be used for nullification purposes as well as monitoring the effectiveness of treatment. The medical review officer categorization was established so workers would not be denied medically prescribed medication in overzealous attempts to extinguish illicit drug use. The following illustrates the MRO Drug Test decision tree and laboratory analysis (Figs. 69.2, 69.3, and 69.4).

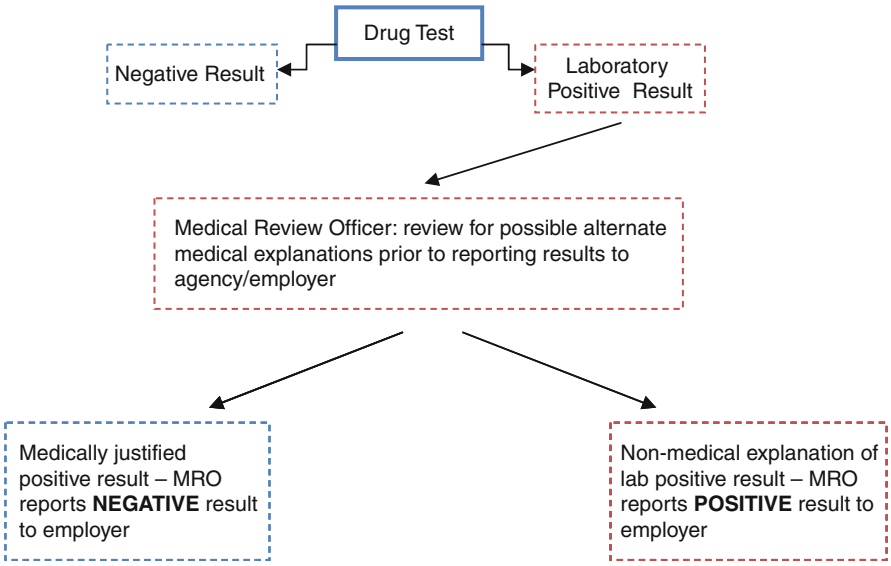

Fig. 69.2 The MRO chain

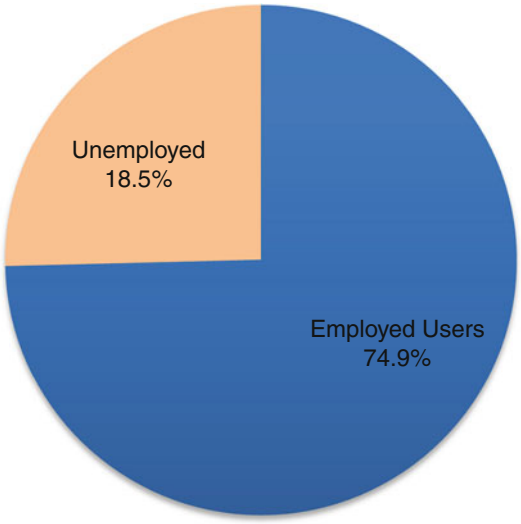

Fig. 69.3 The majority of current drug users are employed (current users of illicit drugs, ages 18 and over) (Source: National Survey on Drug Use and Health: National Findings 2006)

The drugs most often used in the United States are pain relievers. As these drugs are often opioids, they can compromise NIDA-5 results, requiring further validation of the drug test by a medical review officer (MRO).

Companies involved with transportation and use of motor vehicles are usually governed in the United States by the Department of Transportation (DOT) regulations, which specify testing for five illicit drugs: marijuana, cocaine, amphetamine,

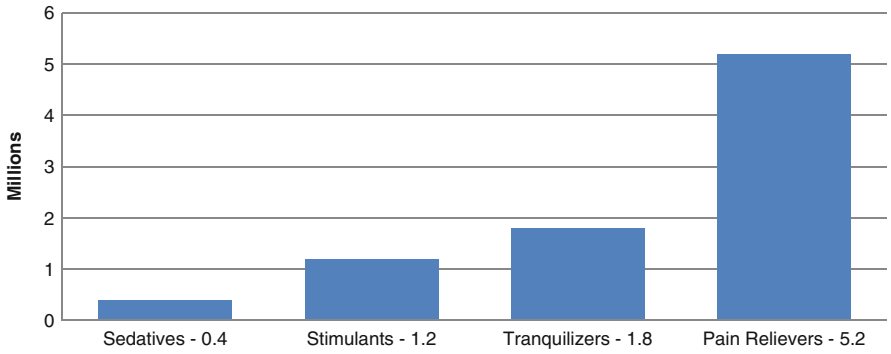

Fig. 69.4 Current use of psychotherapeutic drugs (Source: National Survey on Drug Use and Health: National Findings 2006)

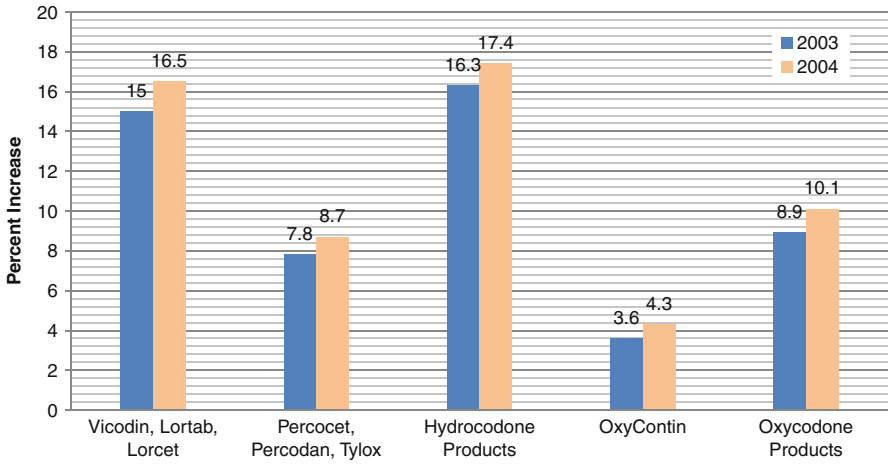

Fig. 69.5 Increase in prescription drug use (Source: National Survey on Drug Use and Health: National Findings 2006)

1-(1-phenylcyclohexyl)piperidine (PCP), and heroin (the NIDA-5). However, there is a growing problem with prescription drug abuse in society as a whole and in the workplace.

The Drug Enforcement Administration (DEA) statistics report that more than six million people in the United States abuse prescription drugs and new drug users use more pain relievers (2.4 million) than marijuana (2.1 million) or cocaine (one million) (Fig. 69.5).

Currently, the prescription drugs most often abused in the United States are opiates, opioids (including codeine, hydrocodone, hydromorphone, oxycodone, oxymorphone, meperidine, tramadol, and fentanyl), benzodiazepines, muscular relaxants, antidepressants, and anticonvulsants.

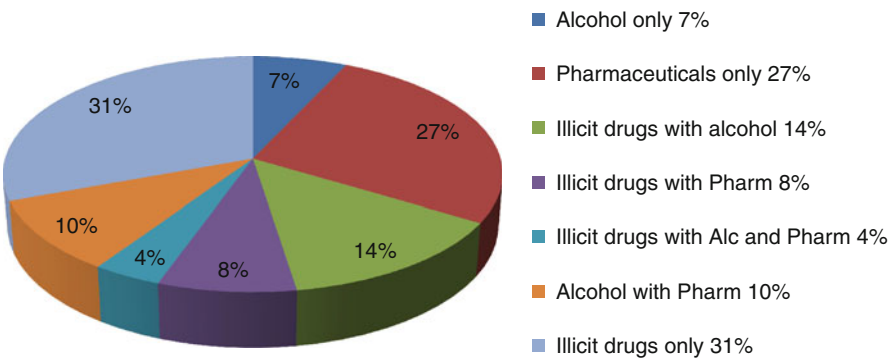

Fig. 69.6 Drug-related ER visits, by type of case: 2005 (Source: SAMHSA, ED Trends from the DAWN Final Estimates 2009)

Since many workers use narcotic pain medication appropriately with physician prescriptions, differentiating between appropriate use, misuse, abuse, addiction, and drug diversion in the workplace is crucial so legitimate pain management is not confused with inappropriate use that produces health consequences and safety risk. When an employee's tests results indicate a positive, the medical review officer (MRO) notifies the employee about his positive test result and requests a copy of the prescription (which should be of recent origin). The MRO instructs the employee to stop work immediately and report to his supervisor. If the employee has no prescription to explain the positive result, the MRO then notifies the employer that the employee is not medically cleared to return to work.

Opioids, unless carefully monitored, even when used for appropriate pain management, can lead to workplace accidents and a variety of related medical, psychological, and behavioral problems. Problems with opioids include side effects such as drowsiness, inattentiveness, impaired judgment, and poor hand/eye coordination; tolerance and physical dependence; loss of function; perception of emotional pain as physical pain (chemical copers); and hyperalgesia.

An issue that has not yet been satisfactorily addressed is establishing protocols for appropriate use of prescription medications that can affect workplace performance. Among the factors involved in the United States is the role of the Americans with Disabilities Act (ADA), which prohibits discrimination against those with disabilities. That is, if an individual requires a medication to maintain a certain quality of life, will denying that person employment due to his medication impair his quality of life?

The medical review officer (MRO) course presented by the American Society of Addiction Medicine (ASAM) provides clinical training on intoxication, overdose, and addiction for the opioid and opioid class of drugs. The course also provides training on the stimulant class of drugs such as amphetamines, methamphetamine, and cocaine, which are widely misused and abused in the workplace (ASAM 2005/2009).

Table 69.1 Levels of alcohol intoxication

BAC (blood alcohol concentration)	% of drivers too intoxicated to drive	Increased risk of accident
0.02 % restraint/awareness	5 %	^1
0.04 % comprehension	15 %	1×
0.06 % judgment	35 %	2×
0.08 % muscle control	65 %	4×
0.10 % coordination	100 %	8×
0.20 % equilibrium/sleep		65×
0.30 % stupor		600×
0.40 % coma		
0.50 % death		

The stimulants are cocaine, amphetamine, methamphetamine, nicotine, and caffeine. The disorders induced, which can affect workplace functioning, include the following, per the Diagnostic and Statistical Manual of Mental Disorders IV (DSM-IV): dependence; abuse; intoxication; withdrawal; intoxication delirium; induced psychotic disorder, with delusions; induced psychotic disorder, with hallucinations; induced mood disorder; induced sexual dysfunction; and induced sleep disorder.

There are a number of adverse drug reactions that require medical attention whether a drug is legal, such as alcohol, prescribed by a physician, or obtained illicitly through the drug culture, particularly when used in a polydrug combination.

Relative to adverse drug reactions requiring emergency room visits, prescription drugs ranked second and drugs in combination with alcohol ranked third (SAMHSA 2009) (Fig. 69.6).

The relationship between blood alcohol concentration (BAC) and accident risk is well established (the US National Transportation Safety Board (NTSB) is currently campaigning to reduce the legal BAC for all drivers). Due to the rapid metabolization of alcohol, urine ethyl glucuronide (EtG)/ethyl sulfate (EtS) testing allows for the detection of alcohol metabolites in urine for up to about 3 days after alcohol consumption, which standard tests may not detect (Table 69.1).

Identification of a drug problem in the workplace requires appropriate training and professional evaluation. As emphasized by Dr. Westley H. Clark, director of the Center for Substance Abuse Treatment (CSAT) and a faculty member of the ASAM MRO course, a positive toxicology screen or adverse drug reaction does not equate with chemical dependence, substance dependence, or substance abuse. Chemical dependence is often used with such terms as addiction, drug dependence, alcoholism, polydrug abuse, or substance dependence, and it depends on the diagnostic system used in the workplace to determine what the level of drug involvement is for the employee. The most severe form of chemical dependence is addictive disease, which is a pathological state with characteristic signs and symptoms, as well as a predictable outcome if not treated. It is characterized by the compulsive desire for the drug, loss of control when exposed to the drug, and continued use in spite of adverse consequences (ASAM 2005/2009).

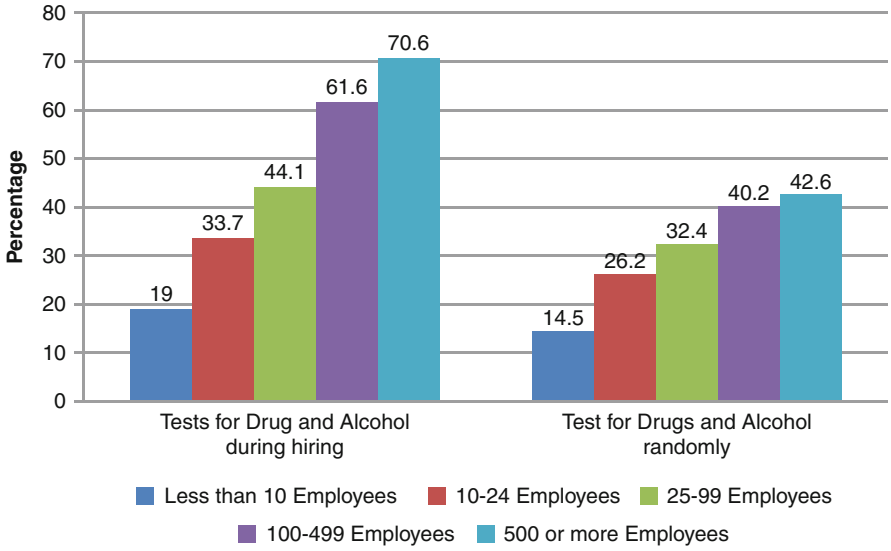

Fig. 69.7 Type of drug and alcohol testing program, aged 18–64 (Source: Worker Substance Use and Workplace Policies and Programs 2007 NSDUH)

Drug testing in the workplace is an essential component of a comprehensive workplace program, but implementation in American industry is quite variable (Fig 69.7).

Indications of treatment for the addicted worker can produce substantial workplace, societal, and personal benefits for both the employee and the company. Studies prepared by the Division of Workplace Programs of SAMHSA have shown that the individual's physical and mental health significantly improve after substance abuse treatment, with a major reduction in healthcare utilization.

Many workers abuse alcohol and illicit drugs in the workplace, violating company policy. However, only about 10 % of this exposed population in the United States display the disease of alcoholism and require longer intensive treatment before returning to work.

Recognizing that addictive drug and alcohol use is a disease has benefits for the employer when the employee is referred to treatment and willing to accept it. If the employee successfully completes treatment, the employer is able to retain a trained, experienced employee and eliminate the costs of recruiting and training a new employee.

69.2.2 Drug Testing in Europe

In European countries, drug testing in the workplace intended to control workplace alcohol and drug use is less standardized and more controversial than in the United States. The conflict revolves around the need for safety in the workplace where

safety concerns are high, such as construction, yet workers' concerns can outweigh the implementation of critical elements of the US testing model. National legislation varies widely in terms of rights and obligations for testing, allowable intake and use of alcohol or other drugs, acceptance of testing, the conditions under which testing can take place, monitoring of tests, and access to the results. Such deviation in policy makes standardized workplace programs associated with testing very difficult across the European Union. Some countries have no specialized programs, and most have limited programs, with the United Kingdom having the most comprehensive program.

Corral et al. (2012) examine in great detail the types of regulation in place across a wide swath of the European countries in their report *Use of alcohol and drugs at the workplace* for the European Foundation for the Improvement of Living and Working Conditions (Eurofound). As in the United States, drug testing is mandated (or not) by a variety of regulating governmental bodies and industries, and in some countries employees have a much louder voice than allowed in the United States. A sampling of study results cited in the Eurofound document follows.

Another major factor is the cultural tolerance, particularly toward alcohol in the workplace, which varies from country to country in contrast to the United States where the model is zero tolerance.

A majority of employers and employees in Europe reject the use of alcohol and drugs in the workplace, but the procedures for implementing this policy are quite varied and strongly influenced by the cultural views of the host country. Furthermore, the cultural stance toward alcohol and drugs in the workplace has grown more conservative based on a variety of studies. The Swedish Construction Federation reported that it was no longer socially acceptable to use drugs in the workplace in contrast to attitudes in the construction industry 30–40 years ago. However, as reported on a presentation of illegal drugs, the topic of drugs in the workplace is still a taboo subject in many member European states.

There is growing awareness of the consequences of alcohol and drugs in the workplace. Ninety percent of Portuguese enterprises had concerns relating to health problems, higher instances of sick leave/short-term absenteeism, reduced performance levels, labor conflicts and an unsettled work environment, and a greater number of work-related accidents. In an Italian study, absenteeism was found to be more than double in Italian employees addicted to drugs than in nonaddicted employees (Mariotti 2004). Alcohol-dependent workers in Austria were on sick leave 16 times more often and were sick 2.5 times more often than those who were not dependent.

Other European studies on drugs and the workplace also demonstrated that alcohol and drug abuse can negatively impact work performance and contribute to workplace accidents. One of the most important negative consequences of alcohol and drug use at work is the increased risk of accidents and potential harm to fellow employees. A 2008 Latvian report indicated that there was substantial economic loss and a damaged public image where the affected employee interacted with the public.

European studies have also documented the large economic costs of substance abuse in the workplace. In Norway, alcohol-related illness represents an economic loss in millions of euros. In Austria, alcohol use accounts for 1.25–2.5 % of the total payroll cost. The Austrian Chamber of Commerce (WKÖ) (p. 35) states that a worker with alcohol and drug problems only performs 75 % of his/her potential output.

Given these significant economic effects, European enterprises are increasing their response to unhealthy alcohol and/or drug involvement in the workplace.

However, it is often some time before a worker's alcohol or drug problem is recognized. A German study indicated that it was 8–10 years for men and 3–5 years for women. The typical response is to dismiss the employee. The workplace strategy of intervention and rehabilitation for first-time offenders widely used in the United States is much less common in Europe.

In contrast with the United States, European countries put more emphasis on workplace conditions that contribute to substance abuse, including work-related and social/personal reasons in which alcohol and illicit drugs are used for coping with their problems.

Work-related reasons include arduous working conditions, irregular work practices, and psychological stress at work.

The European Workplace Drug Testing Society (www.EWDTS.org) is organized to examine issues relating to workplace drug testing and presents annual conferences on the topic, bringing together various stakeholders: employees, employers, human resources, occupational health, compliance officers, attorneys, drug counselors, and treatment providers. EWDTS' stated goal is to ensure that drug testing in Europe is performed in a standard and legal manner. Their website also offers brief summaries of the status of workplace drug testing in various countries.

There is no centralized statistical information source for Europe. However, the European Monitoring Centre for Drugs and Drug Addiction (EMCDDA 2013) reports that cocaine is the second leading drug used after cannabis, with amphetamines and ecstasy a growing problem. If workplace programs exist, they are incorporated into an overall national strategy, with a few exceptions.

In France, the National Research and Safety Institute for the prevention of accidents at work has a program to train employers and managers to identify employees of concern and address their problems. In Germany, the German Centre for Addiction Issues commissioned an expert report on the practice of company-based drug prevention, which in 2006 was debuted by policy makers, health insurers, and social partners.

Various European states have found that alcohol and drugs represent a severe problem for a significant percentage of the working population. National estimates indicate that 5–20 % of workers are impaired by alcohol or other drugs, a problem that is particularly relevant in sectors such as construction, transportation, and farming. Alcohol and drug consumption at work often results in negative workplace consequences in terms of higher incidence of sick leave and reduced performance and productivity, as well as a negative economic impact. However, the United States has more comprehensive data on intervention and rehabilitation of the addicted employee, again highlighting major policy differences.

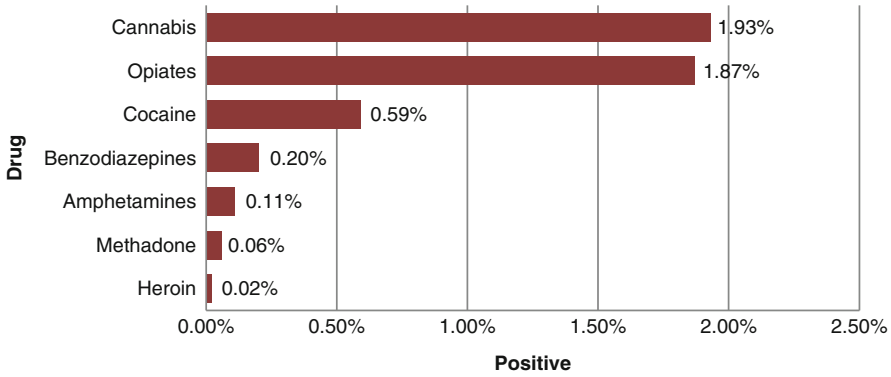

Fig. 69.8 UK drug prevalence within the workplace 2007–2011

Most European countries have some kind of general legislation or agreements in place to prohibit or regulate the consumption of alcohol and other drugs in the workplace, but there is considerable diversity regarding the type of legislation in force and the way policies are implemented. Some countries include the workplace as one area among several for which drug use is addressed. In some countries the approach can be labeled as disciplinary, as the limits on alcohol and drug use in the workplace are established in the national labor code or worker statutes.

In other countries, the approach is more preventative with regulations being established in national health and safety laws. In a small number of countries, such as Germany, Belgium, and Denmark, the regulation of alcohol and drugs in the workplace is based on collective agreements between social partners rather than purely coercive measures.

In some industries, companies institute workplace drug prevention policies because they are operating as multinationals, and drug policies must be in place in certain geographical locales and not others. Airlines and shipping firms illustrate this example.

European studies put more emphasis on work-related reasons for alcohol and drug use, including the existence of demanding physical work, uncomfortable working conditions, and low job satisfaction, including worker rights, whereas in the United States, the emphasis is on zero tolerance. Additionally, European cultures generally have had a more tolerant view of alcohol use during the workday (as was the case in the United States into about the 1980s, giving rise to the concept of the "three-martini lunch"), although some recent reports indicate that this is changing.

In a research report on drug prevalence in the UK workplace by the drug testing provider Concateno (2012), researchers determined that cannabis was the most often used illicit substance, closely followed by opiates (Fig. 69.8).

In comparing the patterns of drugs in the workplace between the United States and the United Kingdom, the positive rate in the United States has decreased,

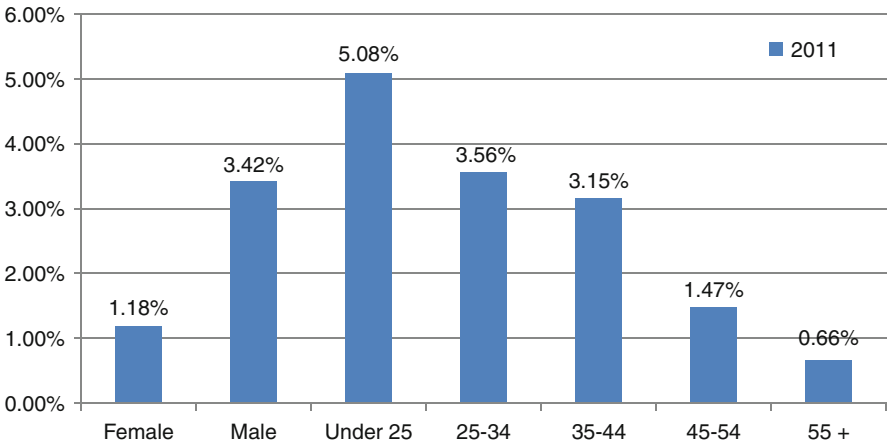

Fig. 69.9 UK workplace drug prevalence demographic for 2011

whereas the UK rate has increased. However, the equivalent rates in the overall populations are approximately the same. The question arises, does variation in workplace strategies between the two countries account for various outcomes? (Fig. 69.9).

The Concateno report further reveals that patterns of drug use change with age. Cannabis use decreases, while use of opiates increases.

A number of European studies have defined patterns of drug abuse in different countries and regions of the world. However, there are far fewer studies of workplace programs, and those that exist focus on the concepts of medical review, addiction medicine, and rehabilitation for the employee. Other countries and continents, particularly in the developing countries, have no studies or uniform policies for alcohol and drugs in the workplace.

As the economy globalizes, much more study is required to determine the most effective workplace programs in order to reduce workplace accidents while providing for the health and safety of the employee as well as increased productivity, which is often the main concern for the employer.

69.2.3 Employee Assistance Programs

Employee assistance programs for alcoholism in the workplace gained prominence after World War II, driven in large part by the influence of Alcoholics Anonymous (AA), which was formed in the 1930s. Individuals influential in the AA movement, such as Marty Mann, who helped found the National Committee for Education on Alcoholism (now the National Council on Alcoholism and Drug Dependence, or NCADD), and Ruth Fox, MD, who helped form the New York Society of Alcoholism, which evolved into the American Society of Addiction Medicine, were

among the guiding forces behind the formation of the American Society of Addiction Medicine (ASAM).

ASAM now recognizes addiction as a disease and has developed a clinical definition for addiction:

> Addiction is a primary, chronic disease of brain reward, motivation, memory and related circuitry. Dysfunction in these circuits leads to characteristic biological, psychological, social and spiritual manifestations. This is reflected in an individual pathologically pursuing reward and/or relief by substance use and other behaviors.
>
> Addiction is characterized by inability to consistently abstain, impairment in behavioral control, craving, diminished recognition of significant problems with one's behaviors and interpersonal relationships, and a dysfunctional emotional response. Like other chronic diseases, addiction often involves cycles of relapse and remission. Without treatment or engagement in recovery activities, addiction is progressive and can result in disability or premature death. (ASAM 2011)

The 4 C's of Addiction

- Craving
- Loss of Control
- Compulsive use
- Continued use despite harm

The key to an effective workplace program is a good employee assistance program (EAP). Identification of the alcohol- and drug-impaired employee can result in disciplinary termination for the employee and/or evaluation with referral to appropriate treatment. The ASAM assessment and patient placement criteria are most effective for such evaluation and referral. Although companies are not required to have workplace EAPs and treatment programs, many do have them because of insurance and liability issues. SAMHSA has determined that such programs produce excellent benefits, both economic, where treatment saves money in health and social costs, and societal, by reducing health and behavioral problems including accidents.

Because many workers use narcotic pain medication appropriately with physician prescription, differentiation between appropriate use, misuse, abuse, addiction, and drug diversion in the workplace is crucial so legitimate pain management is not confused with inappropriate use that produces health consequences and safety risk. The evaluation and selection of an appropriate lab is essential. It is also crucial to have a qualified medical review officer to interpret the drug test to reduce confusion and inappropriate action on either false-positive or false-negative test results.

EAPs may be funded by employers or by employee benefit organizations such as unions and are usually provided at no cost to the employee. They are designed to provide short-term counseling for a variety of personal issues, including legal, financial, life events, and health, including substance use and misuse, that may affect workplace performance. For issues which cannot be resolved quickly, referrals and other resources are typically provided. One might compare the services provided by an EAP to those of an ambulance: get to the patient quickly, stabilize his condition, and transfer to a longer-term facility for further evaluation and care if necessary.

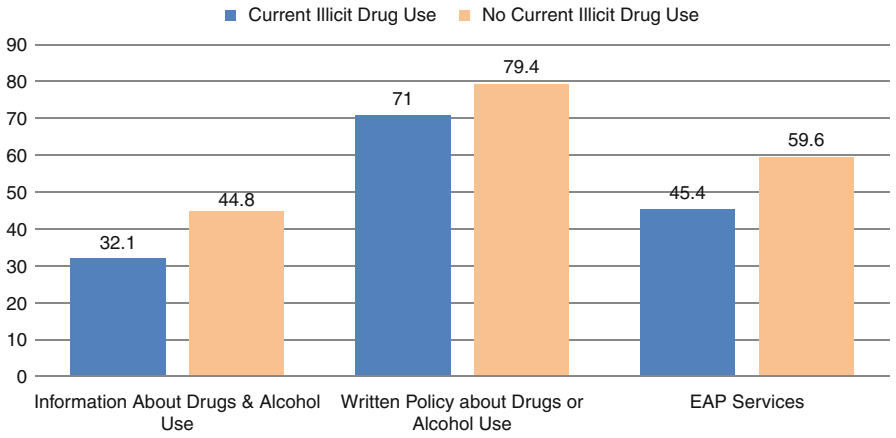

Fig. 69.10 Percentage of full-time workers, aged 18–64, reporting workplace-provided information (Source: 2002–2004 NSDUH, Division of Workplace Programs SAMHSA)

Confidentiality is maintained between employee and counselor; the content of sessions cannot ethically be reported to the employer.

EAPs are available internationally; the Employee Assistance Professionals Association is a worldwide association (www.EAPASSN.org), while several national organizations have their focus on Europe, the United States, Canada, Australia, the United Kingdom, Ireland, or the Asia Pacific region.

EAPs usually have a strong component for the recognition, referral, and treatment of substance misuse and abuse. Some large programs may include substance abuse professionals (SAP), who are trained to identify those with drug issues and provide referrals to treatment. They may also identify practitioners who enable employees who are abusing drugs, misusing their medications, or diverting their prescribed medications for sale to others for profit. Since the provision of prescription drugs is often an employer-paid benefit, identifying prescription misuse can ultimately save the employer funds that can be used in other areas to benefit employees (Fig. 69.10).

The EAP may also play a role in monitoring the return to work of a person with addictive disease, thus providing the employer with the experience and expertise of a trained employee and reducing the costs of recruitment and training of a new employee. Monitoring would typically consist of more frequent random drug testing of the returning employee, in conjunction with regularly scheduled psychotherapy meetings, using a 12-Step or other model.

69.3 Conclusion

In reviewing the broad topic of drugs in the workplace from an international perspective, it is clear there is no uniform approach.

The United States has the most well defined and structured approach, with elements of strict discipline, mandates, treatment, and rehabilitation with drug test monitoring before reentry into the workplace. In the European Union, there is a much broader approach that includes workplace conditions and reasons for alcohol/drug use with a focus on prevention but relying on rehabilitation.

Employee assistance programs offer benefits to both employers and employees. For the employer, they provide an avenue for maintaining productivity, reducing absenteeism and workplace accidents, and retaining skilled employees. For the employee, an EAP provides a lifeline to the recognition of and referral to treatment for debilitating substance abuse.

Abstract

The high prevalence of use among offenders is a consistent trend that transcends international boundaries. Chronic drug users in the criminal justice system pose risks to themselves and the general population through their commission of drug-related property and violent crime, as well as through the spread of infectious diseases, such as HIV and HCV. In this chapter, we review multinational evidence concerning the drug/crime relationship, the use of drugs within correctional settings, the consequences of drug use among offenders, and the intervention approaches for drug-involved offenders in custodial settings as well as those under community supervision. We conclude with several recommendations for practice and research that we consider to be important next steps in advancing this literature: (1) focus on implementation; (2) need for more randomized trials; (3) clarification of the role of coercion – when it helps, when it hurts; (4) distinguish "addicted offenders" from "offender addicts"; and (5) examine the use of depot medications for opiate-dependent offenders.

70.1 Introduction

The prevalence of substance use and substance use disorders among criminal justice populations has remained consistently high for decades – and in some places it continues to increase. It is estimated that half of prisoners in the European Union have lifetime histories of heavy drug or alcohol use (Zurhold et al. 2004). In the United States, the prevalence is estimated at nearly 85 % (Center on Addiction and Substance Abuse [CASA] 2010). Even as US incarceration rates are on the decline, the percentage of offenders incarcerated for drug charges has increased by nearly 20 % (CASA 2010).

The high rates of substance use among criminal offenders are the result of a host of demographic, psychological, sociological, and legal factors that vary across cultures. But despite these variations, one overall trend is clear: In most countries, substance-involved offenders account for a substantial share of criminal activity and criminal justice costs. According to one review, drug offenders account for 3–29 % of those incarcerated in the European Union (EU), 4–29 % of inmates in non-EU European countries, 5–53 % of inmates in the Americas, and 10–58 % of inmates in Asia/Oceania (Bewley-Taylor et al. 2009).

In this chapter, we review multinational evidence concerning the drug/crime relationship, the use of drugs within correctional settings, the consequences of drug use among offenders, and intervention approaches for drug-involved offenders in custodial settings as well as those under community supervision.

70.2 The Evidence for Causes, Consequences, Treatment

70.2.1 Causal Effects of Illicit Drugs on Criminal Behavior

Because the association between drug use and crime is complex, Goldstein's (1985) conceptual framework for the various types of drug/crime relationships is widely accepted and deserves some discussion here. Although originally proposed to explain the relationships between drug use, the drug trade, and violence, this framework can be applied more generally to include property offenses as well. Goldstein argues that drug use can be associated with other forms of criminality because of economic-compulsive, pharmacological, and systemic models of use and/or distribution. These are briefly summarized below:

- Economic-compulsive – resorting to criminal behavior to support one's drug use. Crimes in this category include property crimes to obtain money for drugs, selling drugs to support one's own habit, or having sex with someone in exchange for drugs or money for drugs.
- Pharmacological – engaging in irrational or violent behavior as a result of the acute and/or chronic psychological or physiological effects of a drug. For example, certain offenders might use, or threaten to use, violence because they were intoxicated and were not aware of what they were doing; or in some cases, an offender might use drugs or alcohol expressly to reduce the fear of danger prior to engaging in a criminal act.
- Systemic – engaging in crimes ranging from selling drugs to using violence, or the threat of violence, to protect a drug operation.

Subsequent research testing these relationships has shown that the systemic factors offer the strongest link – particularly for violent crimes (Tardiff et al. 1986). Evidence for the pharmacological link to violence among humans is often confounded by the poor specification of what drugs were used and in what quantity. Cartier and colleagues (2006) examined data from over 600 prison parolees to explore the associations between methamphetamine use and recidivism and found that methamphetamine use was significantly predictive of self-reported violent criminal behavior and general recidivism (i.e., a return to custody for any reason). This analysis controlled for background differences in demographic and criminal history, but was limited to the narrow range of variables available. More controlled animal studies have examined aggressive behaviors (number of initiated bite attacks and latency before attacks) between mice that had received a single injection of methamphetamine versus chronic injections over 8 weeks. The authors found that the single injection did not increase fighting, but chronic injections were associated with increased attacks and decreased latencies in attack behaviors (Sokolov et al. 2004).

Another method to assess the relationship between substance use and crime is to directly ask arrestees whether their drug or alcohol use was a factor in their commission of the arresting offense. Using data from the Drug Use Monitoring in Australia (DUMA) database, Payne and Gaffney (2012) found that 45 % attributed their current offense to either alcohol or drug use. The highest attribution rate was found among heroin users (54 %), followed by alcohol users (41 %).

70.2.2 Drug Use Behind Bars

The research base on drug use in prison is limited. Most of the studies on this topic have been conducted in the United States, Great Britain, and Canada. In the United States, estimates of in-prison drug use based on random drug tests have ranged from 1 % to 27 % (Vigdal and Stadler 1989; Inciardi et al. 1993). Using a combination of convenience and random sampling to survey 1,054 prisoners in 30 prisons in Kentucky, Tennessee, and Ohio in 2001, Gillespie (2005) found that 35 % reported some behavior in the past 12 months related to drug and alcohol use (use and possession, but also manufacture and sale).

Studies in the United Kingdom have revealed even higher prevalence of use in prison. According to Shewan et al. (1994), 74 % of inmates surveyed in four Scottish prisons reported using marijuana while in prison. Using a sample of offenders who had used drugs prior to prison, Bullock (2003) found that 56 % of inmates reported using any illicit drug in prison, with marijuana being the most common drug, followed by heroin. This study also queried inmates about their frequency of use while in prison, finding that 14 % of inmates interviewed reported using marijuana daily or near daily; the figure for daily heroin use was 3 %.

In an interview study (Pernanen et al. 2002) of Canadian prisons, 29 % of the sample reported using any illicit drug in the 3 months prior to the interview, with the most popular drug being marijuana. Alcohol use was reported by 16 %. Nearly 90 % of those interviewed said that their behavior in the past 3 months was typical of their behavior over the past year or since their arrival in prison. Random drug testing results have also been used to develop estimates for drug use. Kendall and Pearce (2000) reported that the percentage of any positive test across Canadian prisons ranged from 10 % and 13 % between 1994 and 1998, most commonly for marijuana.

70.2.3 Mortality Rates Among Just-Released Offenders

Although prison and jail can be effective at reducing levels of crime and drug use during the period of incarceration, resumption of these behaviors upon release is the norm. In the United States, nearly 7 in 10 released offenders are rearrested within 3 years (Bureau of Justice Statistics 2002). Data regarding drug use are even more disquieting, indicating that in many cases, offenders are re-addicted within 1 month of release from incarceration and their drug use and/or crime levels following prison can even exceed those reported prior to incarceration (Hough 2002).

The risk of death among parolees is particularly high – nearly 13 times greater than those of similar demographic background – during the first 2 weeks following release from prison, with drug overdose being the leading cause (Binswanger et al. 2007). As dire as this finding is, it may be an underestimate of the problem. A study of newly released prisoners in England and Wales found that the mortality rate among males was 29 times higher than that of the general population during the first 2 weeks of release. The mortality rate for female offenders was *69 times higher* (Farrell and Marsden 2007). These studies are included in a recent meta-analysis of

drug-related deaths following prison release that revealed a three- to eightfold increase in the risk of drug-related deaths during the first 2 weeks following release (relative to the subsequent 10 weeks), with relatively high risk of death remaining throughout the first month of reentry (Merrall et al. 2010).

70.2.4 Intervention Settings for Drug-Involved Offenders

In most countries, the criminal justice system encompasses offenders who are incarcerated in jail or prison and those under supervision in the community. The latter group – those on probation or parole – constitutes the vast majority of the criminal justice population. Although the treatments described below can be implemented in custody or in the community, both settings have advantages and disadvantages that merit consideration.

70.2.4.1 Prison and Jail Settings

Because prisons and jails are confined settings, they offer an important advantage over community settings: access to a captive population of high-risk substance misusers. This, combined with the tedium of daily life behind bars, provides ample opportunity to screen, assess, and treat those in need of services. Still, in many countries, limited resources are devoted to security and basic services, with little left for substance abuse treatment services (Dolan et al. 2007). Even in more affluent nations, treatment need often exceeds capacity. In the United States, for example, it is estimated that only about one in four inmates in need of substance misuse treatment receives it (Taxman et al. 2007). There are, however, some challenges associated with custody-based treatment that reduce its appeal. Common elements of traditional drug abuse counseling approaches, such as the assurance of confidentiality and mutual self-disclosure between counselor and client, are limited in prison. Consequently, even experienced community-based counselors must learn to adjust their counseling styles in order to be effective in this environment. There is also a conflict between security concerns and rehabilitative goals, often limiting inmates' movement within a prison that may be required for attending groups, counseling sessions, etc. Lastly, a major limitation to providing pharmacotherapy in jail or prison is the risk that inmates will divert psychoactive medications such as buprenorphine and methadone to other inmates for recreational use (Dolan et al. 2007).

70.2.4.2 Community Settings

An important advantage of community settings is that drug-involved offenders are forced to learn and rehearse abstinence-supporting behaviors in the "real world," where drugs and drug-using peers are readily available. However, once an offender leaves the controlled environment of jail or prison, adherence to medication (Stephenson et al. 2005) and psychosocial treatment (Farabee et al. 1999) declines dramatically. For instance, one study of over 2,000 HIV+ inmates released from prison found that only 18 % filled their ART prescription within the first 30 days following discharge (Baillargeon et al. 2009). Particularly in the contexts of

community-based treatment, coercion through legal pressure is often cited as a useful tool. (Our use of the terms "coerced or compulsory" refers to the use of legal pressure and supervision to ensure that drug-involved offenders enter and remain in substance abuse treatment appropriate to their needs. We do not condone the use of compulsory drug detention centers where those arrested for – or accused of – using illicit drugs are remanded without due process to engage in forced labor and live in substandard conditions.) Indeed, some studies have shown that coerced clients do as well or better in treatment as those entering voluntarily (see Leukefeld and Tims 1998). However, it should be noted that few of these studies have measured coercion directly and that the outcome of interest in most of these studies has been program retention and/or completion rates, rather than reductions in drug use or recidivism (Wild et al. 2002). As a result, the effects of coerced treatment remain unclear.

70.2.5 Intervention Models for Drug-Involved Offenders

The associations between substance misuse and crime, and the public health and safety risks posed by ongoing drug use behind bars, underscore the need for prevention and intervention. What is less clear is how to prevent drug use and provide interventions. In this section, we summarize common approaches to reducing drug use (and its attendant problems, such as recidivism and the spread of infectious diseases) among convicted drug-misusing offenders.

70.2.5.1 Psychosocial Treatments

Psychosocial treatments refer to therapeutic interventions aimed at changing offenders' drug-taking behavior by focusing on root causes (psychological and environmental), proximate causes (learned responses to internal and external cues), drug-related knowledge and attitudes, and behavioral change through rehearsal and role play. Psychosocial treatment is common in correctional settings as it is relatively inexpensive and can occur in groups. Two of the most prominent forms of psychosocial treatment in correctional settings are therapeutic communities (TC) and cognitive behavioral therapy (CBT). A third related approach is the 12-step approach (Alcoholics Anonymous [AA] and Narcotics Anonymous [NA]), though this is technically considered peer-led support rather than treatment. Nonetheless, given the ubiquity of AA/NA groups in correctional settings, we include a discussion of the 12-step approach in this section as well.

70.2.5.2 Therapeutic Communities

Among prison-based substance abuse treatment programs, the most commonly evaluated is the therapeutic community (TC). The TC philosophy holds that substance abuse is not the main cause of the offender's problems. Rather, it is a symptom of a larger problem: the disorder of the whole person. Thus, the goal of a TC is to "habilitate" clients in a holistic fashion, emphasizing personal responsibility. Rather than attempting to change offenders through counselor-led, didactic presentations, TCs rely primarily on the residents themselves to effect change on the individual.

After reviewing 11 evaluations of prison-based TCs, Phipps et al. (1999) reported that two of the TC programs showed clear evidence of an effect, three showed some evidence of an effect, three showed no effect, and three were inconclusive. The reviewers further recommended caution in interpreting this literature because the individual studies varied considerably in terms of their quality and conclusions.

A review by Pearson and Lipton (1999) showed more favorable results for TCs, but no support for other types of prison-based substance abuse programs. Again, however, the reviewers noted the generally poor quality of studies in this area. As mentioned earlier, of the seven therapeutic community evaluations in their meta-analysis, only one was rated "good," with the remainder rated "fair" or "poor." Subsequent reviews of the prison-TC literature continue to report positive effects on drug use and recidivism, but these effects are buttressed by the selection effects of the subgroups of TC graduates who voluntarily enter and complete aftercare programs in the community (Bahr et al. 2012).

The popularity of the prison-based TC approach appears to have peaked in the 1990s and declined over the past decade. This may be attributable to its relatively weak empirical support and the perceived advantages of cognitive behavioral therapy.

70.2.5.3 Cognitive Behavioral Therapy

Cognitive behavioral therapy (CBT) refers to a category of approaches designed to change the way offenders process information and perceive their environment and themselves. These treatments focus on providing offenders with the cognitive skills and behavioral methods needed to identify high-risk situations, dysfunctional attitudes, and effective coping strategies. A recent meta-analysis of 53 controlled trials of CBT for alcohol and illicit drug users found a small but statistically significant effect for this approach, though the effects were largely diminished within a year (Magill and Ray 2009). A separate meta-analysis of 58 evaluations (conducted in the United States, Canada, the United Kingdom, and New Zealand) of CBT for offenders also showed positive effects for this approach on recidivism – with an average reduction of about 25 % in recidivism risk. The authors also drew two important conclusions about moderator effects: (1) the strongest treatment effects were found for the highest-risk offenders, and (2) the "brand name" CBT programs produced effects that were similar to the generic versions (Landenberger and Lipsey 2005).

70.2.5.4 12-Step Programs

Support groups, such as Alcoholics Anonymous and Narcotics Anonymous, exist in countries around the world, especially in the United States, Canada, and Latin America. The general approach of 12-step facilitation focuses on self-help and peer support, with a strict emphasis on abstinence. The anonymous nature of these groups has hampered efforts to subject them to rigorous evaluation, but one Cochrane Collaboration review including eight trials (comprising over 3,000 participants) found some evidence that AA participation may aid in retaining patients in formal treatment, but did not find strong evidence for its direct role in reducing alcohol use (Ferri et al. 2006). Our review did not identify any outcome data specific to correctional populations, but the 12-step approach is extremely popular

in these settings. In the United States, for example, more than a quarter of state prison inmates and about one in five federal inmates meeting criteria for substance misuse participate in such groups (Mumola and Karberg 2006).

70.2.6 Medication-Assisted Treatments (MAT)

70.2.6.1 Enhancing Receptivity of MAT in Correctional Settings

A recent survey of criminal justice agencies affiliated with NIDA's Criminal Justice Drug Abuse Treatment Studies (CJ-DATS) collaborative found that MAT is underutilized in the treatment of US offenders with substance use disorders (Friedmann et al. 2012). Offenders most likely to receive MAT were pregnant women and those experiencing opioid withdrawal. Offenders *least* likely to receive MAT were those reentering the community after serving a prison or jail term. Among the primary factors inhibiting the use of MAT in correctional settings were preferences for drug-free treatment and limited knowledge of the benefits of MAT. Addressing these philosophical- and knowledge-related barriers will require relevant data collected in real-world settings, that is, the testing of practical MAT administration models in offender populations.

70.2.6.2 Methadone

Methadone is a synthetic opioid used to reduce craving and block the euphoric effects of heroin, morphine, and other non-prescribed opioids. It is also used for opiate detoxification. Since the 1990s, following the development of maintenance programs in the community, programs have also been introduced in prisons. In-prison methadone provision is now available in Canada, Australia, Poland, Indonesia, Iran, New Zealand, Puerto Rico, and the majority of Western Europe (Betteridge and Jurgens 2008). After researchers in Tehran found that a history of shared injection equipment in prison was the main predictor of HIV infection in the general population, the Iranian government launched a pilot program to provide methadone to 50 opiate-dependent prisoners. The results were promising enough that over 6 years the program was expanded to 142 institutions – offering MMT to more than 25,000 inmates in 2009 (Farnia et al. 2010). At the present time almost every large- and middle-sized prison in Iran provides methadone treatment to injection heroin users, and as of 2011, there were over 38,000 prisoners in Iranian prisons in treatment with methadone (Momtazi et al. 2012). Iran has developed one of the largest systems of methadone treatment in prisons, supported by a clinical trial in an Iranian prison that demonstrated methadone treatment is associated with a significant reduction in injection drug use (Bayanzadeh et al. 2007; cited in Momtazi and Noroozi (this volume)). During that same year, more than 19,000 MMT treatments were provided to inmates in the United Kingdom (Stover and Michels 2010). A key finding regarding methadone induction for this population is that initiation of MMT prior to release produces significantly better outcomes than offering MMT upon release to the community (Gordon et al. 2008).

70.2.6.3 Buprenorphine

A substantial body of research supports the safety and efficacy of buprenorphine and the buprenorphine-naloxone combination (e.g., Ling and Wesson 2003). A recent review of 24 randomized trials revealed that buprenorphine (at medium to high doses) was significantly superior to placebo medication in reducing heroin use (Mattick et al. 2008). Several properties of buprenorphine may make it potentially less objectionable than methadone to criminal justice personnel as a treatment for opiate dependence. First, the agonist activity of buprenorphine has a ceiling effect that decreases the danger of overdose and limits its abuse liability. Second, buprenorphine produces sufficient tolerance to block the effects of heroin and other opiates, thus reducing illicit opiate use. Third, buprenorphine exhibits a slow dissociation from μ-opiate receptors, which results in a long duration of action and a reduced dosing schedule compared with methadone. Fourth, the combination tablet of buprenorphine and naloxone (as Suboxone) reduces the risk of illicit injection – along with injection-related HIV/HCV risk (a common problem in correctional settings where injection equipment is scarce and sharing is common).

In spite of the substantial literature that has accumulated over the past decade supporting the use of buprenorphine, it has not been readily adopted in correctional settings. A recent survey of the US state and federal prison systems showed that only 15 states (29 %) provide any referrals to community buprenorphine providers (Nunn et al. 2009). Although the use of MAT is more common in jails than in prisons (used primarily to manage opiate withdrawal), it is important to note that it remains unavailable in two thirds of US jails (Oser et al. 2009).

70.2.6.4 Naltrexone

Naltrexone is an opioid receptor antagonist that blocks the euphoric effects of heroin and other opioids. This characteristic has fostered growing acceptance of naltrexone by correctional authorities who wish to avoid the perception that they are merely replacing one drug with another. However, it must be taken orally on a daily basis, making adherence a problem among all but the most committed patients. Cornish et al. (1997) randomly assigned federal probationers to a 6-month program of probation plus naltrexone and brief drug counseling or to probation plus counseling alone and found that opioid use was significantly lower in the naltrexone group, with the mean percent of opioid-positive urine tests among the naltrexone subjects at 8 % versus 30 % for control subjects ($p < 0.05$). Likewise 56 % of the controls and 26 % of the naltrexone group ($p < 0.05$) had their probation status revoked within the 6-month study period and were returned to prison. But treatment compliance was a problem, with only 52 % of subjects in the naltrexone group continuing for the 6-month duration of the study.

A depot formulation of naltrexone (e.g., Vivitrol®; approved in 2010 by the U.S. FDA for opioid addiction) addresses the problem of noncompliance with medication dosing, eliminates concerns about potential diversion (an issue with oral buprenorphine and take-home doses of methadone), and lessens the need for frequent patient presentation in the clinic or physician's office. Naltrexone injections reliably prevented relapse within 1 month after detoxification

(Foster et al. 2003), and multi-site research in Russia found Vivitrol effective for treating heroin addiction over 6 months (Krupitsky et al. 2011).

70.2.7 Managing Offenders Under Community Supervision

We have reviewed several prominent psychosocial and pharmacological treatment approaches used for drug-involved offenders. In addition to the specific treatments employed, it is important to consider how best to identify and manage these offenders to maximize accountability, compliance, and clinical progress. Two notable approaches are the drug court model and the application of testing and sanctions.

70.2.7.1 Drug Courts

There are currently more than 2,000 drug courts operating in the United States. Programs can also be found in Australia, Canada, the United Kingdom, and New Zealand. Drug courts vary in how they manage their caseloads, in the ancillary services they offer, and in the testing and sanction schedules they apply. What they all have in common is the provision of ongoing supervision from a judge, with offenders appearing before the judge for regularly scheduled updates. The drug court movement has been very successful. Many evaluations suggest that this is an effective approach to managing offenders in the community (Belenko 1998), though most of the support comes from non-randomized evaluations. The most rigorous evaluation, using a randomized, intent-to-treat design, was conducted on the Baltimore City Drug Court in Maryland (USA). A 1-year follow-up showed significantly lower levels of drug use and fewer arrests among those assigned to the drug court versus the control condition. By the time of the 3-year follow-up, these differences were no longer significant, although trends still favored the drug court participants (Gottfredson and Exum 2002; Gottfredson et al. 2005).

70.2.7.2 Testing and Sanctions

In 2004, a pilot program entitled Hawaii's Opportunity Probation with Enforcement (HOPE) was implemented in Honolulu in response to Judge Steven Alm's frustration with inept probation supervision, particularly in the management of methamphetamine abusers. Honolulu's probation officers were overwhelmed with high caseloads (often over 180:1), were struggling to manage their workloads, and were limited in their ability to detect and respond to violations. These difficulties led to long delays in responses to probation violations (positive urinalyses, missed appointments with probation officers, and missed treatment or failure to comply with drug treatment conditions) and high rates of noncompliance. The typical noncompliant offender would accumulate a long list of violations before action was taken. Under HOPE, offenders were given clear instructions on the content and implications of their community supervision, and the sentencing judge (or hearing officer) clearly laid out the rules of the

supervision program. Offenders who violated the terms of probation were immediately arrested and brought before a judge or hearing officer the same day. Under HOPE, *every* violation of community supervision terms was met with a sanction. *Parsimonious* use of punishment enhanced the legitimacy of the sanction package and reduced the frustrations and costs associated with tougher sentences, such as long prison stays. Results of a randomized evaluation of HOPE showed that drug use, missed appointments, and arrests for new charges in the year following randomization were reduced by one half to two thirds (Hawken and Kleiman 2009).

70.3 Conclusion

This chapter highlights the importance of capitalizing on the criminal justice system to identify and intervene with substance-misusing offenders. The high prevalence of use among offenders is a consistent international trend. Moreover, drug users in the criminal justice system pose risks to themselves and the general population through their commission of drug-related property and violent crime, as well as through the spread of infectious diseases, such as HIV and HCV.

Although the need for some level of intervention is clear, our review of existing treatment options and their supporting research underscores the fact that appropriate solutions are still not well established. Nor can we be certain of the extent to which reductions in substance use will produce commensurate reductions in criminal activity (aside from that inherent to illicit drug use itself).

We conclude this chapter with several recommendations for practice and research that we consider to be important next steps in advancing this literature.

70.3.1 Focus on Implementation

Over a decade ago, Gendreau and colleagues wrote that "of all the issues critical to the development of effective correctional treatment programs, program implementation has been relatively ignored" (Gendreau et al. 1999, p. 180). This observation is no less relevant today. Implementation fidelity is a challenge in any setting, but even more so under the auspices of a correctional system. This is because correctional administrators understandably focus their attention on the primary goals of keeping the general public safe from offenders and incarcerated offenders safe from each other. Successfully carrying out a rehabilitative agenda within these settings requires not only a knowledge of implementation science but also a practical understanding of how the criminal justice system works and why. Identifying effective practices that can be implemented for offenders – whether in custody or under community supervision – is only a first step that must be followed by research on how to encourage other correctional organizations to adopt such practices and how to ensure that the key elements in the original intervention are not lost or diluted in the process.

70.3.2 Need for More Randomized Trials

Selection bias and other less-obvious confounds have historically undermined confidence in evaluations of interventions for substance misusers, and conducting rigorous, randomized trials can be even more difficult in correctional settings, where there is an ongoing concern over disparate treatment of convicted offenders. Awareness of – and appreciation for – experimental research with offenders appears to be growing, however, with the number of published trials between 1982 and 2004 more than double that published in the two decades before (Farrington and Welsh 2005). Correctional research remains a challenge, but Asscher and colleagues (2007) have offered several useful suggestions based on their experiences conducting clinical trials with juvenile offenders in the Netherlands, including methods for overcoming institutional resistance, maintaining cooperation from study participants, and dealing with high staff turnover.

70.3.3 Clarify the Role of Coercion: When It Helps, When It Hurts

As we mentioned earlier in this chapter, reviews of the coerced treatment literature for substance-misusing offenders have not led to conclusive results (Wild et al. 2002). One important weakness of this body of research is that most studies of coerced treatment fail to measure this construct directly, but rather assume its presence given the nature of the criminal justice system. Because offenders who are mandated to participate in treatment can vary substantially in their perceived need for treatment, this methodological shortcoming obscures the extent to which coercion facilitates or undermines the therapeutic process. Another significant weakness is that the majority of coerced treatment studies rely on treatment retention or graduate rates as the outcome, rather than reductions in relapse and recidivism. The continued use of the criminal justice system as a setting for identifying substance misusers and mandating them to treatment should be accompanied by a more nuanced understanding of the effects of formal and informal sources of coercion.

70.3.4 Distinguishing "Addicted Offenders" from "Offender Addicts"

In most countries, the capacity for providing substance abuse treatment services in prison falls well short of the estimated need (Dolan et al. 2007). Absent a dramatic reversal of this trend, it is critical that researchers and practitioners develop criteria for determining which substance misusers are most likely to benefit from treatment and, among these, for whom reduced drug use will produce reduced criminal behavior.

Distinguishing offenders whose drug use impels criminal behavior from those whose drug use is merely coincidental has proven an elusive goal among addiction researchers and criminologists, but there is some evidence that such a distinction

can be made. For example, Nurco and colleagues (1988) classified 214 narcotic addicts according to their criminal involvement during a 2-year pre-addiction period and then compared rates of criminality during addiction periods for those who had engaged in crime prior to becoming addicted (approximately one half of the sample) and those who had not. As hypothesized, both groups increased their rates of criminality during high-addiction periods. However, during subsequent periods of low use, 78 % of the high-crime subjects (based on criminal activity during their pre-addiction period) continued to engage in criminal activity versus only 40 % of those in the low-crime group. Between-group differences were particularly disparate for drug dealing, with the high-crime group being responsible for 91 % of the drug-dealing crimes during the nonaddiction periods.

70.3.5 Examine the Use of Depot Medications for Opiate-Dependent Offenders

The high risk of death among offenders during the first 2 weeks following release from prison – and the fact that drug overdose is the leading cause (Binswanger et al. 2007) – suggests that drug use treatment might be considered effective even if it only reduced use or prevented relapse during the initial post-release phase. Newly approved depot formulations of naltrexone (e.g., Vivitrol®) and buprenorphine (e.g., Probuphine®) offer promise for overcoming poor medication adherence and eliminate the risk of these substances being diverted for recreational use. Moreover, even a single administration of these medications immediately prior to release from custody can reduce the threat of fatal opiate-related overdoses during the initial reentry period, when risks are at their highest. Given their promise, more evaluations of depot pharmacotherapies for released offenders are strongly recommended, particularly concerning strategies to encourage initial interest in these medications and to increase the percentage of offenders who return for subsequent doses.

A Case Study from Egypt

71

Tarek A. Gawad

Contents

71.1 Introduction

The Middle East and North Africa (MENA) continues to be a region with limited data on the extent of the HIV problem. A 2010 review of evidence on HIV in the MENA region concluded that, while there was no evidence of an HIV epidemic, without an aggressive program of HIV prevention among high-risk groups, this situation could rapidly change for the worse (Abu-Radda et al. 2010). According to the Joint United Nations Programme on HIV/AIDS (UNAIDS 2012), the number of people newly infected with HIV in the MENA region increased by 35 % between 2001 and 2011. Consequently, efforts to identify high-risk groups and initiate HIV prevention methods are a priority in the region.

Egypt launched two national strategies in 2008, one on drug use and the other on HIV. Both strategies address the importance of prison inmates as a target population for intervention. In collaboration with the United Nations Office on Drugs and Crime (UNODC) Regional Office of the Middle East and North Africa (ROMENA) regional project on increasing access to drug use and HIV prevention and care services in prison settings, an interministerial national prison task force was

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment: International Perspectives*, DOI 10.1007/978-88-470-5322-9_162,

formulated to coordinate activities aimed at reducing the negative social and health consequences of drug use in prisons. Accordingly, the prison task force has facilitated the implementation of an assessment of drug use and the HIV status of prisoners in six facilities in Egypt. These assessments are used to describe the need for HIV prevention in prison settings and, accordingly, provide the technical expertise and resources required to provide such.

The Egyptian Prison Authority called for a consultation meeting on October 2008 to present the concept of establishment of drug treatment facilities, rehabilitation programs, social reintegration, and vocational training for inmates within the prison premises. The main outcome of this consultation meeting was to conceptualize the prison initiative described below. Besides the prison authorities and UNODC ROMENA representatives, the steering committee permanent members were the Anti-Narcotics General Administration, the National Fund on Drug Use and Addiction, the Ministry of Health (General Secretariat for Mental Health and National AIDS Programme), the International Society of Addiction Medicine (ISAM), UNAIDS Country Office, and Egyptian academic institutions.

Upon recommendation from the members of the steering committee, a baseline study funded through UNODC ROMENA to assess the situation related to drug addiction and HIV infection in prisons and to provide necessary information for planning the best possible intervention was undertaken in 2009. This project aimed to provide specialized treatment and rehabilitation services to drug-dependent prison inmates while minimizing the negative health consequences of drug use within prison settings in Egypt. The project also sought to provide job opportunities for the targeted group of inmates during imprisonment and after release through the establishment of vocational workshops as part of rehabilitation and social reintegration.

71.2 The Survey

71.2.1 Survey of Drug Use in a Cairo Prison (From Ali Kabbash 2009)

One prison in the Cairo area was chosen to conduct a survey on drug use and HIV risk behavior. Individual interviews were conducted by experienced interviewers in a private setting. Participants were assured that their results would not be shared with the prison authorities. In addition to the individual interviews, focus groups of six to eight individuals were conducted. These focus groups included groups of inmates, guards, health-care workers, and social workers (different groups for each category). Data from the focus groups presented a consistent picture across categories. There was general agreement that there is a considerable amount of drugs in the prison and that they come into the prison in a variety of ways: family visits, prisoner trips outside the prison, and with food brought in by prison suppliers.

The quantitative survey study consisted of 1,926 participants, randomly selected, which represented 10 % of the prison population. The mean age of participants was 35 years, and 50 % were married; 36 % were illiterate, and 78 % were manual

laborers. The majority were imprisoned for drug and theft crimes (67.5 %), with sentences ranging from 1 to 10 years (69.9 %). Knowledge about HIV was variable, with 88 % and 82 % reporting that they knew that sexual behavior and sharing injection equipment were methods of HIV transmission, respectively, but only 59 % knew of mother-child transmission and 40 % thought HIV could be transmitted by insect bites. Eighty-nine percent (1,541) agreed to be tested for HIV, although only 43 % were aware there was treatment for HIV.

Fifty-three percent of participants reported that they knew of drug use in the prison, and 49.7 % of participants reported taking drugs in the prison. The majority of prisoners had a history of drug dependence before prison admission, with an average onset age of use of 18.6 ($SD = 5.37$) years. Drug injection had been practiced by 22 % of drug-dependent participants before prison, and 6.7 % reported injecting drugs in prison. The same syringe was generally shared by a group of persons and reused for several days. The common drugs are parkinol, other psychoactive pills, and hashish/bango. Sixty-five percent do not consider themselves to be dependent upon drugs, and 88 % reported they had never experienced withdrawal symptoms. Five percent of participants reported that they had overdosed from drugs, and 3.7 % reported more than one overdose episode. Fewer than 5 % had ever participated in treatment, and only 2.5 % felt they needed treatment in prison.

The combined efforts of the prison officials, the other Egyptian governmental and academic leaders, and the representatives of the UNODC ROMENA program have revealed evidence indicating considerable drug use in Egyptian prisons. The drug use and related behaviors (e.g., needle sharing and sex while under the influence of drugs) are reasons for concern about high-risk behaviors for HIV transmission within Egyptian prisons. According to UNAIDS (2012), new cases of HIV in Egypt are being reported at an increasing rate, and there are few HIV prevention activities in Egypt to address this public health problem. Although rates of HIV are believed to be low in Egypt, relative to other parts of the world, this situation could change rapidly if high-risk groups and high-risk settings are ignored. Clearly the prisons in Egypt are settings where the rates of HIV and the transmission of HIV are seriously elevated as compared to the general society.

Following the collection of the survey data presented above, there were discussions among Egyptian prison, health, and academic leaders about the most effective strategies for addressing the concerns about HIV transmission and drug use in Egyptian prisons. A plan was drafted to consider the development of addiction treatment and HIV prevention programs within Egyptian prison settings, combined with community aftercare to prevent relapse to drug use once individuals are released from prisons into the community. There was an extensive review of prison treatment and aftercare options from the literature around the world. Extensive discussions occurred regarding the possibility that this demonstrated need to address the Egyptian prison situation could be an excellent opportunity to conduct pilot programs in Egypt with addiction medications, including Suboxone® for opioid dependence. Further information is needed on the extent of opioid use in Egyptian prisons. If significant levels of opioid use are found, the induction and

treatment of opioid injectors with Suboxone within Egyptian prisons, along with their continuing treatment in the community provided by university hospital outpatient programs, could be an important innovation. Medication would be restricted to the prison settings and to the pharmacies of the university hospitals to protect against diversion of Suboxone onto the illicit market.

These very innovative and forward-thinking plans were interrupted by the political upheavals in Egypt in early 2011. The prison that was involved in the survey and was a site for the pilot project was severely impacted during the unrest of the "Arab Spring." Subsequently, there have been ongoing changes in government leadership in the prison and health sectors as the political leadership in Egypt has changed. As stability returns to Egypt, there is hope that these plans can be restarted as part of a responsible public health program.

Drug Courts

72

Douglas B. Marlowe

Contents

Abstract

Drug courts provide judicially supervised substance abuse treatment in lieu of criminal prosecution or incarceration. Substantial research demonstrates that drug courts reduce crime, incarceration rates, and substance abuse, improve the psychosocial functioning of offenders, and produce positive cost benefits for taxpayers. Evidence has identified the optimal target population for drug courts and many of the best practices that are associated with improved outcomes in these programs. Although most of the research on drug courts has been conducted in the USA, emerging evidence is beginning to reveal positive benefits in European, Australasian, South American, and Caribbean countries as well. The challenge now is to extend the reach of drug courts without sacrificing their efficacy or safety.

72.1 Introduction

Over 80 % of adult offenders in the USA misuse drugs or alcohol, meaning they were arrested for a drug- or alcohol-related offense, were intoxicated at the time of their offense, reported committing their offense to support a drug or alcohol problem or they have a significant history of substance abuse or substance abuse treatment (National Center on Addiction and Substance Abuse [NCASA] 2012). Approximately one quarter to one half of offenders are estimated to misuse drugs or alcohol in European, Australasian, South American, and Caribbean nations (Cooper et al. 2013). Providing substance abuse treatment can reduce recidivism rates substantially (Chandler et al. 2009); however less than one quarter of drug-involved offenders will complete a substance abuse treatment episode (Marlowe 2002).

Drug courts were created to improve offenders' compliance with substance abuse treatment. The drug court judge leads a multidisciplinary team of professionals that commonly includes representatives from the prosecution, defense bar, treatment agencies, case-management agency, probation department, and law enforcement. These team members meet frequently in staff meetings to review participants' progress in treatment and offer recommendations to the judge about potential consequences to impose (National Association of Drug Court Professionals [NADCP] 1997). The consequences may include rewards such as verbal praise, reduced supervision requirements, or small gifts; punitive sanctions such as verbal reprimands, writing assignments, community service, or brief intervals of jail detention; or adjustments to the participant's treatment regimen. The consequences are administered during regularly scheduled status hearings at which the judge discusses the matter with the participant in court. In pre-adjudication drug courts, the ultimate legal incentive is to have the criminal charge(s) dropped or withdrawn, and in post-adjudication drug courts, the legal incentive is to avoid a sentence of incarceration or reduce the length or conditions of probation.

The first drug court was founded in Miami/Dade County, Florida, in the USA in 1989. Currently, there are more than 2,700 drug courts in the USA (Huddleston and Marlowe 2011). Nearly 30 countries other than the USA have also established or are planning to establish drug courts, including Argentina, Australia, the Bahamas, Barbados, Belgium, Bermuda, Brazil, Canada, Cayman Islands, Chile, Columbia, Costa Rica, the Dominican Republic, El Salvador, England, Grenada, Ireland, Jamaica, Mexico, Norway, Panama, Peru, Scotland, Suriname, and Trinidad and Tobago (Cooper et al. in press).

In 1997, the National Association of Drug Court Professionals in the USA promulgated what are commonly referred to as the "10 Key Components" of drug courts (NADCP 1997). A few years later, the International Association of Drug Treatment Courts (IADTC) adopted the 10 Key Components but added three more components focusing on the social reintegration of participants, ensuring flexible treatment for indigenous populations and ethnic minorities, and planning for aftercare recovery services. The IADTC principles are embodied in a document entitled the *13 Key Principles for Court-Directed Treatment and Rehabilitation Programmes* ("13 Key Principles") [see Text Box].

International Association of Drug Treatment Courts (IADTC)
13 Key Principles for Court-Directed Treatment and Rehabilitation Programmes

1. The programmes integrate substance dependency treatment services with justice system case processing.
2. Using a non-adversarial approach, prosecution and defense lawyers promote public safety while protecting offenders' due process rights.
3. Eligible offenders are identified early and promptly integrated into the programme.
4. The programmes ensure access to a continuum of substance dependency treatment and other rehabilitation services.
5. Compliance is objectively monitored by frequent substance abuse testing.
6. A coordinated strategy governs responses of the court to programme non-compliance (and compliance) by offenders.
7. Ongoing judicial interaction with each offender in a programme is essential.
8. Monitoring and evaluation measure the achievement of programme goals and gauge effectiveness.
9. Continuing interdisciplinary education promotes effective planning, implementation, and operations of these court-directed programmes.
10. Forging partnerships among courts directing treatment programmes, public agencies, and community-based organizations generates local support and enhances programme effectiveness.
11. Ongoing case management includes the social support necessary to achieve social reintegration.
12. There is appropriate flexibility in adjusting programme content, including incentives and sanctions, to better achieve programme results with particular groups, such as women, indigenous people and minority ethnic groups.
13. Post treatment and after-care services should be established in order to enhance long term programme effects.

The success of adult drug courts (described below) has spawned an array of other types of problem-solving courts or treatment courts, including juvenile drug courts, family drug courts (for guardians in child abuse and neglect cases), driving while impaired (DWI) courts, mental health courts, and veterans treatment courts (for impaired military veterans). Considerably less research has been conducted on these newer models than on the original adult criminal model; however, emerging evidence suggests some of the newer programs are beginning to show favorable results. This chapter reviews the large body of research on adult criminal drug courts. The reader is referred to other sources for information on newer variants of the drug court model (Huddleston and Marlowe 2011; Marlowe 2011).

72.2 Effectiveness of Drug Courts

72.2.1 Criminal Recidivism

Meta-analyses are advanced statistical procedures that calculate the average effects of an intervention across numerous research studies. Several meta-analyses performed in the USA and Canada (Aos et al. 2006; Bhati et al. 2008; Downey and Roman 2010; Latimer et al. 2006; Lowenkamp et al. 2005; Mitchell et al. 2012; Shaffer 2010; Wilson et al. 2006) and a national multisite study in the USA (Rossman et al. 2011) concluded that drug courts significantly reduced criminal recidivism – typically measured by rearrest rates within 2 years of entry into the drug court – by an average of 8–14 %. In randomized controlled experiments, the reductions in recidivism were found to have lasted for at least 3 years postentry (Gottfredson et al. 2005; Mitchell et al. 2012; Turner et al. 1999), and in one study the effects lasted 14 years (Finigan et al. 2007).

A recent meta-analysis in the USA concluded that drug courts also significantly reduced incarceration rates by an average of 8–12 % (Sevigny et al. 2013). Notably, however, this impact did not translate into lesser use of jail or prison beds. Although the drug court participants were less likely to be incarcerated than comparable offenders charged with the same crimes, participants who were unsuccessfully terminated from the drug courts ultimately served more jail or prison time. In other words, the drug courts reduced the number of offenders who were sent to jail or prison but increased the length of the jail or prison sentences for the unsuccessfully terminated cases. The net result was that the unsuccessful cases washed out the effects of the successful cases, thus leading to a negligible impact on jail and prison resources.

This finding could be interpreted as an indictment of drug courts because they may not reduce jail or prison overcrowding or overreliance on the most expensive correctional resources. An alternative interpretation, however, is that drug courts reduce crime rates while having no impact on correctional populations or taxpayer expenditures. In other words, they achieve larger crime reductions than other correctional programs without increasing jail or prison censuses. Research does not, as yet, shed light on this debate. It is unknown whether crime rates would increase if drug courts reduced the consequences for unsuccessful termination. Some participants might be less likely to apply themselves in treatment if the consequences for failure were less severe, thus leading to higher termination rates or crime rates. Future research needs to address this important and policy-relevant question.

72.2.2 Cost-Effectiveness

In line with their positive effects on crime reduction, drug courts have also proven to be cost-effective. Meta-analyses of cost-effectiveness studies concluded that drug courts produced an average of approximately $2–2.25 in direct benefits to

the criminal justice system for every $1 invested (Bhati et al. 2008; Downey and Roman 2010; Rossman et al. 2011). These savings reflected measurable cost-offsets to the criminal justice system stemming from reduced rearrests, law enforcement contacts, court hearings, the use of jail or prison beds, and the tangible impacts of crime victimization. When more distal cost-offsets were also taken into account, such as savings from reduced child foster care placements and healthcare service utilization, studies have reported economic benefits ranging from approximately $4 to 27 for every $1 invested, resulting in savings to local communities of roughly $3,000–22,000 per participant (e.g., Aos et al. 2006; Finigan et al. 2007; Mayfield et al. 2013).

72.2.3 Psychosocial Outcomes

In 2005, the US Government Accountability Office (GAO 2005) concluded that drug courts significantly reduced criminal recidivism and saved money for taxpayers as a consequence of their impact on crime. However, the GAO also concluded that little was known about their effects on other important outcomes such as substance abuse, employment, family functioning, and mental health.

In response to the GAO report, the US National Institute of Justice (NIJ) funded a national study of adult drug courts entitled the Multisite Adult Drug Court Evaluation (MADCE; Rossman et al. 2011). The MADCE compared outcomes for participants in 23 drug courts located in seven geographic regions around the USA ($N = 1{,}156$) to those of matched comparison offenders drawn from six nondrug court sites in four geographic regions ($N = 625$). The participants were interviewed in person at entry and at 6- and 18-month follow-ups and provided oral fluid specimens at the 18-month follow-up.

In addition to reporting significantly less involvement in crime, the drug court participants also reported significantly less use of illicit drugs and heavy use of alcohol (defined as $\geq$4 drinks per day for women or $\geq$5 drinks per day for men) at the 6- and 18-month follow-ups. These self-report findings were confirmed by saliva drug tests which revealed significantly fewer positive results for the drug court participants at the 18-month assessment. The drug court participants also reported significantly greater improvements in their family relationships and non-significant trends favoring higher employment rates and school enrollment. These findings confirmed that drug courts produce psychosocial benefits for participants beyond crime reduction.

72.2.4 International Perspective

Rigorous studies in Australia (Jones 2013) and Canada (Somers et al. 2011) have demonstrated that drug courts can significantly reduce crime and produce cost benefits in those countries as well. In other nations, most drug courts are still in

the formative stages and efforts to evaluate their outcomes have only recently been initiated.

A 2010 survey conducted by American University on behalf of the Organization of American States (OAS) analyzed responses from drug court officials in several South American, Central American, and Caribbean nations (Cooper et al. 2010). The majority of the respondents reported that drug courts in their countries appeared to be reducing crime better than traditional correctional dispositions and approximately half of the respondents reported notable cost savings. Brazil, for example, reported 12 % recidivism for participants in its drug court in Rio de Janeiro as compared to a general recidivism rate of 80 % for nontreatment-oriented criminal dispositions. These figures are merely estimates but they do suggest that drug courts are feasible and potentially desirable to implement in South American and Caribbean nations.

72.3 Effective vs. Ineffective Drug Courts

Because meta-analyses calculate the *average* effects of an intervention, the results can mask substantial variability in the performance of individual programs. On the plus side, approximately three quarters (78 %) of the drug courts in the meta-analyses significantly reduced criminal recidivism (Shaffer 2006) with the best drug courts reducing recidivism by as much as 35 % (Lowenkamp et al. 2005; Shaffer 2006). These positive findings were, however, by no means universal. A substantial minority (22 %) of the drug courts were found to have had no impact on recidivism (Shaffer 2006), and in a few instances some drug courts were associated with increases in recidivism of as much as 15 % (Lowenkamp et al. 2005).

These findings underscore the importance of identifying the best practices in drug courts that minimize harms and optimize positive impacts. The critical task facing the drug court field is to determine what distinguishes effective drug courts from the ineffective or harmful ones. A substantial body of evidence is beginning to answer this important question. Studies reveal the poorest performing drug courts (1) targeted their services to the wrong types of drug-involved offenders, (2) delivered ineffective or contraindicated services, or (3) both.

72.3.1 Target Population

A growing body of research indicates which types of offenders are most in need of the full range of interventions embodied in drug courts. These are the offenders who are (1) addicted to or dependent on illicit drugs or alcohol and (2) at substantial risk for criminal recidivism or failure in less intensive rehabilitative dispositions. Drug courts that focus their efforts on these individuals – commonly referred to as high-need and high-risk offenders – reduce crime approximately twice as much as those serving less serious offenders and return approximately 50 % greater cost savings to

their communities (Bhati et al. 2008; Carey et al. 2012; Downey and Roman 2010; Lowenkamp et al. 2005).

These findings are consistent with a well-validated criminological theory called Risk-Needs-Responsivity (RNR). According to RNR, intensive programs such as drug courts offer the greatest benefits for high-risk offenders who have more severe antisocial propensities or treatment-refractory histories; however, such programs are often unnecessary or counterproductive for low-risk offenders (Andrews and Bonta 2010). High-risk offenders have a generally poor prognosis for success in standard treatment and often require intensive and sustained interventions to dislodge their entrenched, negative behavioral patterns. Low-risk offenders, in contrast, are less likely to be on a fixed antisocial trajectory and are apt to improve their conduct following a run-in with the law. Therefore, intensive interventions may offer small benefits for low-risk individuals but at a substantial cost (DeMatteo et al. 2006). Worse still, low-risk offenders may learn antisocial attitudes and behaviors from associating with high-risk offenders, which can make their outcomes worse. It has been found that providing formal substance abuse treatment for nonaddicted substance abusers can lead to higher rates of reoffending and a greater likelihood of those individuals becoming addicted (Lowenkamp and Latessa 2005; Wexler et al. 2004). This might be an unintended effect of exposing them to antisocial peers or interfering with their engagement in productive activities, such as work or school.

72.3.2 Best Practices

In fiscally challenging times, there is always the pressure to do more with less. This raises the question of whether certain components of the drug court model can be dropped or the dosage decreased without eroding the effects. The key components of drug courts are hypothesized to include an ongoing schedule of judicial status hearings, a multidisciplinary team approach to managing cases, a standardized regimen of evidence-based substance abuse treatment, frequent drug and alcohol testing, and contingent sanctions and incentives (NADCP 1997). Each of these hypothesized key components has been examined by researchers to determine whether it is required for effective results.

72.3.2.1 Judicial Status Hearings

Judicial status hearings are the defining ingredient of a drug court. Many correctional programs offer substance abuse treatment, urine drug testing, and sanctions and rewards for drug-involved offenders; however, only drug courts are led by a judge and require participants to appear frequently in court for status hearings. The evidence is exceptionally strong that judicial status hearings are a critical ingredient for effective outcomes in drug courts, assuming the programs are treating the appropriate target population of high-risk and high-need offenders.

A substantial body of research establishes the importance of scheduling status hearings no less frequently than every 2 weeks (biweekly) during the first phase of

a drug court. In a series of experiments, researchers randomly assigned drug court participants to appear before the judge every 2 weeks for status hearings or to be supervised instead by their clinical case managers and brought into court only in response to repetitive rule violations. The results revealed that high-risk participants had significantly better counseling attendance, drug abstinence, and graduation rates when they were required to appear before the judge every 2 weeks (Festinger et al. 2002). This finding was replicated in Australia (Jones 2013) and subsequently confirmed in a prospective matching study in which the participants were assigned at entry to biweekly hearings if they were assessed as being high risk (Marlowe et al. 2007).

Similarly, a meta-analysis involving 92 adult drug courts (Mitchell et al. 2012) and a multisite study of nearly 70 drug courts (Carey et al. 2012) reported significantly better outcomes for drug courts that scheduled their status hearings every 2 weeks during the first phase of the program. Scheduling status hearings at least once per month until the last phase of the program was also associated with significantly better outcomes and nearly three times greater cost savings (Carey et al. 2012).

Not surprising, outcomes are influenced not only by how often judges interact with participants but also by the length and quality of those interactions. Outcomes have been found to be significantly better when judges spent an average of at least 3 min, and as much as 7 min, interacting with the participants in court (Carey et al. 2012). Studies consistently find that drug court participants perceived the quality of their interactions with the judge to be among the most influential factors for success in the program (Goldkamp et al. 2002; National Institute of Justice [NIJ] 2006; Turner et al. 1999). The MADCE reported significantly greater reductions in crime and substance use for judges who were rated by independent observers as being more respectful, fair, attentive, enthusiastic, consistent, and caring in their interactions with participants in court (Rossman et al. 2011). Similarly, a statewide study in New York reported significantly better outcomes for judges who were perceived by the participants as being fair, sympathetic, caring, concerned, understanding, and open to learning about the disease of addiction (Farole and Cissner 2007). Outcomes were generally poor for judges who were perceived as being arbitrary, jumping to conclusions, or not giving participants an opportunity to explain their sides of the controversies.

A study of approximately 70 drug courts reported nearly three times greater cost savings and significantly lower recidivism when the judges presided over the drug courts for at least two consecutive years and thus had greater seniority and experience (Carey et al. 2012). Significantly larger reductions in crime were also found when the judges were assigned to the drug courts on a voluntary basis and their terms on the drug court bench were indefinite in duration. Evidence suggests most judges are less effective at reducing crime during their first year on the drug court bench than during ensuing years (Finigan et al. 2007). Presumably this is because judges, like most professionals, require time and experience to learn their jobs effectively. For this reason, drug courts that annually rotated their judicial assignments or had participants appear before alternating judges had the poorest outcomes

in several research studies (Finigan et al. 2007; NIJ 2006). Participants in drug courts often lead chaotic lives and require substantial structure and consistency to change their maladaptive behaviors. Unstable staffing patterns, particularly when they involve the central figure of the judge, are apt to exacerbate rather than ameliorate the disorganization in participants' lives.

72.3.2.2 Multidisciplinary Team

One of the more controversial features of drug courts is having professionals from different disciplines meet regularly to coordinate their functions as a team (NADCP 1997). Traditionally, judges, prosecutors, defense attorneys, and treatment providers did not sit down together to decide how best to respond to offenders' behaviors. This practice has raised concerns among some commentators about whether drug court professionals might be sacrificing their ethical obligations of neutrality, objectivity, confidentiality, or zealous representation. Although anecdotal arguments abound on both sides of the debate, no empirical evidence indicates whether such ethical concerns are justified.

Evidence is beginning to emerge to indicate whether a multidisciplinary team is necessary to improve outcomes. Research reveals the more effective drug courts do require ongoing attendance at staff meetings and status hearings by the judge, defense counsel, prosecutor, treatment providers, and law enforcement (Carey et al. 2012). When any one of these professional disciplines was absent regularly from team discussions, the programs had outcomes that were, on average, approximately 50 % less favorable. In other words, if any one professional discipline walks away from the table, there is reason to anticipate the effectiveness of a drug court could be reduced by as much as one half.

Studies indicate the drug court judge, in particular, should attend pre-court staff meetings regularly (Carey et al. 2012). The staff meeting is where team members share their observations and impressions about participants' performance and propose consequences for the judge to consider. The judge's presence at the staff meeting ensures that each team member's perspective is taken into account when important decisions are made. Observational studies have revealed that when judges did not attend pre-court staff meetings, they were unlikely to be adequately informed or prepared when they interacted with the participants in court (Portillo et al. 2013).

72.3.2.3 Substance Abuse Treatment

Substance abuse treatment forms the heart of a drug court program. The basic assumption underlying drug courts is that addiction is fueling or exacerbating criminal activity. Therefore, it is hypothesized to be necessary to treat this disorder in order to reduce crime and improve the psychosocial functioning of offenders (NADCP 1997).

Early studies did not cast a favorable light on the quality of substance abuse treatment in drug courts. Treatment services in several US drug courts were characterized as being nonevidence based, lacking in a coherent focus or structure,

and delivered by inadequately trained staff. The services also tended to be indistinguishable from those routinely offered to noncriminal justice populations and thus might not have adequately addressed the unique needs and risk factors presented by offenders.

Recent studies provide a more informative and sanguine picture of the impact of substance abuse treatment on drug court outcomes. The success of drug courts appears to be attributable, at least in part, to the fact that they significantly increased participants' exposure to substance abuse treatment. The longer drug court participants remained in treatment and the more sessions they attended, the better were their outcomes (Gottfredson et al. 2007; Peters et al. 2002; Shaffer 2010).

Outcomes are also significantly better in drug courts that offer a continuum of care for substance abuse treatment which includes residential treatment and recovery housing in addition to outpatient services (Carey et al. 2012; Koob et al. 2011). The best results are achieved when participants are required to meet with a treatment provider or clinical case manager for at least one individual session per week during the first phase of the program (Carey et al. 2012; Rossman et al. 2011). Many participants are unstable clinically and in a state of crisis when they first enter a drug court, and group sessions might not provide adequate time or opportunities to address each participant's clinical and social service needs. Individual sessions may reduce the likelihood that participants will fall through the cracks during the early stages of treatment when they are most vulnerable to cravings, withdrawal symptoms, and relapse.

Better results have been reported in drug courts that developed specialized therapy groups for participants with specific clinical needs or demographic characteristics, such as women with trauma histories (Messina et al. 2012) and young African-American male participants (Vito and Tewksbury 1998). Young African-American males have commonly expressed dissatisfaction with group-based services in drug courts; therefore, it may be especially important to develop effective and culturally tailored services for this demographic group.

A substantial body of research spanning several decades reveals that outcomes from correctional rehabilitation are significantly better when (1) the offenders received behavioral or cognitive-behavioral treatment (CBT) interventions, (2) the interventions were carefully documented in treatment manuals, (3) the treatment providers were trained to deliver the interventions reliably according to the manual, and (4) fidelity to the treatment model was maintained through continuous supervision of the treatment providers (Andrews and Bonta 2010). Adherence to these same principles has been associated with significantly better outcomes in drug courts (Gutierrez and Bourgon 2012). Examples of manualized CBT curricula that have been shown to reduce criminal recidivism in adult drug courts include Moral Reconation Therapy (MRT) (Cheesman and Kunkel 2012) and the MATRIX Model (Marinelli-Casey et al. 2008).

Finally, research reveals outcomes were better for drug courts that contracted with a single coordinating agency to serve as the primary case manager for treatment services (Carey et al. 2012). The coordinating agencies did not

necessarily provide all of the clinical services, but they were responsible for assessing the participants, referring them to the appropriate treatment programs, and providing routine progress reports to the judge and drug court team. It can be exceedingly difficult to stay abreast of participants' progress when they have been referred to numerous treatment providers. Designating a primary case manager to coordinate the referrals appears to be essential for maintaining an accurate flow of up-to-date information and administering consistent and timely consequences for participants' performance in treatment.

72.3.2.4 Medically Assisted Treatment

Medically assisted treatment (MAT) can significantly improve outcomes for addicted offenders (NCASA 2012). Buprenorphine or methadone maintenance administered prior to and immediately after release from jail or prison has been shown to significantly increase opiate-addicted inmates' engagement in treatment; reduce illicit opiate use; reduce rearrests, technical parole violations, and reincarceration rates; and reduce mortality and hepatitis C infections (Chandler et al. 2009). These medications are referred to as agonists or partial agonists because they stimulate the central nervous system (CNS) via a comparable neural mechanism as illicit drugs. Because they can be addictive and may produce euphoria in non-tolerant individuals, they may be resisted by some criminal justice professionals.

Positive outcomes have also been reported for antagonist medications such as naltrexone which are nonaddictive and nonintoxicating. Naltrexone blocks the effects of opiates and partially blocks the effects of alcohol without producing psychoactive effects of its own. Two small-scale, open-label studies reported better outcomes in drug courts for alcohol-dependent participants receiving an injected form of naltrexone called Vivitrol (Finigan et al. 2011).

A recent national survey found that nearly half of US drug courts do not use medications in their programs (Matusow et al. 2013). One of the primary barriers to using medications was a lack of awareness of or familiarity with medical treatments. For this reason, the NADCP Board of Directors issued a unanimous resolution directing drug courts in the USA to learn the facts about MAT and obtain expert consultation from duly trained addiction psychiatrists or addiction physicians.

72.3.2.5 Drug and Alcohol Testing

The success of any drug court depends on the reliable monitoring of participants' behaviors. If the drug court team does not have accurate information about whether participants are being compliant or noncompliant in the program, there is no way to apply incentives or sanctions correctly or to adjust treatment and supervision services accordingly.

The most effective drug courts perform urine drug testing at least twice per week during the first several months of the program (Carey et al. 2012). Because the metabolites of most commonly abused drugs are detectable in human bodily fluids for only about 1–4 days, testing less frequently leaves an unacceptable time gap during which participants can abuse substances and evade detection.

In addition, drug testing is most effective when it is performed on a random basis. If participants know in advance when they will be drug tested, they can adjust the timing of their usage accordingly or take other countermeasures, such as frontloading on water, to elude the tests.

Although urine testing is the most common testing procedure in drug courts, other technologies which extend the time window for detection are becoming commonplace. The Secure Continuous Remote Alcohol Monitor (SCRAM) is an anklet-monitoring device that detects alcohol vapor in sweat and transmits a signal wirelessly to a remote monitoring station. Research suggests SCRAM monitoring can be effective at deterring alcohol consumption among recidivist offenders in drug courts when it is worn for at least 90 consecutive days (Flango and Cheesman 2009). Similarly, ethyl glucuronide (EtG) and ethyl sulfate (EtS) testing extend the time window for detection of alcohol metabolites from a few hours to several days. At least one randomized controlled trial has reported improved outcomes when a drug court used EtG/EtS testing (Gibbs and Wakefield 2014).

72.3.2.6 Graduated Sanctions and Rewards

Drug courts administer gradually escalating sanctions for infractions and rewards for accomplishments (NADCP 1997). The nearly unanimous perception of staff members and participants is that sanctions and incentives are strong motivators of behavioral change in drug courts (Lindquist et al. 2006; Goldkamp et al. 2002). Two randomized controlled experiments confirmed that administering gradually escalating sanctions for positive drug tests and other infractions significantly reduced substance use and crime among drug-involved offenders (Harrell et al. 1999; Hawken and Kleiman 2009).

The use of jail sanctions is highly controversial in drug courts. Although some commentators have theorized that the realistic threat of a jail sanction provides the necessary leverage for drug courts to retain recalcitrant offenders in treatment, research on this issue is sparse for understandable reasons. It is very difficult, if not impossible, to study the question in a controlled experiment. Few participants, staff members, or research ethics boards would permit jail to be imposed in a nonindividualized and randomized manner.

The most practical way to study this issue is to compare outcomes between similarly matched drug court participants who did or did not face the realistic possibility of receiving a jail sanction. So far, such studies have yielded mixed findings. One study reported better outcomes when drug court participants faced a realistic prospect of jail (Carey et al. 2008) whereas another study found no differences in outcomes regardless of whether jail could be imposed (Hepburn and Harvey 2007). Another practical method for addressing this question is to interview the drug court participants themselves. A consistent finding from focus-group studies is that drug court participants viewed the threat of jail to be a highly motivating factor that kept them engaged in treatment and committed to their sobriety (Goldkamp et al. 2002; Farole and Cissner 2007).

At least two randomized experiments investigated the effects of enhancing the positive rewards that were available to participants for desired achievements in

drug courts (Marlowe et al. 2008; Prendergast et al. 2008). The rewards were delivered in the form of payment vouchers or gift certificates for negative urine tests and other desired accomplishments. Neither study found improved outcomes apparently due to a statistical ceiling effect. The outcomes were so favorable in both of the drug courts that it was difficult to improve any further upon those outcomes. In one of the studies, however, a preplanned interaction analysis revealed a nonsignificant trend ($p = .08$) in which high-risk offenders with more serious criminal histories performed relatively better in the enhanced reward conditions (Marlowe et al. 2008). This preliminary finding might suggest that when drug courts treat the most incorrigible drug offenders, tangible rewards may make additive contributions to outcomes. More research is needed to confirm and explain this interaction effect.

72.3.3 International Perspective

As was mentioned earlier, research on drug courts is just starting to be implemented in countries other than the USA. No studies have been published that have addressed the appropriate target population or best practices for drug courts in other countries. It does appear that the average risk and need level for drug court participants may be substantially higher in some other countries. Much of the increase in the US arrestee population has been fueled by drug-possession cases, and in some US jurisdictions offenders can be sentenced to jail or prison for simple drug possession. Because drug possession is less likely to receive an incarcerative sentence in many European and South American nations, drug courts in those countries are apt to treat offenders having more serious criminal charges and addiction backgrounds. Future studies should address this question and determine whether offenders' risk and need levels influence drug court outcomes in other countries.

Virtually all of the countries surveyed by American University reported that they were providing services in their drug courts consistent with the 10 Key Components or the 13 Key Principles. It appears that many international drug courts are exporting the model from the USA largely as it was designed and with relatively modest adaptations. Future research will hopefully reveal what changes, if any, may be required to adapt the drug court model to the needs and traditions of other countries and peoples.

72.4 Conclusion

Despite their unquestionable efficacy, drug courts in the USA serve only a small fraction (about 5–10 %) of the roughly 1.5 million adults arrested each year who meet criteria for substance abuse or dependence (Bhati et al. 2008). The primary obstacle to expanding the reach of drug courts in the USA is a lack of funding and not an absence of judicial interest or public support (Huddleston and Marlowe 2011). Convincing lawmakers that they will recoup their investments and reap

substantial economic gains by investing in drug courts is now a primary goal of rational drug policy in the USA.

Other countries seeking to extend the reach of drug courts will almost certainly face comparable challenges. The American University survey identified a number of barriers to implementing drug courts that were reported by several countries. The most frequently reported barriers were a lack of adequate funding (especially for treatment services), high rates of staff turnover, an underappreciation for the serious problems faced by participants, inadequate services for teens and young adults, and an insufficient availability of adjunctive services such as childcare and vocational training (Cooper et al. 2010). These barriers are virtually identical to those reported in the USA and do not appear to reflect unique problems encountered by Latin-American or Caribbean nations.

The major challenge for all nations is to extend the reach of drug courts without diluting the intervention below effective levels. Any program can be made cheaper simply by lowering the dosage and providing fewer services to more participants. The difficult task is to maintain effectiveness in the process. Many interventions show efficacy on a small scale only to have the quality of implementation drift unacceptably downward as they are applied on a large scale in day-to-day practice.

The big question is whether the criminal justice systems in various countries will move in the indicated direction. Facing huge budget deficits, some governments are imposing across-the-board funding cuts to correctional and treatment programs. There is no need to speculate about the likely effects of such actions. If history is a guide, any cost savings that might be realized in the short term will shift the financial burden to a later date as the result of increased crime, drug abuse, and related impairments. The appropriate course of action is to shift funds away from costly and ineffective programs, such as prison, to those that are proven to reduce crime and conserve public resources. Rather than taking an "axe" to cost-effective programs, policymakers should reallocate funds away from inefficient programs, reinvest them in evidence-based programs, and return the net cost savings to taxpayers. Much is possible if lawmakers apply what works rather than what is expedient, comfortable, or popular. If lawmakers do not rise to this challenge, then all of the research in the world will have little impact on public health or public safety.

Trauma and Addiction Medicine

73

Michael Dinh and Matthew Oliver

Contents

Abstract

Injuries represent a major burden of illness across the world, and injuries are disproportionately represented amongst those with concurrent *addiction disorders*. In this patient population, various behavioral, mental state, social, and clinical factors conspire to increase the risk of injury-related harms, ranging from road crashes due to drink driving to interpersonal violence and self-harm behaviors as a result of acute behavioral disturbance. *Trauma-related presentations* to the emergency department in drug-affected patients therefore represent some of the most dramatic clinical scenarios in acute medicine. Not only are there injury-related management issues, but also clinical concerns related to drug intoxication and the possibility of withdrawal syndromes masking serious injury. This brief chapter highlights these considerations in this complex group of patients and outlines a structured clinical approach in the *emergency department*.

73.1 Introduction

Injuries remain the leading cause of death around the world in people under 45 years of age (Krug et al. 2000). It is estimated that over 16,000 people die every day from injuries and many more are left with permanent disabilities. As a result of increased urbanization and road transportation in developing countries over the past 20 years, road trauma is projected to rise to the fifth most common cause of death by 2020 (WHO 2013). In recognition of this, the World Health Organization set out to reverse this trend by supporting a global decade of action on improving road safety from 2011 to 2020. Disturbingly, intentional or self-inflicted injuries follow closely behind road trauma as a cause of death in these age groups and, as the population ages, particularly in developed nations, falls have become an increasingly common cause of morbidity in the elderly (Stevens et al. 2006).

Substance abuse, particularly alcohol, has long been recognized as a risk factor for injury (Cherpitel et al. 2005; WHO Department of Mental Health and Substance Abuse 2004). Causal associations exist on a number of levels. Firstly, there are dose-related effects of certain drugs ranging from disinhibition and impaired concentration to aggression and impaired level of consciousness that increase the risk of road crashes, falls, and assaults (Australian Institute of Health and Welfare 2011). Secondly, social factors related to the acquisition and distribution of illicit drug use increase exposure to violent crime and penetrating trauma. Thirdly, substance abuse often coexists with or results in psychiatric disorders, increasing the risk of self-inflicted harm and harm to others (Cunningham et al. 2003). Finally, major trauma is a well-described risk factor for the development of post-traumatic stress disorder, which itself leads to substance abuse and a vicious cycle of further injury (Yehuda 2002). For these reasons and more, substance abuse exacts an enormous cost to society. In Australia in 2009, the costs of alcohol abuse alone were estimated to be over $15 billion dollars, which include tangible costs such as costs of road trauma, hospital treatment, and crime and intangible costs such as lost productivity and emotional distress (Laslett et al. 2010).

Emergency departments (ED) function within health systems to triage, identify and stabilize acute undifferentiated health problems (Schuur and Venkatesh 2012). This paradigm is exemplified by the modern trauma system, where the trauma team assesses and manages patients with life-threatening injuries with the ED and prepares the patient for definitive surgical treatment. EDs are also an important point of episodic health care for many people through unplanned admissions and exacerbations of chronic conditions. In most societies EDs also provide access to basic level care and a safety net for socially disadvantaged and isolated populations. Therefore, EDs commonly identify and treat patients with substance abuse disorders ranging from simple to complex conditions (McGeary and French 2000).

As such patients present to ED with a wide spectrum of problems, some of which are listed in Table 73.1. The effect of alcohol and drugs of addiction on a patient's cognition and physical abilities means that these patients are at a higher likelihood

Table 73.1 Common emergency presentations for patients with substance abuse

of suffering trauma. A study in Louisiana found that up to 70 % of patients admitted after severe injuries had positive drug or ethanol urine screens (Madan et al. 1999). A similar study of over 1,000 trauma patients at the R Adams Cowley Shock Trauma Center found that rates of positive drug screen around 64 % (opiates, cocaine, and marijuana) in trauma patients (Soderstrom et al. 1997). Patients with substance abuse disorders often present with multiple complaints, confounding even the simplest presentations like a sprained ankle and making such patients amongst the most complex patients to deal with safely and successfully in the ED environment. These management difficulties are often compounded by a patient's own impaired judgment and increased risk-taking behaviors (Field et al. 2001). As a consequence the severity of injury and the likelihood of suffering trauma tend to be higher in acutely intoxicated individuals than the general population (Waller et al. 1986; Rivara et al. 1993; Soderstrom et al. 1997). Despite these increased chances of trauma, the evidence that these patients have a worse outcome compared

Table 73.2 Risk behaviors found of acute and chronic alcohol users

Behavior	Percentage of patients ($n = 145$)
Driving	
Do not always wear seat belt	37.9 %
Do not always obey speed limit	71.1 %
Ridden with driver under the influence	41.1 %
Driving under the influence	33.8 %
Additional driving	
Recent citation/arrest/license suspension	44.1 %
Prior DWI/DUI arrest	17.2 %
Violence	
Carried a weapon	10.3 %
Recent physical altercation	35.2 %
Prior assault with weapon	30.3 %
Suicide	
Suicidal ideation in last year	26.9 %
Prior suicide attempt	13.8 %
Additional risk factors	
Lifetime drug use	57.9 %
Current drug use	32.5 %
Prior alcohol/drug treatment	20.0 %

Table adapted from Field et al. (2001)
DWI driving while intoxicated, *DUI* driving under the influence

to nonintoxicated patients is sparse. Only a handful of studies demonstrate worse outcomes for drug and alcohol-intoxicated patients compared to nonintoxicated patients with the same injuries (Chen et al. 1999; Tulloh and Collopy 1994; Swanson et al. 2007; Dischinger et al. 2001; Hadjizacharia et al. 2011) (Table 73.2).

As a consequence this population is at an increased risk of motor vehicle accidents (MVAs), pedestrian injuries, blunt assault, penetrating assault (stab wound or gunshot wound), self-harm, and falls (Savola et al. 2005; Demetriades et al. 2004). One study reviewing the odds of patients suffering from severe injury following an MVA identified alcohol use as the greatest predictor over other factors such as age, seat belt use, and vehicle crash. The presence of alcohol intoxication more than doubled the risk for serious injury (Waller et al. 1986).

73.1.1 Injury Profiles

A variety of injury profiles are found in drug and alcohol users ranging from minor to major injuries depending on the mechanism. Minor injuries may include

orthopedic injuries such as ankle sprains or rib fractures, minor burns, or soft tissue injuries. Although not requiring operative intervention in the majority of cases, minor injuries still account for a large burden on emergency department resources (London et al. 2009; Tominaga et al. 2004). Conversely major injuries, such as severe head injuries, and multisystem trauma require intensive care, operating rooms, and rehabilitation care which explains the high cost of these patients to the healthcare system (Moore 2005; Lucas 2005).

73.2 Clinical Aspects of Trauma

73.2.1 Clinical Considerations

73.2.1.1 Initial Assessment and Management

When patients arrive at trauma centers, an initial assessment of patient's injuries is made concurrently with initial interventions. Most centers follow an Advanced Trauma Life Support (ATLS) structure, whereby evaluations of a patient's Airway, Breathing, Circulation, and Neurological state (ABCs) form part of the "primary survey" (ATLS Subcommittee, American College of Surgeons' Committee on Trauma, and the International ATLS working group 2013). If a life-threatening abnormality is detected during assessment of these areas, then necessary interventions such as airway intubation and intravenous fluid resuscitation are commenced immediately. These are usually undertaken in the context of a distressed patient with limited corroborative history or available information about medical or social background. Following on from this, a "secondary survey" is commenced whereby a more complete medical history is obtained and the patient examined systematically to detect any other significant injuries. Further investigations often include radiographs, computed tomography (CT), and focused abdominal sonography in trauma (FAST). Many of these processes occur simultaneously by numerous clinicians working in a resuscitation or trauma team.

A number of variables dictate a patient's disposition and treatment in the emergency setting. For example, if a patient is severely injured and has tachycardia and hypotension, then they will often be treated presumptively for hemorrhagic shock with blood product transfusion and consideration for urgent operative intervention. However, similar injuries without clinical evidence of ongoing hemorrhage may not require urgent operative intervention and may simply require observation. Another example may be the patient with a head injury and a normal Glasgow Coma Scale (GCS) of 15 who may not require further urgent management. However, a head-injured patient with reduced conscious level, i.e., GCS < 9, or evidence of cerebral agitation (e.g., vomiting, confusion, or seizures) may require emergent airway intubation, urgent cranial CT, and craniotomy if there is evidence of intracranial hematoma.

Case Scenario
A 24-year-old male presents to an inner city emergency department with head and chest injuries following an assault in which he was beaten about the head with a baseball bat and stabbed with a small knife. He has a history of alcohol and cannabis use. He admits to injecting "ice" prior to the incident. He does not have family and frequently presents to this emergency department where he is well known for being disruptive and aggressive towards the nursing staff. On presentation he is sweaty and agitated and has a Glasgow Coma Score of 13, a heart rate of 130, and a blood pressure of 90/50. He has multiple facial abrasions, a large occipital scalp hematoma, and a small 2 cm penetrating wound to his left upper chest. The patient becomes violent and demands to leave the emergency department stating that there are people out to "get him."

73.2.1.2 Acute Physiological Changes Related to Drugs and Alcohol

As shown in Table 73.3 there are a number of affects from alcohol and drugs that make standard assessment and management of an intoxicated patient a clinical challenge. The main areas of concern specific to these individuals are (i) hemodynamic status and (ii) neurological status.

Hemodynamic Status

Nearly all drug and alcohol use can affect blood pressure or pulse as shown in Table 73.3. The most concerning presentation to any physician managing trauma

Table 73.3 Physiological effects of common drugs and alcohol

	Cardiovascular affects	Respiratory affects	Neurological affects
Alcohol	Peripheral vasodilation	Respiratory depression	Reduced conscious level and airway compromise, disinhibition
	Increased risk of arrhythmias	Reduced pulmonary clearance	
	Myocardial dysfunction	Higher incidence of pneumonia	
		Reduced pulmonary vascular resistance	
Stimulants, e.g., cocaine, methamphetamine, MDMA ecstasy	Tachycardia, hypertension, vasoconstriction, arrhythmias, myocardial ischemia	Increased respiratory rate	Agitation, aggression, anxiety, delirium, seizures
Sedatives/ depressants, benzodiazepines, opiates, marijuana	Increased systemic vascular resistance	Reduced respiratory drive with opiate used	Depressed conscious level, confusion, psychosis

patients in general is hemorrhage. Signs of hemorrhage in nonintoxicated adult may include increased respiratory rate, tachycardia, peripheral vasoconstriction, anxiety, and, later on, hypotension. Patients therefore intoxicated with any of the common substances of abuse could fit any of these criteria at any one time. Animal models have demonstrated the increased likelihood of bleeding with alcohol intoxication (MOSS et al. 1960; Zink et al. 1998; Blomqvist et al. 1987; Brackett et al. 1994; McDonough et al. 2002), most likely due to the inability to cause peripheral vasoconstriction to shunt blood to vital areas such as the heart, lungs, and brain. Stimulant-affected patients such as cocaine or methamphetamine users are typically tachycardic and agitated, giving the appearance of someone who is in hypovolemic shock. As a consequence not only is the patient's ability to cope with blood loss affected but also the assessment by treating physicians may be confounded. Drug-affected patients are therefore more likely to get over-investigated due to the concern for missing potentially life-threatening injuries not detected on routine assessment. However, the converse could be true in that physicians may be tempted to attribute exam findings and vital signs to drug intoxication and potentially miss life-threatening injuries, resulting in delays to definitive care and misdiagnosis. This has large implications for health-care resources because as blood transfusion requirements are increased, rates of CT scanning increased resulting in longer inpatient length of stays (Swanson et al. 2007; Moore 2005; Lucas 2005).

Neurological Status

Most drug abuse syndromes have potentially significant effects on cognitive function. The primary difficulty with any drug-intoxicated patient therefore is the assessment of the cognitive state and whether this is due to the intoxication or traumatic brain injury (TBI). Any unconscious patient (GCS < 9) requires urgent airway intubation and mechanical ventilation to prevent the occurrence of gastric aspiration and prevent secondary brain injury. Previous evidence has demonstrated that alcohol-intoxicated patients are more than twice as likely to require airway intubation compared to nonintoxicated patients with head injury (Gurney et al. 1992). Due to the alteration in cognitive level including aggression, agitation, and sedation, intoxicated patients with evidence of head injury or involved in serious mechanisms of injury are more likely to undergo CT scanning (Moore 2005). Also due to the inability to perform an adequate physical exam, patients are more likely to require imaging of multiple body areas for evaluation (Roudsari et al. 2012). Part of this imaging will frequently require not only cranial CT but also CT scans of the cervical spine. Well-described criteria are used in trauma patients to evaluate for cervical spine injury; however, patients must be alert and nonintoxicated to meet criteria for cervical spine clearance (Hoffman et al. 1998; Mower et al. 2004). Patients failing the criteria typically require CT cervical spine imaging with evidence of head injury or concerning mechanism of injury.

73.2.1.3 Chronic Physiological Affects of Drugs and Alcohol

Intravenous drug use has a number of implications for acute injury management particularly in relation to difficult intravenous access (Lucas 2005). However, chronic alcohol use is associated with a much more serious problem of coagulopathy and bone marrow suppression making hemorrhage control more problematic. The liver is responsible for the production of clotting factors II, VII, IX, and X as well as other components, all of which form essential elements of the coagulation cascade. Chronic alcohol users have reduced hepatic synthetic function, and therefore, production of these clotting factors is reduced. Normal patients suffering trauma are at an increased risk of bleeding from a variety of mechanisms (Brohi et al. 2003), and those patients with a pre-morbid reduction in clotting activity therefore have an increased risk of hemorrhage and death. Chronic alcohol use also impairs the immune response, and subsequently these patients are at increased risk of post-injury sepsis, acute respiratory distress syndrome (ARDS), and multiple organ failure (MOF) (Moore 2005).

Patients chronically abusing analgesic-related medications such as oxycodone, codeine and oral morphine, as well as illicit narcotics may require higher doses of analgesia due to tolerance and dependence. This creates significant challenges to health-care workers caring for patients in the acute care setting. Physicians need to be aware of the risks of under- and overtreating patients in this situation, and a multidisciplinary approach should be taken with early intervention from drug and alcohol specialists. Patients with alcohol dependence are also at serious risks of withdrawal and as a consequence are at risk of a myriad of signs and symptoms such as seizures, nausea, vomiting, abdominal pain, and diaphoresis. Treating physicians need to be vigilant to this condition and take appropriate steps to prevent withdrawal features while excluding other trauma-related complications such as sepsis, raised intracranial pressure, and ongoing hemorrhagic shock.

73.2.2 Emergency Department Considerations

73.2.2.1 Behavioral Management

Patients experiencing the acute effects of illicit drugs particularly methamphetamines are at risk of violent or aggressive behavior, requiring behavioral control in ED (Swanson et al. 2007; Latt et al. 2011; Degenhardt et al. 2007; Van der Swan et al. 2011). Measures include various de-escalation strategies, physical restraints, chemical sedation, and seclusion. The most appropriate strategy is usually one which allows safe and thorough clinical assessment while minimizing the risk of over-sedation and the complications associated with it, such as apnoea and hypotension. Restraint and sedation strategies should be consistent with local and institutional policies.

73.2.2.2 Mental Health Assessment

Patients with self-inflicted physical injuries can range from superficial lacerations to gun trauma and attempted hangings. Concurrent drug ingestion is common in

these presentations. Patients with acute substance use like cannabis or amphetamines may also express ongoing thoughts of self-harm or hallucinations. A mental state assessment should be made in the acute setting to diagnose the presence of an acute mental health disorder and determine the need to detain a patient for ongoing psychiatric care. This becomes a critical decision when a patient with a possible serious injury requests to leave against medical advice (see case scenario). If the patient has a potentially life-threatening condition and the patient's capacity to make an informed decision is impaired, then a patient may be detained for treatment necessary to preserve life and immediate well-being under the common law principal of duty of care (Wand and Wand 2013). In this context, a patient who is mentally disordered due to acute drug ingestion should not be released until the person is deemed to be capable of making an informed choice and potentially life-threatening injuries have been assessed for and excluded.

73.2.2.3 Social Problems

Patients with substance abuse disorders often access EDs due to poor social supports or financial difficulties (McGeary and French 2000). In addition family members, partners, or children of individuals with substance abuse disorders may also present with injuries as a result of interpersonal violence. It is important for EDs to have screening tools for these conditions as many jurisdictions have mandatory reporting requirements for suspected domestic violence and child abuse.

73.2.2.4 Security

Security personnel are often available in EDs to assist in the management of violent behavior. Additional staff are often required to ensure patient safety by preventing them from absconding or to monitor and prevent harmful behaviors such as further self-inflicted harm while in ED. Patients presenting with gun-related injuries, particularly gang-related crime, should be managed as a potential security threat, and patients and visitors should be searched for potential weapons. The police should be notified if the clinician has reason to believe that a patient is in possession of a firearm and poses an ongoing risk to self or others.

73.2.2.5 Emergency Department Overcrowding

One of the most important challenges currently facing emergency departments around the world is overcrowding (Richardson and Mountain 2009). Lack of staffing and beds required to meet the demands of the health-care system means that many EDs are chronically overcrowded with patients. The main manifestations are longer waiting times and reduced efficiency and patient safety. In this often chaotic environment, patients with substance abuse disorders particularly those with behavioral or mental health problems are more likely to escalate to violent or aggressive behavior. Some emergency departments have implemented models of care that involve dedicated mental health and drug and alcohol clinicians in an attempt to meet the demands of these patients at an earlier stage of management in ED.

73.2.2.6 Screening and Brief Intervention

Although systematic reviews have confirmed the effectiveness of screening and brief alcohol intervention in the primary care setting, it is difficult to extrapolate these to the emergency setting for trauma patients. Acute distress due to a combination of injuries, mental health disorders, and toxicological effects, in addition to the environmental considerations outlined above, make brief intervention less likely to be effective in this context. Indeed a meta-analysis of brief alcohol intervention in EDs highlighted the heterogeneity of studies giving rise to conflicting results (Havard et al. 2008). Nevertheless, given the frequency at which patients with substance abuse disorders present to ED and the ability to connect a patient with the direct consequences of their substance use, screening and brief intervention in ED would appear to be at least an initial opportunity to discuss these issues with the patient and lend itself to other opportunities such as follow-up referrals to specialized drug and alcohol services.

Level one trauma center hospitals (those accredited to manage the most severe trauma patients) in the United States are now required by the American College of Surgeons to have an alcohol screening and brief intervention program for patients admitted under trauma. Few studies have investigated the effect of brief interventions in this context, and ones that have are limited by low follow-up rates (50–70 %). Screening and brief intervention within trauma inpatient units offer a number of advantages to the ED setting, namely, the more controlled environment where injuries have been definitively treated, concomitant effects of drug intoxication have cleared, and the patient being more likely to be cooperative.

Mandatory Versus Voluntary Treatment and Rehabilitation of People Abusing Drugs: Initiatives from Malaysia

74

Mahmood Nazar Mohamed and Sabitha Marican

Contents

Abstract

Compulsory Centers for Drug Users (CCDU) were established in many countries to address the issue of drugaddiction such as drug treatment and rehabilitation center, drug detention center, drug prison, and others. Here, drug users were called inmates, were sent for mandatory treatment, and were subjected to "boot camp" approach with emphasis on discipline, religious values, social acceptable behavior, and punishment like canning. Little medical attention was given to these inmates and many contracted communicable diseases such as hepatitis, STIs, HIV, and tuberculosis while in mandated detention. Living conditions in very tight living quarters in these detention centers were very poor. As an

alternative to compulsory drug detention and rehabilitation centers, the UN agencies and entities that are signatories to the Joint Statement that called for the closure of drug detention centers advocated for states to make available voluntary treatment, evidence-informed, and rights-based health and social services in the community. Several agencies especially under UNODC provide data, evidences, training, workshops, conferences, sponsored visitations to alternative sites, and consultations to target countries in order to reduce the number of CCDUs and to introduce a proper evidenced and outcome-based drug treatment and rehabilitation center. In Malaysia, the government set up an innovative project to harmonize the country's drug laws, addressing the CCDUs and human rights issue. The Cure and Care (C&C) project was established in 2010 in response to low treatment outcome such as high-relapse rates, poor reemployment capacities, and reengagement to criminal behavior associated with CCDUs. They began gradually to move away from CCDU and introduced a number of evidence and community-based treatment (CBTx) services for illicit drug users. Since then, Malaysia has made considerable progress in the provision of voluntary drug treatment and rehabilitation. This chapter discussed several challenges faced by countries that still practice CCDU and the success of some states that has introduced evidence and outcome-based drug treatment and rehabilitation center.

74.1 Introduction

Drug treatment and rehabilitation is one of the major inputs to the demand reduction strategy which is endorsed by the United Nations Office of Drug and Crime (UNODC) to reduce the burden of drug on its users and the society at large. The nature of the addiction disease requires people dependent to drugs to be treated and rehabilitated and later to be reintegrated back into society (Mahmood 2005). However, often enough as observed in the Asian countries, the method of drug treatment do not follow the science of what is evidenced and what is not. Many operate on the assumption that any treatment for drug addiction is better than no treatment, which is not true at all (Simpson et al. 1997). Many treatment programs in Asian countries prescribed to local norms, religious, spiritual, and the punitive discipline-based methodologies to "treat" drug addicts (Mahmood et al. 2006). Drug laws were enacted to contain the epidemic of drug addiction in their countries. People tested for drugs and found positive are taken in for mandatory treatment in government-operated treatment facilities. As such, human rights issues are often infringed (Tongue and Turner 1988; UNODC 2010c). This chapter looks at the shift from the mandatory to voluntary treatment of drug dependents and how innovative projects undertaken in the Asian countries have been made models for other countries to replicate.

74.2 Drug Use, Treatment and Rehabilitation

74.2.1 The Extent of Drug Use

The United Nations Office on Drug and Crime (UNODC) reported that in the year 2011, between 167 and 315 million people aged between 15 and 64 were estimated to have used an illicit substance in the preceding year, which is between 3.6 % and 6.9 % of the global adult population. Since 2008, there has been an overall 18 % increase in the estimated total number of people who had used an illicit substance in the preceding year, which to some extent reflects both an increase in the global population and a slight increase in the prevalence of illicit drug use. This implies that there is now more need, if not demand, for drug and substance addiction treatment and rehabilitation globally (WDR 2013).

Asia is one region that has been hardest hit by problematic drug use (APAIC 2013). There is an estimated of 25–40 % of all illicit drug users worldwide, as well as 60 % of opiate users and between 30 % and 60 % of ATS users coming from this region (WDR 2013). Data from Pakistan and China indicated an increase in the use of all types of drugs.

In 2012, Pakistan reported cannabis as the most commonly used drug, with an annual prevalence of 3.6 %, followed by prescription opioids (1.5 %) and tranquilizers and sedatives (1.4 %). Use of ATS (0.1 %) and cocaine (0.01 %) appeared to be low but emerging in this country (WDR 2013). The number of people addicted to drugs is also on the rise. At present, 5.8 % of the adult population, which is approximately 6.4 million persons or one in every 27 persons in Pakistan, is using drugs, while nearly 25 % of the youth population is involved in some form of drug abuse (Muhammad Qasim 2013).

In China, opioid use remains high. The number of registered heroin users is increasing each year. There were 1.24 million in 2011, compared with 1.06 million in 2010 (WDR 2013). There is a wide difference between the country's number of registered addicts (e.g., 900,000 in 2007) with an estimate of 12 million drug addicts (Michels et al. 2007). The number and proportion of registered users of ATS are also increasing (38 % of all registered users in 2012, compared with 28 % in 2010). In addition, there has been a major increase in the number of drug users registered for use of other substances, such as ketamine. In 2012, more than 7 % of registered drug users were using ketamine.

There are various forms of drug treatment facilities that have been reported for China. For example, in 2000, there were 717 compulsory detoxification units (CDU) with 105,529 beds, 69 work education units (WEU) with 52,598 beds, and 119 voluntary units with 7,020 beds. In 2006, a total of 377,000 drug addicts were detoxified and treated in these facilities, and only 9.5 % of this number is receiving MMT, while 4.3 % are from voluntary units (Michels et al. 2007).

Data from East and Southeast Asia reported higher levels of ATS use in 2011. DAINAP reports ATS use, in particular methamphetamine, continues to increase in most countries in East and Southeast Asia (APAIC 2013). The illicit manufacture of

ATS continues at high levels in the region. Methamphetamine seizures also remained high in 2011. Ecstasy has been in decline in recent years, but there are signs at the global level that the "ecstasy" market is recovering (APAIC 2013). The demand for specific ATS-related abuse treatment is at its peak; however, not many countries other than Japan, the Philippines, and Thailand are able to provide effective hospital-based treatment. Many countries in this region treated ATS abusers the same as opiate and marijuana users, thus lacking in treatment efficacy.

Ketamine use also remained widespread in some countries in the region and was reported in Brunei Darussalam, China, Indonesia, Malaysia, and Singapore. A recent study in Hong Kong of 97 drug users, most of whom primarily took ketamine, found that over 60 % of them suffered depression, 31 % complained of poor concentration, and 23 % had memory problems. This adds new dimension to substance abuse treatment in Asia especially for the younger age group (Tan Ee Lyn 2009).

To curb the growing problem with drug use and abuse, most countries in Asia enforced the supply and demand reduction strategies. Many also has prescribed to harm reduction strategies specifically opioids replacement therapies and needle and syringe exchange programs. However, with the existence of drug laws, mandatory (i.e., legally enforced) treatment for drug and/or alcohol abuse is being enforced in many Asian countries. Court-mandated alternatives to incarceration are still not available in many countries. Even in countries like Malaysia and Singapore which is considered to have departed from the more traditional "boot camp" drug treatment program, till to date, there are no legal provisions for a drug user to be mandated to MMT program.

74.2.2 Compulsory Center for Drug Users (CCDU)

The existence of CCDU has been observed in many countries since the onset of drug problem in this region. In the 1970s, CCDU is probably the only available facility used under the demand reduction strategy in the Asian countries albeit some treatment conducted in hospitals and medical clinics. In Southeast Asia countries, various forms of CCDU take place such as drug treatment and rehabilitation center, drug detention center, drug prison, and many more. Frequently, "boot camp" modality is used with emphasis on discipline, religious values, social acceptable behavior, and punishment like canning and chaining. Drug users mandated for drug treatment were often labeled as inmates. Little medical attention was given to these "inmates," and many contracted communicable diseases such as hepatitis, STIs, HIV, tuberculosis, and others as a result of their drug use, injecting drugs, multiple sexual partners, and, on top of that, poor living condition and very tight living quarters in the detention centers (Fu et al. 2012).

At present, over 300,000 men, women, and children suspected of using drugs are detained in some 1,000 compulsory centers for drug users (CCDUs) in East and Southeast Asia alone (UNODC 2012b). A large number of drug dependents were registered at CCDU because most often they were legally mandated by drug

(or antidrug) laws in their country to undergo treatment here. Almost all of these CCDUs are free or the parents have to pay a minimal fee for treatment and rehabilitation as compared to receiving treatment in hospitals and voluntary units or private treatment centers. As a point of comparison, in Malaysia, private treatment at private centers costs between 300 and 3,000 USD dollars; in Indonesia, it is between 250 and 5,000 USD; in the Philippines, it costs between 600 and 8,000 USD; and in Thailand, it is between 500 and 5,000 USD as compared to government CCDU which is generally free of charge (Mahmood et al. 2006). However, many drug dependents receiving treatment at CCDU reported being beaten, abused, raped, locked, chained, and treated like criminals. Followings are some testimonies by former detainees of drug treatment centers in China, Vietnam, Lao PDR, and Cambodia:

> If we opposed the staff they beat us with a one-meter, six-sided wooden truncheon. Detainees had the bones in their arms and legs broken. This was normal life inside. – Former detainee, Ho Chi Minh City, Vietnam, 2010 (UNODC 2011a).
>
> They try to teach not to use drugs, that it isn't good to use [drugs], while showing that normal people have a good future. I don't think the classes helped me stop using drugs... Some people use more drugs when they come out of Somsanga. – Former detainee, Vientiane, Lao PDR, late 2010 (UNODC 2012a).
>
> There are lots of people and not enough food. It was hard to sleep there because in my room there were 60 people. There was not enough water for the showers, only a few minutes to shower every day. – Former detainee, Vientiane, Lao PDR, late 2010 (UNODC 2011b).
>
> I tried to run away, and in the process, I broke both feet. When I went to the hospital for treatment, I was arrested and sent back to the drug addiction center... Inside I was given very little food, and they never gave me any medicine at all to treat my feet. I was locked up for about half a year and my feet became crippled. – Written account from former detainee, Yunnan, China, 2009 (UNODC 2012a).
>
> All drug detention must work. We get up at five in the morning to make shoes. We work all day and into the night. That's all it is. – Former detainee, Yunnan, China, 2009 (UNODC 2010a).
>
> There were about seven children in my room but maybe about 100 children altogether. The youngest was about 7 years old. The children are not drug users but homeless, like beggars on the street. – Former detainee, Vientiane, Lao PDR, late 2010 (UNODC 2011b).
>
> [A staff member] would use the cable to beat people...On each whip the person's skin would come off and stick on the cable... – Former detainee, age 16, describing whippings he witnessed in the Social Affairs Youth Rehabilitation Center in Choam Chao, Cambodia (UNODC 2010b).

The situation of CCDU in East and Southeast Asia was reviewed at the first Regional Consultation for Drug Users, organized by UNODC Regional Centre for East Asia and the Pacific, ESCAP, and UNAIDS Regional Support Team in December 2010 in Thailand. On March 9, 2012, a Joint Statement was issued by 12 United Nations agencies, including the UN Office on Drugs and Crime (UNODC), the World Health Organization (WHO), the UN Children's Fund (UNICEF), and UNAIDS, calling for the closure of drug detention centers and the release of the people detained there "without delay" (UNOCD 2012b).

This UN Joint Statement highlights the concerns associated with the CCDUs, including increased vulnerability to HIV and tuberculosis infection as well as

insufficient legal safeguards and judicial review. Detention of people in such centers has also been reported to involve a range of other measures that violate human rights, including substandard conditions, forced labor, physical and sexual violence, and lack of access to health care, including HIV prevention services, among others (UNODC 2012b).

As an alternative to compulsory drug detention and rehabilitation centers, the UN agencies and entities that are signatories to the Joint Statement advocate for states to make available voluntary, evidence-informed, and rights-based health and social services in the community. Several agencies especially under UNODC such as TREATNET, DAINAP, and APAIC provide data, evidences, training, workshops, conferences, sponsor visitations to alternative sites, and consultations to target countries in order to reduce the number of CCDU and to introduce a proper evidence-based and outcome-based drug treatment and rehabilitation center.

74.2.3 Human Rights and Alternatives to Drug Treatment

Throughout the Asian region, there are a plethora of concerns about human rights violations; forced labor; physical and sexual violence; substandard living conditions; a lack of access to health care (Fu et al. 2012); ineffective, nonevidence-based treatment modalities (Noor Zurina et al. 2012); and an increasing awareness that CCDUs fail to address drug use as a chronic relapsing health disorder (Mahmood and Dzahir 2007; UNODC 2010c). Relapse rates among these "inmates" are high, and drug use occurs as immediately as they were released from the detention centers. At this juncture, many treatment experts want the government to make it a priority to end these abuses and redirect their support to voluntary, community-based treatment and other programs that truly respect drug users' human rights. This has led many governments to look at evidence- and rights-based alternatives to CCDUs (UNODC 2012b).

Harm reduction was introduced in the Asian countries before the turn of the millennium when a number of countries are facing epidemic numbers of HIV infections (Mahmood 2005). Many opposed the idea of substitution therapy and needle exchange because of religious values and beliefs that giving needles and syringes will not help drug addicts to stay off drugs (Mahmood and Dzahir 2007). In Malaysia, harm reduction strategies were endorsed by the government in 2001, and by 2005, many of the strategies has been implemented with good success. These set of strategies were also widespread in other Asian and ASEAN countries with strong support from UNODC (Mahmood and Dzahir 2007; Mahmood 2010; UNODC 2013).

Other pertinent issues faced by Asian countries are the well-established drug control and fast emerging drug laws for mandatory treatment and rehabilitation. In Malaysia, the government set up an innovative project to harmonize between the country's drug laws, addressing the CCDUs and human rights issue (Mahmood 2011). The Cure and Care project was established in 2010 in response to low treatment outcome such as high-relapse rates, poor reemployment capacities, and

reengagement to criminal behavior associated with CCDUs. Here, the government, through the National Anti-Drug Agency (NADA), began gradually to move away from CCDUs and introduced a number of evidence- and community-based treatment (CBTx) services for illicit drug users. Since then, Malaysia has made considerable progress in the provision of voluntary drug treatment and rehabilitation (Mahmood 2012; UNODC 2013).

The statistics related to mandatory treatment in Malaysia is also evident to these new initiatives. The number of drug addicts caught under the Drug Dependent Act 1983 (Treatment & Rehabilitation) peaks at 38,672 in the year 2004; 97 % were male and 64.1 % are of the Malay ethnic origin. At this time, drug treatment and rehabilitation is mostly conducted at government CCDUs, also known as "Pusat Serenti" for a period not less than 2 years. Voluntary treatment centers are still very limited, and many do not practice evidence-based drug treatment. In 2008, the government permits the prescription of MMT by private medical practitioners for treatment of opiate dependents. Many came forward to pay for the treatment, ranging between 10 and 25 USD per treatment. In addition the Ministry of Health dispensed free methadone through NADA. As a result, the number of drug dependents arrested in 2010 decreased to 23,642. Then, in 2010, the Malaysian government initiated the Cure and Care project, which is a voluntary drug treatment clinic-based program, and the number caught in 2011 and 2012 reduced to, respectively, 11,154 and 9,015 (Mahmood 2012; NADA 2013).

The pioneering Cure and Care (C&C) clinic in Kuala Lumpur was the first to be set up by NADA in 2010 in response to the growing drug problem. The C&C clinic represents a shift in Malaysia's approach to drug treatment and a move away from institutionalized punitive rehabilitation. It offers non-court-mandated voluntary treatment program for drug users and addicts with no question asked for them to access to drug treatment and rehabilitation and health and psychosocial services free of charge.

At about the same time, the Cure and Care Service Centre (CCSC) was established with its first establishment in the drug-stricken area of Chow Kit Kuala Lumpur. CCSC provides the community-based treatment (CBTx) and gives basic support services such as food for the day and a place to rest, clean, bathe, and wash clothes. It also functions as an outreach center, providing counseling, medical checkups, psychosocial programs, methadone maintenance therapy, spiritual and moral education, and support for integration. About 100–150 clients visited CCSC Chow Kit daily; and over a span of 1 year, more than 200 were referred to the C&C clinics for treatment, and more than 500 gets referral to the methadone program at hospitals in Kuala Lumpur. Additional NGO-operated CCSC were also set up in the city of Ipoh and the rural area at Jengka Pahang to address to many drug dependents and IDUs who need to access to such services.

Under these initiatives, the Malaysian Government did not change its drug laws. The Drug Dependent Act (Treatment and Rehabilitation) (1983) is still being used to arrest drug addicts, but as shown in the above statistics, the number has been reduced over the years. The current UNODC-endorsed initiatives operate within the existing legal framework; they developed an open system with community-based

services and comprehensive interagency collaboration. This is one of the drug treatment and rehabilitation models in Asian countries acknowledged by UNODC to be considered as applicable in countries with strict laws on drugs but with much interest in human rights and public health (UNODC 2013).

74.3 Conclusion

In conclusion, UNODC has reported some positive efforts taken by many countries in the Asian region to depart from the traditional boot camp drug treatment modality to a more evidence-based substance abuse treatment. Countries like Malaysia, Thailand, and the Philippines have made tremendous effort to introduce MMT and other opiate substitution available for heroin abusers; however, no substitution is currently available for the ever popular ATS in the region. Many Asian countries like Afghanistan, Brunei, Cambodia, China, Iran, Laos, Pakistan, and Vietnam are studying efforts taken by Malaysia to harmonize between its strict drug laws and the humane, voluntary-based drug treatment program for drug users (NADA 2013). Positive responses and outcome of the C&C projects are being documented for the benefit of countries who wish to replicate the project for its own high-risk population.

Opportunities for Addiction Service System Development: Case Studies from Vietnam, Lebanon and United Arab Emirates

75

Contents

Abstract

In the twenty-first century, the development of addiction treatment services around the world has been increasingly guided by science and the use of evidence-based practices. This advancement can be seen in the three very different examples of Vietnam, Lebanon, and Abu Dhabi. Since 2008, the government of Vietnam, together with substantial support from international donors and technical experts, has established a network of over 60 methadone treatment programs, distributed

around the country, to reduce the use of injected heroin and the related transmission of HIV. In Lebanon, a group of clinicians, with support from international organizations and a receptive government, have introduced buprenorphine into use for the treatment of opioid dependence. In Abu Dhabi, a concerted effort has been undertaken by the national government to build a comprehensive continuum of services, including addiction medications and evidence-based behavioral services, resulting in a fivefold increase in patients treated from 2009 to 2012. Despite substantial differences in the circumstances that generated these initiatives and their varying scope of services, the common theme across these efforts has been the implementation of science-based approaches with demonstrated effectiveness. The application of these effective strategies will provide a strong rationale and increase support for a public health approach to addressing drug abuse and addiction.

75.1 Introduction

Drug abuse and addiction "treatment" services began in many societies as part of their criminal justice system, social services system, community-based self-help efforts, or some combination of all three. The initial efforts to develop "treatments" for addicted individuals were frequently unclear about what they were treating. Was drug addiction a moral problem or a medical problem? Were addicted individuals bad people, weak in character, or sick people, with a medical/psychiatric condition? Among the factors that have spurred societies to develop drug treatment services are concerns about the following: drug-related crime, drug injection-related infectious diseases (e.g., HIV, hepatitis C), loss of work productivity, and the disruption caused to family members and communities (National Center on Addiction and Substance Abuse [NCASA] 2005; National Drug Intelligence Center [NDIC] 2011; UNDCP 1995). In many societies, the first response to drug use has been a public safety response addressing drug-related crime, including criminal penalties for drug possession and use (Chandler et al. 2009). A variation of incarceration in some societies is mandatory commitment in psychiatric institutions. Initial treatment alternatives to incarceration or commitment have typically been a patchwork of storefront counseling centers, therapeutic communities, sober living houses, self-help programs, and medical treatments for overdose and withdrawal. Part of the reason for this haphazard societal response has been that the fundamental nature of addiction was poorly understood, and even if it was viewed as a health problem or disease, there were no identified medical paradigms to treat this disease.

One thing was consistent across all parts of the world – until the late twentieth century, the initial treatment services for drug abuse and addiction had very little foundation in scientific research about addiction or evidence-based medicine. By the late twentieth century, the role of injection drug use in the AIDS pandemic stimulated, in some parts of the world, the interest of global public health leaders in efficient and effective evidence-based treatments for heroin use. The documented efficacy of methadone in decreasing injection drug use and reducing transmission of HIV has clearly been a major factor endorsing the implementation of methadone treatment services. To a lesser extent, the widespread increase in use of cocaine and

amphetamine-type stimulants (ATS) in many parts of the world has also increased interest in behavioral treatment approaches for individuals with psychostimulant disorders, whose psychotic and violent behavior can cause a serious detrimental effect on individuals and communities (UNODC 2013).

To further the global awareness of addiction science, the US National Institute on Drug Abuse (NIDA) initiated an international program in the early 1990s that has played a major role in engaging international investigators and institutions in addiction research and has served as a vehicle for the dissemination of addiction science. NIDA has sponsored and cosponsored dozens of international conferences and training events over the past 20 years to increase awareness of addiction science and its application. In addition, from 1990 through July 2013, NIDA has sponsored 408 international fellows from 103 countries for training fellowships via the NIH Humphrey program, the NIDA INVEST program, and other such programs (NIDA 2013). Further, NIDA has established seven binational agreements with other countries to promote co-funding of research and has added an international satellite meeting to its annual College on Problems of Drug Dependence (CPDD) meeting. This CPDD international satellite meeting has shown tremendous growth from a meeting of 20–25 participants at the first meeting in 2000, to a meeting of 300 enrollees from over 40 countries in 2013 (S.W. Gust, personal communication).

Another contributing factor to dissemination of addiction science is the establishment of the International Society of Addiction Medicine (ISAM), which developed from a small forum of MDs interested in addiction, to a large annual meeting of 400–500 participants. The latest developments in the field, with an emphasis on clinical applications of addiction medicine, are reflected in the annual ISAM meeting agenda. Finally, the World Health Organization (WHO) and United Nations Office on Drugs and Crime (UNODC) have been active contributors to the dissemination of addiction science. The UNODC Treatnet Program, initiated in 2007, has been incorporated into a joint WHO-UNODC effort to provide training and technical assistance internationally to regions developing treatment and harm reduction services. The Treatnet curriculum was created with an emphasis on science-based knowledge and evidence-based practices at its core (Tomás-Rosselló et al. 2010). As of 2013, over 1,200 individuals have been trained as trainers and 9,000 clinicians have received training via Treatnet (Saenz et al. 2015; UNODC 2007).

75.2 The Changing Face of Substance Abuse Treatment in Vietnam, Lebanon, and United Arab Emirates

75.2.1 Case Studies

The following international case studies provide examples of successful and diverse advancements in addiction treatment and public health service that were driven by the best scientific evidence, multiagency international collaborative efforts, and the influence of public health leaders and committed service providers with a vision for the future.

75.2.1.1 Vietnam

Vietnam, a country of 90 million people, has a significant prevalence of drug use and HIV. Injected heroin became a significant public health problem from the time of the war with the United States in the 1970s. In 1993, the government of Vietnam opened compulsory centers (06 centers), where drug users were reeducated, punished, and rehabilitated, since addicts were viewed as a "social evil." The 06 centers were part of a policy toward drug users in which drug users could be arrested and, without due process, immediately transported to the 06 centers, where they were routinely held involuntarily for 2 years; repeat offenders were held for even longer periods. While in the 06 centers, there was no identifiable drug treatment, and the primary activity was long hours of tedious manual labor. Although the 06 centers were not called jails, they were far more oriented to punishment and control than to medical or psychiatric treatment.

The first case of HIV infection was detected in Vietnam in 1990; by 1999, there were 17,046 diagnosed cases of HIV infection. By 2012, the estimated number of HIV-infected individuals was estimated at 206,887. Studies over this time period suggest that injection drug use (IDU) was the likely route of HIV transmission in 85–90 % of HIV-positive individuals. As of 2012, there were an estimated 220,000 injection drug users in Vietnam (Vietnam Ministry of Health 2012). Following passage in 2006 of the Law on HIV/AIDS Prevention and Control (known as the "HIV law"), the Vietnamese government, led by the Deputy Prime Minister, initiated a plan to change the focus of the response to the IDU/heroin problem in Vietnam. The Ministry of Health, with support from UNODC, WHO, Global Fund, USAID, Family Health International, and the United States President's Emergency Plan for AIDS Relief (PEPFAR), began plans to introduce methadone into Vietnam.

Methadone treatment programs were piloted in 2008 in Hai Phong and Ho Chi Minh City as a result of the 2006 HIV law. These pilot programs operated under guidelines developed by Vietnamese leaders and with extensive consultation from international experts. The guidelines were grounded in the best scientific evidence, and an extensive training program was implemented by local and international clinical experts to promote development of a methadone treatment system based on best practices. With the success of the pilot programs, the government decided to scale-up methadone programs in other provinces (Vuong et al. 2011). By July, 2013, 14,000 patients were in methadone treatment in 62 clinics in 20 Vietnamese provinces. The Ministry of Health (MOH) has projected that methadone treatment will be provided to about 80,000 drug users in 2015.

Studies on the outcomes of the methadone implementation in Vietnam have demonstrated promising results. In a four-site cohort study of 965 heroin users who started treatment in 2009, 88.3 % were retained in methadone treatment for 12 months (U.S. Agency for International Development 2011). Heroin use, as measured by urinalyses, was reduced from 100 % positive at admission to 21 % positive at 60 days in treatment; and over the subsequent 10 months, rates varied from 17 % to 10 % positive. Other study results indicated substantial reductions in injection drug use and crime, as well as improvements in mental health and quality of life.

If the Ministry of Health succeeds in its planned service development, Vietnam will have gone from two pilot project clinics in 2008 to treating over 80,000 patients with methadone in 2015 (Nguyen et al. 2012). This extraordinary expansion of treatment capacity brings with it huge challenges of service funding and workforce development. In 2011, Hanoi Medical University, in collaboration with UCLA, established an Addiction Technology Transfer Center to lead efforts to train clinical staff for the clinics being developed. Compounding the challenges, amphetamine-type stimulants (ATS) consumption has rapidly increased in Vietnam – 1.5 % of drug users in Vietnam in 2001 used ATS, whereas 6.5 % did in 2012 (Department for Social Evils Prevention [DSEP] 1995–2012). In order to address this emerging problem, training programs in motivational interviewing and the Matrix Model of treatment have been initiated to provide services to address the needs of treatment-seeking ATS users. In less than a decade, Vietnam has mounted a major public health effort to address the problems of drug use and HIV, and the policies that have guided this system development have been firmly grounded in addiction science.

The development of the Vietnamese treatment system and capacity-building effort has been the result of well-informed and responsive public health officials in the Vietnamese government, in cooperation with international funding organizations and technical assistance. The urgency for developing these services has been accomplished in parallel with an equally impressive HIV testing and treatment program. The challenge for the next decade will be to continue the expansion of the services to provide treatment access for all individuals who need them, to maintain the quality of the services, and to better integrate addiction services with HIV services and the larger health-care system. The development of addiction services in Vietnam over the past decade was an impressive exercise in public health service development, guided by the best scientific evidence and implemented by a multiagency international collaborative effort.

75.2.1.2 Lebanon

At the start of the twenty-first century, services for the treatment of substance use disorders in Lebanon were a collection of faith-based therapeutic communities and a limited set of treatment services from psychiatrists and psychiatric hospitals. Although these resources were helpful to patients and communities, there was no organized outpatient treatment and no use of addiction medications. In 2003, an organization named Skoun was created to deliver high-quality, evidence-based outpatient addiction services. Heroin addiction was the primary drug problem that was not being effectively addressed by existing treatment services. Skoun initiated their treatment services using a combination of harm reduction strategies, together with cognitive behavioral therapy (CBT), motivational interviewing, and psychiatric treatment. It was clear to Skoun staff from the beginning that to effectively engage and treat individuals addicted to opiates using a harm reduction philosophy, they would need addiction medications as part of their services. Therefore, an initial question was whether to introduce methadone or buprenorphine into Lebanon, where, to date, no medication-assisted treatment had been available. As they

reviewed practices associated with methadone and buprenorphine in Europe and the United States, they decided that the clinical data on the efficacy of buprenorphine and flexibility in its dosing and service delivery logistics made buprenorphine the preferable agonist medication to bring to Lebanon. Furthermore, in their initial discussions with the Ministry of Health, there were some concerns about methadone diversion, but there was general support for the idea of buprenorphine. However, because rates of HIV are low in Lebanon, there was no perceived public health urgency for addressing the injection drug use problem as there was in Vietnam, China, and countries in Eastern Europe.

Because there are close historical and cultural ties between Lebanon and France, it was not uncommon for opiate-addicted individuals from Lebanon to go to France to receive buprenorphine and return to Lebanon to participate in counseling treatment services at Skoun. As this practice developed and some pharmacies in Beirut established relationships with French pharmacies, buprenorphine became available, in a limited manner, for patients at Skoun. From 2005 to 2011, several hundred patients were treated with buprenorphine in Lebanon. During this period, discussions continued with government officials about the clinical effectiveness of buprenorphine and its value in improving the lives of addicted individuals. The Pompidou Group, UNODC, and the WHO Eastern Mediterranean office (EMRO) played important roles in hosting meetings to promote discussions of the use of buprenorphine in Lebanon and arranging visits for Ministry of Health officials to France and Iran to visit treatment centers using medications to treat opiate addiction. The persistent advocacy and encouragement by individuals at Skoun, along with other addiction and public health leaders in Lebanon and representatives of international organizations, resulted in official governmental approval for the importation and use of buprenorphine for the treatment of opiate addiction in February 2012.

During the first year since the passage of the approval of buprenorphine in Lebanon, 690 cumulative patients have been treated with buprenorphine, with the majority being in Beirut. Skoun has expanded services from its original clinic in Eastern Beirut to a second clinic in South Beirut, sponsored by the Drosos Foundation, a Swiss organization. This clinic, which was projected to enroll 75 individuals on buprenorphine in its first year, was met with tremendous demand for services and enrolled double that number (150) in its first 9 months of operation. In addition to the buprenorphine services provided at Skoun, a total of 45 psychiatrists have been registered by the Ministry of Health to prescribe buprenorphine. The use of buprenorphine in Lebanon is currently limited by a somewhat restricted distribution system (all medication has to be dispensed from two government hospitals in Beirut), and all buprenorphine is available only through patient fees, which are several hundred US dollars per month. Currently there are efforts to work with the government to promote treatment (including treatment with buprenorphine) in place of incarceration for drug offenders. Although the law to allow treatment rather than incarceration has been in place for almost a decade, it has not been implemented. The availability and effectiveness of buprenorphine has made it possible to convince judges to implement this law, and so this practice is currently expanding.

Unlike the situation in Vietnam, where an internationally financed, large-scale multiagency partnership produced a major "roll out" of methadone treatment and other addiction services, the situation in Lebanon was on a smaller scale, but the accomplishment was equally impressive. The introduction of buprenorphine and other outpatient evidence-based services was the result of the persistence and commitment of Lebanese clinicians, the Pompidou Group, UNODC, National Aids Program, and WHO, together with receptive Ministry of Health officials. The use of opiate substitution therapy in the Middle East is very limited, as public health pressure for introducing this treatment is limited due to the low rates of HIV throughout much of the region. The political situation over the past decade in Lebanon has made it challenging to bring the issue of addiction treatment onto the governmental agenda. However, the diligence of a small group of dedicated professionals, together with international organizations has added an important addiction service in Lebanon and has provided an example for the region of the feasibility and value of medication-assisted treatment for addiction.

75.2.1.3 Abu Dhabi, United Arab Emirates (UAE)

Abu Dhabi is one of the seven Emirates on the Persian Gulf that make up the United Arab Emirates, a country of great wealth as a result of its extensive petroleum production. The population of the UAE is approximately eight million. It is a country of rapid change and extensive infrastructure development in all areas, including health care. The National Rehabilitation Center (NRC) was established in 2002 under the direction of the late President of the UAE. It is the principal source of treatment and rehabilitation for Emiratis who have substance use disorders. It is also the organization that coordinates all aspects of drug abuse epidemiology, prevention, and workforce development. As of 2008, the NRC consisted of an 18-bed residential treatment and rehabilitation center, a nine-bed halfway house, and some outpatient services. The NRC was the officially recognized addiction treatment facility in Abu Dhabi, even though there were also some detoxification services provided in the major mental hospital in Abu Dhabi and some private psychiatric services were available.

In early 2009, a six-person team representing the International Society of Addiction Medicine was invited to visit the NRC to provide technical assistance and recommendations for service development. At the time of this site visit, the NRC had a patient census of nine patients who were undergoing extended hospital-based residential care for 9–12 months and three individuals living in the halfway house. At that point, the majority of the patients being treated in the NRC facility were individuals released from prison, and it was not altogether clear if the NRC was completely a clinical program or if it also served as an extension of the prison authority. The nature of treatment services at the time was somewhat unclear, and while there were some very well qualified and knowledgeable psychiatrists and clinical staff, there was minimal organization to the clinical program being offered and little indication of evidence-based practices being offered.

Over the next 3 years, the NRC instituted a major expansion of addiction services, with a commitment to developing a quality continuum of care based on

evidence-based medicine. The NRC recruited a medical director from Cairo University, Egypt, who was then the president of the International Society of Addiction Medicine, and two other Egyptian psychiatrists who had extensive expertise and specialized training in addiction. The NRC appointed a training director who, together with a training expert from Kings College in London, implemented a comprehensive program of staff training in evidence-based practices with quality clinical supervision. A team of clinicians received extensive training in the Matrix Model of outpatient treatment to address the substantial problem of ATS use and dependence, and the NRC arranged for the importation of Suboxone to treat opioid dependence. A research director, who had previously held a senior position at NIDA, was hired to develop a program of clinical and services research. In 2013, an electronic medical record (EMR) system was implemented, and, at present, the entire clinical record-keeping system at the NRC is incorporated into this EMR system.

The NRC has moved from the 18-bed residential facility in the city of Abu Dhabi to a much larger set of offices and villas in the suburbs of Abu Dhabi. The residential capacity has been expanded to 110 beds for men and a separate facility for women. Outpatient services (medical services, psychiatric services, addiction medications, and behavioral treatments) are integrated with the residential programs into a connected continuum of care. The treatment capacity has increased fivefold, from 67 patients treated in 2009 to 338 in 2012. Plans are underway for the development of a satellite facility in a northern sector of the Emirates to make services more geographically accessible, and ground has been broken for a comprehensive treatment center that will provide an even greater treatment capacity. The service development at the NRC over the past 5 years has been extensive, and a foundational part of the service philosophy is the use of good science and treatments with a strong evidence base.

75.3 Conclusion

The early twenty-first century has seen an expansion of addiction treatment services throughout the world, with evidence-based treatments applied as core features of the service continuum. This application of medical and behavioral health research findings to addiction service system development is a welcome step toward the establishment of drug treatment as a public health domain. As these services evolve and demonstrate effectiveness in reducing drug use and related infectious disease and drug-related crime, a significant challenge will be to find and mount the political will to redirect investments from incarceration/public safety interests to addiction treatment/public health interests that require preventative and clinical skills, medication, and coordination with related health conditions services.

Disclosures and Acknowledgements The authors have no conflicts of interest. Dr. Rawson is the Principal Investigator for the Cooperative Agreement for Workforce Development in Vietnam: HIV-Addiction Technology Transfer Center (2011–2014) and has served as a training consultant to the Substance Abuse and Mental Health Services Administration (SAMHSA) on addiction treatment in Vietnam. Dr. Rawson was a member of the ISAM site visit team to the Abu Dhabi

National Rehabilitation Center in 2009 and provided consultation to the NRC on outpatient services. Dr. Rawson and Dr. Rieckmann are Co-Principal Investigators on an evaluation of the Skoun Program in Beirut, under contract to the Drosos Foundation. Victor Capoccia was supported by UNODC to describe the development of community-based care in Vietnam in June and July 2012.

Abstract

This chapter aims to present various facets of addiction-related problems in Iceland and the unique features of Icelandic society that have molded the attitudes and ways of dealing with these problems. Although Iceland is geographically isolated, it has seen changes in drug use following international trends. Due to the small size of the population and its centralized health care, Iceland is in a unique position to follow such trends and monitor the course of those treated for addiction. These trends in drug use as well as epidemiological information and social policy issues are discussed. The development of addiction treatment services in Iceland is also reviewed with special emphasis on social aspects of treatment, such as high availability of treatment and the equality of access to health care. These aspects have yielded a smaller treatment gap in Iceland than in many other countries. In addition inpatient

treatment services in follow-up care have been preserved within the addiction treatment system, complementing a comprehensive treatment model of addiction with a view of addiction as a chronic disease. These features are discussed in order to highlight their importance and contribution to effective clinical practices.

76.1 Introduction

Substance use disorder treatment in Iceland has a history spanning more than 50 years, during which treatment approaches and the general understanding of substance use disorder have changed dramatically. The development of treatments has been influenced both by general advancement in medicine and psychosocial treatments and by unique factors of the Icelandic society. This chapter reviews these cultural aspects of addiction-related attitudes and describes addiction treatment in Iceland with the aim of highlighting factors important in understanding how different societal factors may impact addiction treatment in an international context.

76.2 Treatment in Iceland

Iceland is a small island country in the North Atlantic Sea with a homogenous population of 321,857 (Statistics Iceland 2013). It is sparsely populated, with more than two-thirds of the population living in the capital of Reykjavik or its neighboring towns. Icelandic society upholds a Nordic social welfare system providing universal health care, including substance use treatment, and tertiary education for all. Equality is greatly valued and Iceland has been rated the country with the world's smallest gender gap 5 years in a row by the World Economic Forum (2013) reflecting equal access to education and health care. The standard of living is high and Iceland has been ranked as the 13th most-developed country in the world by the United Nations' Human Development Index (2013).

These unique features frame the substance disorder treatment system and high accessibility to treatment resulting in a smaller treatment gap than in most other countries. It has been estimated that in the United States, only one in ten in need of addiction treatment receives it (NDSUH 2010), compared to estimates of 50 % receiving treatment needed in Iceland (Tyrfingsson et al. 2010).

In addition to accessibility to services being high, another important aspect of the treatment milieu is that addiction has been seen as a biological disorder needing professional treatment. Treatment has thus been part of mainstream health care with treatment being provided by health-care professionals such as physicians, nurses, addiction counselors, psychologists alongside social workers, and other health-care professions. Thus, the emphasis has been on the disease model of addiction. This view of addiction among professionals is disseminated to the mainstream, making it easier for people to address their addiction problems, and this is reflected, e.g., in the lenient outlook of most employers who grant sick leave on pay for those

seeking addiction treatment. Social security also provides financial support to those with substance use disorders, just as for any other medical condition further reducing barriers to treatment.

Alcohol and drug policies have been strict in Iceland and have shaped consumption patterns. Alcohol sales are controlled and monopolized by the government, and the price of alcohol and tobacco has been kept high. Iceland has been second only to Norway for the highest retail prices of alcoholic beverages in Europe (WHO 2012). Strict tobacco use restrictions have led to steadily decreasing rates of smoking in the general population with the current rate standing at 17.4 % (Directorate of Health 2012); however, nicotine addiction has been relatively stable at 79 % among patients receiving addiction treatment (SAA 2012).

Drinking patterns in Iceland have been similar to drinking patterns in the Nordic countries. These patterns were characterized by infrequent use of alcohol, mainly heavy drinking or binge drinking of strong liquor, for the purpose of intoxication during weekends or festivities as the Scandinavian Drinking Survey in 1979 carried out in Iceland, Norway, Sweden, and Finland showed; in addition there was a higher level of acceptance of drunkenness in public than in other countries (Makela 1984, 1986; Room 2010; Room and Mäkelä 2000). The overall volume of alcohol consumption in the Nordic countries has been lower than the EU average, and Iceland has had the lowest consumption of alcohol per capita of the Scandinavian countries, with alcohol consumption rates of between 4 and 5 l from 1970 (3.82 l) until the 1990s, when consumption showed an increase when beer was legalized 1989, but its sale had been banned from 1915. The total amount of alcohol consumption has risen steadily since the introduction of beer, and sold liters of pure alcohol per capita, 15 years and older in 2012, were 6.93 l. In addition to increased alcohol consumption, there has also been a shift in consumption patterns from distilled spirits to beer (Olafsdottir 1998, 2002), and consumption of wine during the last decade of the twentieth century increased by 80 % (Directorate of Health 2003) with drinking patterns becoming more similar to those in Western Europe. However, Iceland still holds the distinction of having one of the lowest rates of alcohol consumed in Europe or almost half the mean rate of consumption in the EU countries (12.5 l pure alcohol per year) but higher than the global average of 6.1 l per capita consumption (WHO 2011).

Thus, strict alcohol legislation and a good treatment system have gone hand in hand in the effort to tackle the harmful consequences of alcohol abuse. Despite lower rates of consumption, the prevalence rates of substance use disorders have been similar in Iceland as in other countries. A recent study (Stefansson and Lindal 2009) of the prevalence of mental disorders in Reykjavik and its' vicinity using a random sample of three birth cohorts (born 1931, 1951, and 1971 and aged 34, 54, and 74 during the assessment) showed that the lifetime prevalence of the ICD-10 mental and behavioral disorders due to use of alcohol was 10.8 % with 1-year prevalence for alcohol use disorder 6 %, being more prevalent among men. These are similar to prevalence estimates using DSM-IV diagnoses in epidemiological surveys in the United States, showing prevalence of lifetime and 12-month alcohol dependence rates of 12.5 % and 3.8 % (Hasin et al. 2007).

Treatment of alcohol and drug use disorders in Iceland has involved different treatment settings with mental health services and specialized alcohol and drug services as the main providers of treatment for people with alcohol and drug use disorders. Services for this population began with the foundation of a rehabilitation home (Bláa bandið) based on AA principles in 1955, following the foundation of AA in Iceland 1954, with two meetings per week. Icelanders embraced the AA tradition from the start and today it is thriving, with about 300 meetings per week (see Olafsdottir 2000 for the history of AA in Iceland). Substance use disorder treatment has emphasized the AA approach and encouraged patients to engage in the AA community. The rehabilitation home was shortly subsumed into the mental health-care system.

The next significant development in addiction treatment in Iceland was during the 1970s. A number of people went to the United States for treatment and were exposed to what is called the Minnesota Model, consisting of intensive treatment for 4–6 weeks based on the 12-step approach of AA. Those that came back energized the AA society and decided to form a nonprofit layman's association for the advancement of alcohol treatment in Iceland. This association, Society of Alcoholism and other Addictions (SAA), was founded in 1977 and had as its goal to inform and influence the general public on the nature of the disease of alcoholism and to establish treatment and counseling services. Thus, the emphasis was placed on the disease concept, and the treatment of alcoholism was seen as a health-care issue as opposed to a social problem. SAA's treatment for addiction was started that same year, 1977. SAA built Vogur Hospital, the National Center of Addiction Medicine, in 1980 with donations from the Icelandic people to serve as a national center for addiction treatment. Vogur Hospital thus gained the recognition of the nation as the main addiction treatment facility, a welcome addition to the services provided by the National Hospital. The availability and salience of treatment options grew dramatically and high rates of available treatments have been maintained ever since (Olafsdottir and Helgason 1988). This high rate of available treatment is also unique to Iceland. The WHO has estimated worldwide that there are 1.7 beds per 100,000 population available for the treatment of drug and alcohol use disorders, with Iceland ranking the highest, with 52.4 beds according to the report on Resources for the Prevention and Treatment of Substance Use Disorders (WHO 2012).

Since its establishment SAA has become the leading treatment facility of alcohol and drug dependence in Iceland providing treatment at Vogur Hospital to more than 22000 patients (15.880 males (70.9%) and 6.522 females (29.1%)) or a significant proportion of the nation (10.5 % males over 15 years of age and 4.4 % of women of the same age). Approximately 1,800 individuals are admitted each year to Vogur Hospital, with about 600 newcomers annually with roughly 2,400 admissions yearly or 6–7 patients daily. This accounts for a large proportion of the treatment addiction services in Iceland. At the University Hospital Psychiatric Ward, about 500–600 patients are admitted yearly, mostly patients with concomitant mental (50 %) or other physical disorders (38 %) (Birgisdottir 2013). Other facilities that provide rehabilitation services are outside of mainstream health care.

76.2.1 Services at SAA's Facilities

Most patients start their treatment in detoxification at Vogur Hospital. They are mostly self-referred. During the average stay of 7–10 days, patients are detoxified, mental and physical diseases are stabilized, and psychoeducation is started and the process of motivation for change begins. Personnel consist of health-care professionals working full time, most are certified, as well as students in training. These include medical doctors, registered nurses and nurses' aids, and certified addiction counselors. In addition to Vogur Hospital with its 60 beds for adults and 11 beds for adolescents, SAA runs two inpatient rehabilitation centers, each with 30 beds with services tailored to specific groups (women, older men, younger men); three outpatient units, two in the capital Reykjavik and one in a town on the north coast, Akureyri; a recovery house with 20 beds for IV users without a home; and a social center.

After detoxification at Vogur Hospital, a majority of patients or two-thirds continue treatment and rehabilitation. One-third goes for further therapy in a residential setting (4 weeks) and one-third to intensive outpatient (4 weeks) after detoxification. Recognizing that better outcomes are related to adequate treatment length (NIDA 2009), residential treatment is the treatment of choice and treatment providers collaborate with the patient and aim for intense treatment options when possible and appropriate. Residential treatments are delivered in nonhospital settings outside of the city. Residential treatment consists of daily group therapy sessions and psychoeducation as well as individual counseling if needed (total of 60 h of treatment). Self-help meetings are facilitated in order to help patients gain community-level support to support recovery and maintain abstinence after formal treatment ends, with an additional 3 months of weekly sessions (additional 12 h treatment). The follow-up phase of the inpatient option consists of biweekly sessions for 3 months (24 h total) followed by weekly sessions for up to 9 months (36 h total). Group therapy and individual counseling sessions are guided by principles and techniques of cognitive behavioral therapy and motivational interviewing and are delivered by certified addiction counselors. Treatment protocols and staff training follow the NIDA recommendations (2012) of an evidence-based approach to treatment and training. Recognizing that addiction is a chronic disease, readmissions are not uncommon and are welcomed. About half of the patients that have come for treatment over the past three decades have been admitted only once to the hospital, and the majority, 78 %, three or fewer times. A subgroup of patients need additional assistance and about 4 % have been admitted more than 10 times.

Another important aspect emphasized in SAA treatment services is relapse prevention, and follow-up treatment is provided for up to 1 year as described above, with less intense outpatient services following the more intense options to closely monitor progress and support relapse prevention.

SAA offers a wide range of treatment options tailored to various levels of disease severity and different needs of patients based on factors such as gender and age. These specialized treatment options range from opioid maintenance therapy to adolescent

treatment; in addition there is specialized treatment for women, for men over 55 years of age, and for relapse-prone men; treatment is offered for gambling and to families dealing with addiction. Treatment modality also varies, with counseling, education, and group therapy provided within both inpatient and outpatient rehabilitation settings, with long-term treatment available for the most severely affected patients and an intensive outpatient therapy with assisted housing. Particular emphasis during the last decade has been placed on counseling one of the high-risk groups in a preventive effort, i.e., the children of patients growing up with the addiction.

76.2.1.1 Changes in Addiction-Related Problems

Because SAA has been a lynchpin in addiction treatment delivering a high proportion of treatment to all Icelanders, the treatment cohort is representative of the Icelandic treatment-seeking population. Clinical data have been gathered in a systematic way over the past two decades providing DSM-IIIR/DSM-IV diagnoses as well as other clinical information. This unique database provides important information and allows for tracking trends in the patient population. To name a few, the makeup of the patient population has changed with the proportion of women increasing over the years (about 20 % of hospital admissions in 1980s, increasing steadily to 30 % of admissions during the past decade), as well as patients being admitted at a younger age than before. Another age trend has been an increase in admissions of patients over 55 years of age, possibly reflecting changes in drinking habits within this age cohort (less binge drinking and more daily drinking over a period of years). The majority of patients are treated for alcohol dependence, but the proportion of these patients has given way to other substances over the years. In 2012, 41 % of patients had a primary diagnosis of only alcohol use disorder alone, while more than half of the patients were also diagnosed with other substance use disorders in addition to alcohol mainly cannabis (21 %) and amphetamine (13 %). Iceland has never had a problem with heroin; however, opioids are abused, with about 4 % of the patient population seeking treatment for opioid dependence. About 80 patients currently receive opioid maintenance therapy, mostly with buprenorphine but some with methadone.

There have also been changes in substances of abuse. The abuse of amphetamine has been a growing problem in Iceland while the use of cocaine has subsided mainly because of its' high price. Over the past decade, the number of patients seeking treatment for amphetamine dependence has almost tripled, and in 2012, 39 % of all of patients seeking treatment at SAA had a diagnosis of amphetamine dependence (SAA 2010). In addition to the marked increase in amphetamine addiction, amphetamines are also being used intravenously (IV), thus markedly increasing the risk for hepatitis and HIV. SAA is seeing most of the injectors as it is estimated that 90 % of IV users have sought treatment at SAA. The prevalence of hepatitis C was studied among IV amphetamine users that entered treatment at SAA between 1991 and 2006, and it was found that approximately 30 % were infected. Infections were related to the frequency of injection; 14 % of patients that injected amphetamines less than ten times in the previous year were infected, while among those who injected regularly, 60 % were infected. Outside this population of amphetamine injectors, hepatitis C

infections are rare in Iceland as is HIV, though the situation could change rapidly if injecting use continues and spreads. Currently the abuse of methylphenidate, mainly provided by medical subscription, has rapidly risen the past years, and Iceland is second only to the United States in the medical consumption per capita of methylphenidate from 2004 to 2009 (Kaye and Drake 2012). Other IV substances used in Iceland are also prescription drugs, mainly opioids.

The use of amphetamines by adolescents is another area of great concern as use in this age group has steadily grown over the past 15 years. For example, among those 19 years old and younger and seeking treatment at SAA, over 92 % have tried amphetamines and over 60 % reported using amphetamines weekly for six or more months (SAA 2010). Previously, regular users in this age group entering treatment at SAA were few (less than 30 per year before 1995) but the numbers recently doubled, and sometimes tripled, with admissions ranging between 100 and 150 regular teenaged users annually, mostly 18 or 19 years of age.

Looking at all diagnoses, primary and otherwise, the proportion with cannabis addiction has doubled over the past 20 years, and now about 35 % of the overall patient population in treatment meet diagnostic criteria for cannabis dependence. Among those younger than 25 years, cannabis is the main substance of abuse although multiple drug use is most common. Two-thirds (76 %) of young people 19 years old and younger meet criteria for cannabis dependence and 62 % meet criteria for amphetamine dependence (SAA 2010). Thus, international trends are reflected in the patient population.

76.2.2 Treatment Outcomes

Studies on treatment outcomes have been scant in Iceland. In an Icelandic study on the genetics of addiction (Tyrfingsson et al. 2010), survey data collected on abstinence rates of 920 patients previously seeking treatment at SAA showed that 59 % had been abstinent for the past year and 51 % had been abstinent the past 2 years. Twenty-seven percent reported having used alcohol or other drugs during the past month. This gives an indication of treatment success in regard to abstinence rates. These rates of remission of disease are quite good considering the chronic nature of the disease. This is an area in need of further research.

Another way of evaluating treatment outcomes is assessing dropout rates. At Vogur Hospital, the first point of entry of treatment at SAA, about 20 % of all admissions do not finish the recommended length of stay (average 10 days), but 70 % complete detoxification and are discharged with a plan for further treatment, which is regarded a successful completion of the stay.

76.3 Conclusion

In summary, addiction treatment at SAA provides a comprehensive treatment approach for a medical disease of the brain, a variety of options at different levels

of care. It offers medically assisted detoxification and a well-structured psychosocial treatment approach. The motivation and intent of the patient is reevaluated repeatedly and treatment planning negotiated according to changing patient's needs. It emphasizes a continuum of care akin to the treatment of other chronic diseases, where relapses are seen as a need for increased treatment. The access to treatment is exceptional, as no specific referral is needed and admission is free of charge. Treatment is tailored to meet the needs of specific groups, such as adolescents, women, older, relapse prone, opioid dependent, and pregnant women are admitted to services without delay. Close collaboration is maintained with specialty care, such as psychiatric, infectious disease, emergency room, and social services. Screening for blood-borne infections is thorough, other medical and mental disorders are treated as needed, and referral to special care is followed through. Twelve-step self-help groups are introduced and encouraged.

This treatment approach is based on the disease model of addiction, and SAA has emphasized disseminating this view of addiction in order to reduce stigma and decrease treatment barriers. This has been a key element in decreasing the treatment gap, along with other social system variables such as equality in access to health care and socialized medicine for all. Strict alcohol and drug policies have simultaneously been enforced thus supporting prevention efforts. The AA community in Iceland has been a strong force and is a key factor in supporting recovery in patients. In order to continue improving treatment of addiction, we must address issues of dropout and preserve long-term treatment options under pressures of delivering treatment in an outpatient setting only in the brief term. It is clear that staying in treatment is the most important aspect of any therapy, and at SAA the inpatient settings are conducive to adherence to treatment and are thus vital to ensure good treatment outcomes.

Main Elements of a Systems Approach to Addiction Treatment: An Introduction

77

Ambros Uchtenhagen and Giuseppe Carrà

Abstract

This section is dedicated to a range of issues which go beyond the clinical practice in providing specific treatment options to specific populations, in specific services by specialists or in primary health care. The focus here is on the treatment system in the community, at a regional or national level, as a comprehensive network integrating different approaches, services and actors, including harm reduction interventions. The various aspects of building up such a network and of improving an existing system are discussed, legal and ethical frameworks and rules are described, as well as the evidence base for good quality interventions and ways how to monitor and evaluate their outcomes.

The focus on the treatment system as a comprehensive network of all services, covering all types of addictive behaviors. implies the preference for a public health perspective, combining the care for the individual patients in their diversity with the intention to cover the treatment needs in a specific catchment area and for a given population.

This aim has to consider the availability, affordability, and accessibility of appropriate and qualified treatment. It has to build on effective treatment, provided in an efficient and cost-effective way. It has to stress connections among services, shared concepts of different indications, and routine rules for patient pathways through treatment phases, ranging from first contact, screening, and assessment to treatment planning and monitoring, rehabilitation, and aftercare. Pathways may

also follow models of stepped care in an attempt to avoid misplacement of patients and to make best use of the available human and financial resources.

A comprehensive network goes beyond formal therapeutic regimes, by including low-threshold approaches for establishing contact by outreach activities, by harm reduction interventions in support of those still actively engaging in addictive behavior. This includes measures to reduce the risks of injecting, of acquiring blood-borne infectious diseases, and of overdose-related mortality. Such interventions are not in contradiction to others offering a structured regime of substitution medication (e.g., for opiates or nicotine) or even aiming at abstinence from substance use and full recovery. The system has to integrate all these approaches in order to best meet the needs and preferences of the equally diverse people with substance use disorders. Everyone should be able to find what is appropriate and suits him or her best under present conditions.

Such a comprehensive network is work in progress, as addictive behaviors and treatment populations change over time. New therapeutic methods and instruments also ask for adaptation and suited implementation at the system level. Where no such network is in place, the relevant steps for building up a system responding to the needs are recommended. All this goes not without a political support to provide adequate and sustainable resources, in the framework of a treatment policy which is in line with an overall drug policy.

Major instruments for assessing process and efficacy of the treatment system are monitoring and evaluation. They allow the identification of weaknesses of the system, as a starting point for improvements. Monitoring and evaluation are crucial for adapting the system to new challenges. A certain flexibility and readiness for adaptations are pivotal for their implementation. Education and training of staff, including continued education, are instrumental not only for good quality and best practice but also for such implementation.

Quality of intervention is embedded in evidence base, also in the field of drug addiction treatment. It is crucial that all the stakeholders, including drugs users, their families, and the public, are involved in the selection of priorities to offer the best possible evidence-based treatment. Language to translate evidence thus needs to be understandable to empower stakeholders.

A solid basis of the treatment system must include the consideration of ethical and legal aspects. Human rights and medical ethics apply. National legislation and international conventions are to be respected or – if outdated or ineffective – revised. The prominence of designing treatment systems creates opportunities, challenges, and dangers for addiction scientific community. The future standing of the specialty will depend on not only the practical utility of its responses to those opportunities and challenges but also the ethical integrity of those responses.

Treatment Systems for Population Management of Substance Use Disorders: Requirements and Priorities from a Public Health Perspective

78

Thomas F. Babor

Contents

Abstract

This chapter describes the requirements and priorities of service systems designed to treat persons with substance use disorders. Research and theory are reviewed to inform policymakers, program administrators, and treatment providers about the best ways to organize or to expand treatment services using a public health systems perspective, which is concerned primarily with how services contribute to the health and welfare of a population. The requirements of a service system include sound policies (especially stable financing); appropriate structural features, such as facilities and trained personnel; and services that are accessible, affordable, and integrated. The priorities for establishing such a system will depend on the assessment of population needs, as well as needs-based planning and the support of mutual help organizations. It is concluded that a public health approach to the development of treatment systems provides a useful way of responding to the changing needs of the population in relation to substance use disorders.

78.1 Introduction

At a time when health-care delivery is changing rapidly throughout the world and new substance abuse treatment services are being developed and evaluated, it is critical that services for persons with alcohol and drug problems be delivered in the most effective as well as in the most efficient manner. The focus on treatment system issues represented in the title of this chapter is designed to direct attention at the growing body of research and theory that can be used to inform treatment planning and quality improvement at the community and national levels.

The development of an effective treatment system is a crucial part of a country's public health response to the problems associated with substance use disorders. Although a great amount of research has been conducted on treatment of substance use disorders, most of it deals with clinical issues, such as the efficacy of different psychotherapies or pharmacotherapies, rather than the larger treatment policy issues that often result from tradition, budget constraints, or political decisions. As described in a conceptual paper by Babor et al. (2008), what is now needed is a comparable effort to use systems-level research to inform policymakers and program administrators about the best ways to configure or to expand their treatment services in order to maximize the impact of treatment services at the population level.

This chapter deals with the requirements and priorities of the treatment system, which are approached from a public health perspective. The requirements of a service system include sound policies (especially stable financing); appropriate structural features, such as facilities and trained personnel; and services that are accessible, affordable, and integrated. The priorities of such a system include the accurate estimation of population needs through service mapping and needs assessment, as well as rational service planning that includes an emphasis on community support networks such as mutual help organizations.

78.2 Concepts, Requirements, Priorities

78.2.1 Definitions and Rationale

A treatment system for persons with substance use disorders is an arrangement of facilities, programs, and personnel that is designed to function in a coordinated way. Such an arrangement includes linkages between specialized care and other types of services, such as mental health, general medicine, social welfare, criminal justice, and mutual help organizations (Babor et al. 2008).

The focus on the arrangement and coordination of services, rather than just the personnel, programs, and therapeutic aspects of treatment, raises a new set of questions for clinicians, program administrators, and policymakers. Can systems concepts help to reduce the gap between population needs and the current availability of substance abuse services? How can treatment services be made more accessible to those in need? Are the needs of affected populations being met by the

current array of services? Are services being distributed and accessed appropriately? Are screening and referral conducted at gateway institutions, such as primary health care, schools, and employment settings? Are there appropriate diagnostic capabilities? What are the most effective administrative linkages between substance abuse services and criminal justice, mental health, general medicine, primary care, and other human services? Are they coordinated with other specialized services in a continuum of care? Are evidence-based services available and relevant? What is the policy support for integrated structures? What can be done to build stronger community support networks (e.g., AA, family social clubs)? To what extent can mental health and general medical services be better integrated with addiction treatment? Are there advantages to having separate systems for substance abuse, or should they be integrated administratively with services for other health conditions or social problems?

These questions define issues that can be addressed by a public health systems perspective, which is concerned primarily with how services contribute to the health and welfare of a population. Services for substance use disorders expanded dramatically in developed countries in the 1970s but often in a fragmented and arbitrary way. Resource allocation decisions and treatment policies have a major effect on the development of services for persons with substance use disorders, but there is little knowledge to guide service planning or to indicate whether services achieve their public health objectives. Low- and middle-income countries are now investing in services as substance use prevalence rates increase with rising incomes, but there is little systematic knowledge to guide the development of service systems that would best address the needs of their populations.

78.2.2 History and Conceptual Developments

Conceptual, theoretical, and empirical work on treatment systems is a recent development, but substance abuse treatment has a long history that can be traced back at least 200 years in some countries (White 1998; Souria 1990). A rudimentary set of treatment services, mostly specialized residential programs, emerged from the nineteenth century asylum movement originally designed for mental patients but which also served large numbers of alcoholics (White 1998). Since the 1960s in the industrialized countries, there has been a steady growth of specialized medical, psychiatric, and social services for individuals with substance use disorders (Makela et al. 1981). Although each country developed a different mix of services and administrative structures, there were some commonalities across national systems in the types of service settings (residential, detoxification, and outpatient) and therapeutic approaches (Klingemann and Hunt 1998). As treatment services became more numerous and specialized, new concepts were developed to describe how they related to the different types of population needs. These concepts include the continuum of care, broadening the base of treatment, the chronic care model, and service system levels.

The *continuum of care* concept, as described by Rush et al. (2013), refers to the mix of services available to patients and the way patients are expected to pass through it. The services are generally arranged sequentially beginning with screening and diagnostic assessment and then assignment to different settings and services depending on acuity, severity, and complexity. The main services that have been incorporated into the systems framework in most countries are withdrawal management and detoxification, residential rehabilitation, outpatient counseling, continuing care, and community support networks such as Alcoholics Anonymous. Variations of the continuum of care concept are the core-shell model and the stepped-care approach. In the core-shell model, core functions, such as intake assessment and treatment assignment to the most appropriate type of care (the shell), are facilitated by case management (Glaser et al. 1978). In the stepped-care approach, patients are assigned to the least intensive level of care initially. If outcomes are not optimal, they can be "stepped up" to a more intensive level, and if outcomes are positive, they can be "stepped down" to appropriate continuing services.

Another innovation that has contributed to the systems concept is SBIRT, which refers to screening, brief intervention, and referral to treatment, typically in the context of early intervention in primary health-care settings (Babor et al. 2007). The SBIRT model grew out of a seminal report issued by the US Institute of Medicine (1990), called *Broadening the Base of Treatment for Alcohol Problems*. SBIRT is a comprehensive and integrated approach to the delivery of early intervention and treatment services through universal screening for persons with substance use disorders and those at risk. Beginning in the 1980s, concerted efforts were made by the World Health Organization (WHO) to provide an evidence base for alcohol screening and brief intervention in primary health-care settings, in order to *broaden the base of treatment* in countries where specialized services were unavailable. With the development of reliable and accurate screening tests for alcohol, more than a hundred clinical trials were conducted to evaluate the efficacy and cost-effectiveness of alcohol screening and brief intervention in primary care, emergency departments, and trauma centers (Babor et al. 2007).

Just as SBIRT attempts to integrate specialized substance abuse treatment services with outreach to the general health-care system, the *chronic care model* addresses the needs of more serious cases of substance dependence by coordinating specialized services over time under the assumption that once substance dependence has developed, there is a need for continuing care and management, as is done with chronic conditions like diabetes and hypertension. The chronic care model has been adapted to substance abuse by Rush (2010, 2013) who has defined a series of "tiers" that constitute the most important elements of a continuum of services for the management of chronic substance users. Five tiers are defined on the basis of their functions, which are higher-order groupings of similar services or interventions.

Tier 1 refers to health promotion and prevention functions targeted at the general population. This tier recognizes the likelihood that public policies, the regulatory environment, and lifestyle factors contribute to the risk of substance abuse and the

need for treatment. Tier 2 consists of early intervention and self-management functions directed at persons at risk. This incorporates the SBIRT activities that have provided an important link to other health-care settings. Tier 3 consists of treatment planning, crisis management, and support functions for persons with identified substance-related problems. Tier 4 includes specialized care for people in need of more intensive services, such as residential programs, outpatient counseling, and pharmacotherapy. Finally, Tier 5 comprises highly specialized care functions for individuals with complex problems, such as inpatient withdrawal management, forensic services, or long-term psychiatric care. The tiered framework is designed to be used as a planning tool for the development of an integrated system of service functions for substance abuse, mental disorders, and gambling problems.

Despite the growth of treatment services and systems of care in many countries, the services in most parts of the world are fragmentary and lack coordination. Four development levels have been proposed to account for the range of systems that have evolved in different countries (Babor and Poznyak 2010). Level I refers to services that are "minimal" in relation to population needs. If they exist at all, services tend to be fragmentary, with rudimentary care available in some settings (e.g., emergency departments or psychiatric wards) and perhaps specialized services in medical and psychiatric settings where a residential unit might provide training and care for a limited number of patients. Level II is described as "limited" in terms of systems development, with some specialized services in medical and psychiatric settings. Level III refers to a "modest" level of development where a variety of services are delivered in most settings and there is some regional coordination and planning. Level IV refers to "mature" systems, with a variety of integrated services in a range of settings and stable financing for these services. The specification of these levels is useful for suggesting ways in which a system at a particular level of development can be improved and for monitoring changes in systems development over time.

78.2.3 Requirements of an Optimal Treatment System

Babor et al. (2008, 2010) have described the components and dynamics of an optimal treatment system from a public health perspective. These are what have been referred to as the basic "building blocks" of a service system (Huntington et al. 2012). As described in Fig. 78.1, the first requirement is a set of policies that make the governance of the service system and its constituent parts possible. The second component is the system's structural resources, including infrastructure, technologies, personnel, programs, and facilities. The third component consists of system qualities, such as accessibility, economy, and efficiency, which contribute to the smooth functioning of the service system. According to this model, the policies, resources, and qualities of the system should not only translate into the effectiveness of services on individuals exposed to them, it should also contribute to population health through reductions in death, disease, and disability.

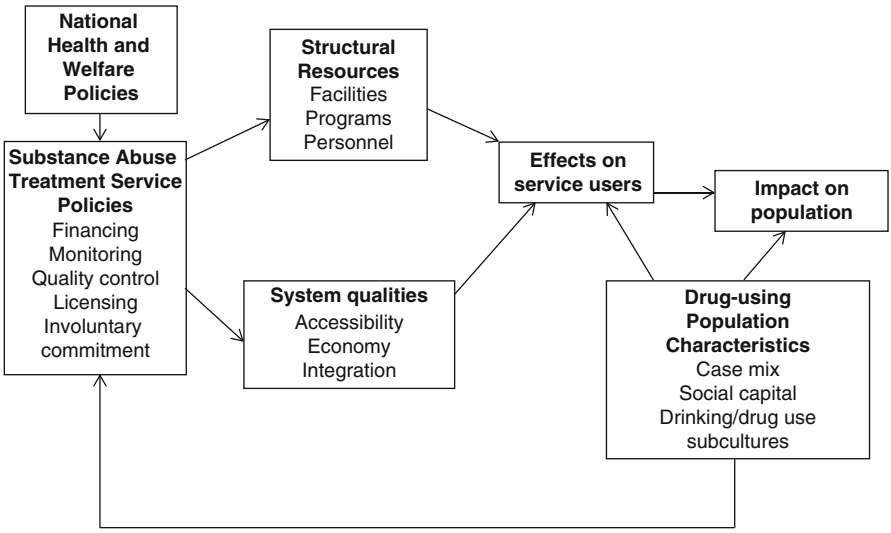

Fig. 78.1 Conceptual model of service system policies, resources, and qualities and their potential impact on population health (SOURCE: Adapted from Babor et al. (2008))

The components of this model and the research supporting it are discussed in the remainder of this section in order to indicate how a systems model might best contribute to population health.

78.2.3.1 Policies

The first requirement of an effective treatment system is appropriate treatment policies that provide a statutory basis for designing treatment programs, licensing treatment providers, and providing funding for programs and personnel. Policies determine the size, the administrative location, and the organization of the treatment system. They provide a framework for the allocation of resources.

According to Room (2010), there is a great deal of legislation for the treatment and rehabilitation of persons with substance use disorders, but much of the legislation is concerned with provisions for compulsory treatment or for treatment in lieu of jail. Other kinds of policy include national standards for clinical practices and licensing requirements for treatment personnel.

According to a survey conducted by the World Health Organization (2010), 66.2 % of the 145 countries surveyed have a government unit or government official responsible for treatment services for substance use disorders, but fewer than half of these countries have a specific budget line for these services. Financing mechanisms vary but most countries use tax revenues, user fees, and private insurance to pay for alcohol and drug services.

Resource allocation decisions have had a major effect on the development of these services. For example, the number and variety of services increased dramatically in the United States when the US Public Health Service invested in treatment

services as part of a broader public health approach to reduce the burden of disease, disability, and social problems that accompany substance use (White 1998). The rapid development of federally supported residential and outpatient treatment programs, along with an expansion of insurance coverage for private programs, established the feasibility of serving large numbers of alcohol- and drug-dependent patients within a specialized set of services.

Treatment policies and financing mechanisms affect the degree of centralized management of treatment services and their incorporation into other human service areas, such as social welfare, mental health, general medicine, and criminal justice. In Denmark, policies were used to decentralize treatment services, whereas in Norway, they moved the system toward a more centralized, medically oriented structure (Stenius et al. 2010). In Canada and the Netherlands, mental health and substance abuse treatment systems have been integrated (Rush 2010). In Finland, services are being reformed by merging mental health and addiction outpatient services and by emphasizing the management of patients in primary care (Kuussaari and Partanen 2010). Although policy changes designed to reform the organization of treatment services may have sound assumptions and a good rationale, they are rarely accompanied by systematic evaluation research to inform future decisions.

78.2.3.2 Structural Resources

The next requirement of an effective treatment system is to have sufficient resources to meet population needs and demands for treatment services. The core structural elements are facilities, personnel, and programs. Alcohol and drug services in "mature" treatment systems form a continuum ranging from primary prevention activities designed to ensure that a disorder or problem will not occur, through secondary prevention activities (including early identification and management of substance use disorders), to tertiary prevention activities that aim to stop or retard the progress of a disorder. In many countries, these services have generally developed separately and are rarely integrated into a single service delivery system.

Figure 78.2 summarizes data from the WHO *ATLAS on Substance Abuse* (2010) describing the most common settings in countries for the treatment of alcohol and drug disorders. In the plurality of the responding countries (39.8 %), mental health services are the most common treatment setting for alcohol use disorders, whereas the main setting for the treatment of drug use disorders (51.5 %) is specialized treatment services. Approximately 10 % of the countries reported primary health care to be the most commonly used setting for treating alcohol and drug use disorders.

Another structural resource is the capacity of the system in terms of the number of beds and length of stay. The median number of beds for alcohol and drug use disorders globally was 1.7 per 100,000 population (range 0–52) (WHO 2010). The lowest number of beds was reported in the African regions, whereas the highest number was reported from countries in the European Region (10.3 beds per 100,000 population). Median length of stay for drug and alcohol detoxification was found to be 14.0 and 10.3 days, respectively, with low-income countries reporting a longer median length of stay than high-income countries.

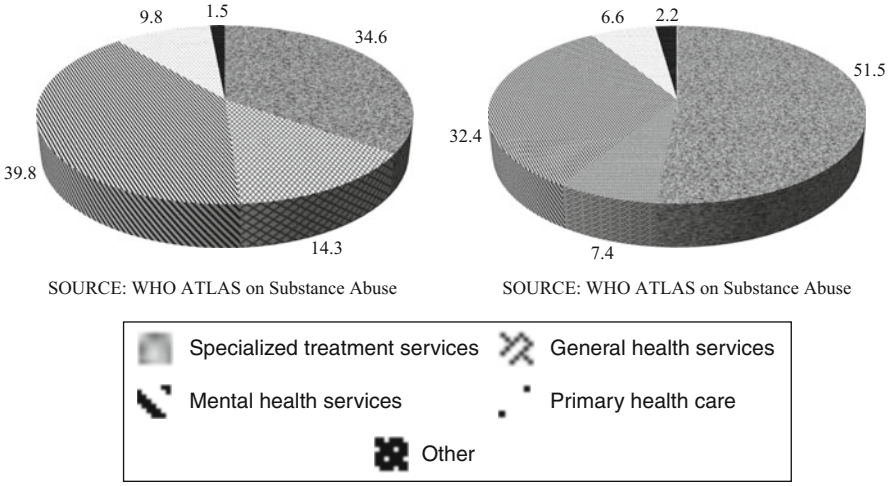

Fig. 78.2 Most common settings for treatment of alcohol and drug disorders in WHO member states

Finally, treatment personnel have become a central feature of a country's treatment infrastructure. Among the various health professions involved in treating substance use disorders, the majority of countries reporting in the WHO ATLAS include psychiatrists, general practitioners, and addictionologists/narcologists as the most important (WHO 2010). In addition to these professional addiction specialist groups, nonprofessional organizations have increasingly emerged as a critical part of the workforce in the formation of self-help organizations. Former alcoholics and drug addicts play an important role in providing community support services in many countries (WHO 2010).

78.2.3.3 System Qualities

Over time, the collection of services used to manage persons with substance use disorders takes on the characteristics of a system, with differences emerging not only in terms of policies and structural resources but also in terms of system qualities that characterize the functioning of a system. According to the model in Fig. 78.1, these qualities can be described in terms of equity, efficiency, and integration.

Equity refers to the extent to which services are equally available and accessible to all population groups. In South Africa, a study found inequitable access to substance abuse treatment services among the poor, with non-need factors, such as gender, mainly determining utilization (Myers et al. 2011). Access to treatment may be as important as the type of treatment. Findings from large-scale treatment matching studies indicate that the decision to enter treatment is associated with considerable reductions in drinking, but once someone is admitted to a particular program or is exposed to a particular type of psychotherapy, they do equally well regardless of their personal characteristics or severity of dependence

(Babor and Del Boca 2003). Thus, the value of different types of treatment may be to convince clients that treatment is going to help them. Research (Cooney et al. 2003) suggests that the key ingredient of the success of any therapy may be its ability to attract clients and generate enthusiasm among therapists. Instead of distinct nonoverlapping elements, therapy may work through common mechanisms, such as empathy, an effective therapist-client alliance, a desire to change, inner resources, a supportive social network, and the provision of a culturally appropriate solution to a socially defined problem. Thus, the more that treatment services are made available to all population segments, the greater the system's effectiveness is likely to be, regardless of the specific type of services.

Some therapeutic interventions are more cost-effective than others, suggesting that resources could be allocated more efficiently and economically without compromising effectiveness. One way to improve the efficiency of treatment is to organize treatment teams or sites to work together for a 12- to 24-month period with the aim of improving a specific area of care. This "improvement collaborative" approach combines traditional quality improvement methods of teamwork, process analysis, adoption of standards, training, and coaching. In a study by Gustafson and colleagues (2013), the use of collaborative methods, especially coaching, was found to decrease waiting time, improve treatment retention, and increase recruitment of new patients. Humphreys and McLellan (2011) found that process improvements can change the efficiency of treatment programs, but the link to better outcomes is weak, in part because outcomes are mainly influenced by environmental factors and life events outside of formal treatment.

System integration means the amount of interconnectedness among the organizations in a network. Research suggests several ways to improve system integration: drug courts, SBIRT, integrated treatment programs for pregnant drug users, managed care, and case management. There is some evidence to suggest that drug courts can increase social controls, lengthen the duration of treatment, reduce criminal behavior, and lower rates of recidivism (Eibner et al. 2006).

The elements of SBIRT have been evaluated in clinical trials and found to be effective (Babor et al. 2007) to such an extent that demonstration programs have been conducted in large population areas of several countries, including Finland (Seppä and Kuokkanen 2008), Norway (Aasland and Johannesen 2008), Denmark (Barfod 2008), South Africa (Seale and Monteiro 2008), Brazil (Souza-Formigoni et al. 2008), and the United States (Madras et al. 2009). Despite some successes in primary health care (Souza-Formigoni et al. 2008), the results of programs relying on the training of physicians and other health personnel without adequate logistical support have not been encouraging.

In the United States, a large-scale demonstration of programs operating in 27 states since 2005 has been found (McRee et al. in press) to enhance the states' continuum of care to include universal, adult SBIRT services in primary care and other community settings (e.g., health centers, nursing homes, university health centers, hospitals, emergency departments, and military). In an evaluation of SBIRT's system effects, McRee et al. (in press) found that the program filled

gaps in services for substance users in both the medical and specialty treatment systems of care. It was also associated with improved system equity (i.e., equal access to all population groups) and efficiency by extending services to underserved populations, expanding services within facilities and across tasks, and improving system linkages.

Another way to improve the integration of treatment is through integrated treatment programs. Examples include treatment of pregnant women who have substance use disorders and the delivery of mental health services to patients with co-occurring mental disorders. Integrated women's programs providing pregnancy and parenting services have been associated with improvements in child development (Niccols et al. 2012). But the results of integrating care for clients with co-occurring mental health and substance use disorders have been equivocal (Donald et al. 2005).

78.2.3.4 Effectiveness and Population Impact

When the requirements for an optimal treatment system are approached, treatment services are available, affordable, and accessible. Under these conditions, the system should not only deliver effective services, it should also have a population impact.

Effectiveness means the extent to which one or more services are responsible for positive changes in substance use and substance-related problems. Effective services should promote abstinence (or at least reduce substance use), prevent relapse, and address such substance-related problems as unemployment and marital adjustment. As suggested in Fig. 78.1, the impact of these services should translate into population health benefits, such as reduced mortality and alcohol-related disease rates, as well as benefits to social welfare, such as reduced unemployment, disability, crime, suicide, and health-care costs.

Can the integrative effects of prevention, early intervention, and treatment systems reduce population rates of alcohol and drug problems? This issue has not been investigated extensively, but there is suggestive evidence for such an effect. For example, growth in the availability of opioid maintenance treatment is associated with reductions in illicit opiate use, crime, and HIV risk behaviors in the United Kingdom, France, Norway, and the United States (Bukten et al. 2012; Marsch 1998). Increases in the proportion of alcoholics in treatment have been linked to decreases in liver cirrhosis morbidity (Mann et al. 1988; Holder and Parker 1992), and increases in AA membership and amount of treatment linked to decreased alcohol problems (Smart and Mann 2000).

Given the possibility that policies, resources, and system qualities, as core requirements, can be used to provide a more effective set of services and contribute to the system's public health impact, the next section of this chapter considers the main priorities for developing such a system.

78.2.4 Priorities

Substance use services have traditionally been established without the benefit of a comprehensive, quantitative planning process that is closely aligned with

population needs. Priorities for developing an optimal treatment service system will vary according to a country's current level of services, as well as the nature of their alcohol and drug problems. Among the highest priorities are service mapping, needs assessment, and service planning. Another priority that is often neglected despite its recognized effectiveness is the establishment and support of mutual help organizations that provide a critical community resource for the maintenance of recovery.

78.2.4.1 Service Mapping

Treatment service mapping involves the description of system structures and qualities. Treatment mapping research has been conducted in Hungary, Poland, the Russian Federation, France, Switzerland, Germany, the United Kingdom of Great Britain and Northern Ireland, the United States of America, Finland, Sweden, and a variety of other countries (Klingemann et al. 1992, 1993; Klingemann and Hunt 1998). Data collection tools have been developed for treatment mapping purposes, but most of these instruments do not examine the broad treatment system issues described in this chapter.

To promote the orderly planning and dissemination of evidence-based addiction treatment within national health-care systems, the WHO has designed a new procedure for assessing, monitoring, and evaluating treatment systems for substance use disorders, in relation to population needs (Babor and Poznyak 2010). The WHO Substance Abuse Instrument for Mapping Services (WHO-SAIMS) was developed to provide information on prevention and treatment services that can be used for policy planning, service design, and service improvement. In its present form, the WHO-SAIMS has a primarily descriptive function that identifies gaps in service delivery and areas for system improvement.

The primary purpose of the WHO-SAIMS is to examine the structure and functioning of alcohol and drug service systems in terms of resources, facilities, personnel, and programs. It can also be used at the national and subnational levels for monitoring and process evaluation to identify changes in the system over time and to assess the extent to which system improvement strategies have been implemented. In assessing how well the system functions, indicators include equity, efficiency, and accessibility, as well as system malfunctions such as waiting times for services, underutilization of services, and gatekeepers to access. The instrument asks detailed questions about the provision of alcohol and drug services in multiple settings, including specialist inpatient facilities, outpatient settings, and community programs. It also inquires about the professional sector's linkages with mutual help organizations and other lay service providers. It examines interactions between different levels of care, such as patient movements from less intensive to more intensive levels of care.

The WHO-SAIMS consists of a core instrument appropriate for use in all countries, irrespective of development level. The scope and configuration of the instrument are described in Table 78.1. The SAIMS also has supplementary modules that can be used for estimating the potential demand for treatment and

Table 78.1 Scope and configuration of the World Health Organization's Substance Abuse Instrument for Mapping Services (WHO-SAIMS)

Policy and legislative domain: includes items about national alcohol and drug policies; legislation governing drug control, prevention, and treatment; strategic plans that address substance use disorders, workforce development for substance abuse professionals, and resource allocation to and the financing of alcohol and drug services
The substance abuse situation and current alcohol and drug service needs: this section is designed to (i) help identify whether current services match needs and (ii) estimate service coverage
Current alcohol and drug treatment system. This domain describes the type and mix of services provided, service integration, and system complexity
The alcohol and drug services domain. This section covers (1) other residential services for alcohol and drug problems such as halfway houses and sober living environments; (2) alcohol and drug services provided by other sectors such as mental health facilities, primary health-care services, and the criminal justice sector; (3) the linkages between these services; (4) the availability of psychosocial treatments and psychotropic medications; and (5) drug substitution therapies and harm reduction services for opioid users
The primary care domain. Items in this category refer to interventions used in primary care settings
The human resource domain. This describes the quantity of human resources as well as human resource development, including mutual help organizations and recovering communities such as AA and NA

treatment needs. (The WHO-SAIMS instrument and accompanying modules are currently being published for public use and will be made available on the WHO website.)

78.2.4.2 Estimating Treatment Needs and Demand for Treatment

Demand for treatment refers to the number of people who want to access treatment, including those who receive treatment (met demand) and those who want treatment but cannot access it (unmet demand). Unmet demand may exist because services do not exist, are not available, are too expensive, or are inaccessible.

Need for treatment refers to the number of people in a geographic region who meet the criteria for dependence or harmful use and who would benefit from treatment but do not access it. Some of these people want treatment but cannot access it (for the above reasons), while others do not want treatment nor do they seek it. The numbers of "unmet need" are likely to be greater than the numbers of "demand for treatment" as "unmet need" includes those people who do not perceive the need for or do not desire any treatment.

There are several methods to identify unmet treatment need, some involving primary data collection and others relying on secondary analysis of existing data sources. Although there are no international standards for assessing unmet need, the SAIMS approach permits incremental planning that directs resources at the most important and manageable treatment needs in a population. The simplest procedure is to use population surveys to estimate the number of people in need of treatment (see Ritter et al. 2003; Ungemack et al. 2001). If the rates of dependence and

harmful use are used, these can translate into the potential demand for specialized services (residential and outpatient) as well as early intervention services in other health-care settings. These services can be directed at patients with dependence and harmful use, respectively. Population survey data can be supplemented by obtaining prevalence estimates from settings where substance users are likely to be encountered, such as prisons, emergency departments, HIV clinics, etc. The need for substance abuse services among the general population can also be estimated through the use of health and social indicators, such as substance-related mortality, morbidity, social problem statistics, and expert opinion on treatment needs.

Regarding the latter, the SAIMS includes a qualitative module that provides a way to rapidly collect descriptive information that should be useful to supplement the quantitative data collected in the core instrument or to provide a minimum of information to begin the planning process. The qualitative module requires key informants to collect the information.

78.2.4.3 Needs-Based Planning

For service systems at a modest (Level III) or mature (Level IV) stage of development, it may be more fruitful to conduct "needs-based planning." This approach requires the development of a "model" of the service system and uses population prevalence data to estimate the types of treatment services to be received by subgroups in the population. As such, it is more advanced than the SAIMS methods because it takes into account different types of treatment and respective "need" by treatment type. Two examples of innovative planning methods come from Canada and Australia.

In the Australian project (Ritter et al. 2013), a procedure was developed to provide health planners with estimates of the gap between current service provision and best practice service provision. This planning tool takes into account the epidemiology and severity of substance use disorders, as well as treatment seeking and best practice care pathways.

Epidemiological data are used to derive prevalences of five substance use disorders, and probable cases are apportioned to categories of severity. Expert opinion and a literature review of best practices were used to determine care pathways by drug type and age group for Australia. The model specifies care by drug type, by severity of presentation, and by age ranges. The resulting model is capable of predicting resource use in an optimal alcohol and other drug treatment service system.

In the Canadian project (Rush et al. 2013), the need for treatment is based on five categories of problem severity derived from national survey data and levels of probable help seeking that are projected from a narrative synthesis of international literature. A pan-Canadian Delphi procedure was employed to allocate this probable help-seeking population across an agreed upon set of treatment service categories, which includes three levels each of withdrawal management, community, and residential services. The planning model also includes consideration of screening, brief intervention, and referral to treatment from generic services and placeholders in the model for innovations with respect to interventions based on the Internet and

mobile technology. The resulting capacity projection for each heath planning area in the country can be contrasted with current treatment capacity to yield an estimate of the treatment gap.

78.2.4.4 Mutual Help Organizations

Alcoholics Anonymous and other mutual help organizations represent a critical resource both in countries with mature systems and in those with limited resources. Not only do these approaches provide continued support in the community, they do so at minimal cost. A variety of mutual help models have been developed throughout the world (Humphreys 2004), many of them seemingly capable of managing some of the most difficult cases of drug and alcohol dependence. With an estimated 2.2 million members affiliated with more than 100,000 groups in 150 countries, AA is by far the most widely utilized source of help for drinking problems in the world (Humphreys 2004). Related organizations have been developed in a number of other countries, such as Danshukai in Japan, Kreuzbund in Germany, Croix d'Or and Vie Libre in France, Abstainers Clubs in Poland, Family Clubs in Italy, Links in the Scandinavian countries, Pui Hong self-help organizations in Hong Kong, Oxford House in North America and Australia, and Narcotics Anonymous worldwide (Babor et al. 2010; Humphreys 2004; White 1998).

Although it is regarded as one of the most useful resources for recovering alcoholics, the research literature supporting the efficacy of AA is limited (McCrady and Miller 1993). Attendance at AA tends to be correlated with long-term abstinence (Timko et al. 2000; Humphreys 2004), but this may reflect motivation for recovery. Several large-scale, well-designed studies (Ouimette et al. 1999; Walsh et al. 1991) suggest that AA can have an incremental effect when combined with formal treatment, and AA attendance alone may be better than no intervention. When AA is combined with a 12-week individual therapy called Twelve-Step Facilitation (TSF), one study (Babor and Del Boca 2003) found that TSF not only increased affiliation with AA, it also had a demonstrable effect on clients whose social networks contained many drinking companions. This study suggested that AA is effective because it helps to change the drinker's social environment rather than through some form of spiritual conversion.

78.3 Conclusion

Treatment systems for substance use disorders are a significant part of national responses to the burden of disease and disability resulting from substance abuse. In well-resourced countries, a relatively integrated system of services has been developed in response to population needs. In less-resourced countries, treatment services are often inadequate and fragmentary. Regardless of development level, appropriate population health-care management requires the allocation of resources to preventive, curative, restorative, and rehabilitative services, using the most effective and efficient evidence-based practices. By organizing service providers

into networks, it should be possible to shift utilization to lower cost settings or the most appropriate level of care.

A system-wide holistic approach to the planning and coordination of services for substance use disorders is more than the mere sum of gains attributable to discrete interventions and technologies, such as new screening tools, better diagnostic instruments, improved intervention techniques, and more numerous services. The systems approach goes beyond capacity building and technical innovation. It is designed to coordinate services so that they are capable of responding to the changing needs of the population.

An Integrated Approach to the Treatment of Drug Dependence: The English Experience

79

Alex Stevens

Contents

Abstract

This chapter focuses on the English experience of developing integrated drug treatment services. It discusses the principles that underlie an integrated approach to the treatment of drug dependence, presents possible methods for integration, and argues that there is no inherent conflict between providing services that both keep people alive through harm reduction and help them to overcome dependence. Treatment services can maximize the benefits that they offer by providing a coordinated continuum of care that ranges from low-threshold harm reduction services to higher-threshold services that give service users the help they may need to make lasting changes to their patterns of dependence and to achieve abstinence. Evidence-based principles that may help people move along this continuum are presented.

79.1 Introduction

79.1.1 The Need for Integration

At the birth of the current international regime for the control and regulation of illicit drugs, in Article 38 of the 1961 *Single Convention on Narcotic Drugs*, states committed themselves to the creation of a system for the "identification, treatment, education, aftercare, rehabilitation and social reintegration" of drug users. More than 50 years later, we have much more knowledge about what the elements of such a system should be. But debate continues on the best way to coordinate such services. Specifically, it is often suggested that there is an inherent conflict between providing low-threshold, harm reduction services and high-threshold, abstinence-based treatment. This debate has been long running in the UK, but pragmatic solutions have been found to integrate services. These solutions are varied across the countries of the UK. This chapter will focus on the English experience.

It will discuss the principles that underlie an integrated approach to the treatment of drug dependence, will present possible methods for integration, and will argue that there is no inherent conflict between providing services that both keep people alive and help them to overcome dependence. This discussion has two starting points. One, which is often debated, is the evidence that is available to inform the development of treatment systems. The other, which is more rarely discussed in the academic literature, is the normative basis for decisions on treatment provision. Both will be discussed here. This chapter draws on earlier work completed for the Beckley Foundation (Stevens et al. 2006) and more recent research.

79.2 The Integrated Approach

79.2.1 Evidence-Based Services for Dependent Drug Users

The evidence in this area has been repeatedly distilled by distinguished agencies and researchers, including the World Health Organization (WHO), the US National Institute on Drug Abuse (NIDA), the UK National Institute for Health and Clinical Excellence (NICE), the European Monitoring Centre for Drugs and Drug Addiction (EMCDDA), and the United Nations Office on Drugs and Crime (UNODC). A useful summary of this evidence base has been provided by Babor et al. (2010). The interventions that they list as being supported by the evidence can be split into two categories, depending on how much commitment to change they require from the drug user. Effective low-threshold services, which tolerate continued drug use, include opiate substitution treatment (with substitution by methadone, buprenorphine, or heroin), needle exchange programs, naloxone distribution for the prevention of fatalities in overdose, and brief interventions in medical settings. Higher-threshold services, which require more commitment to change, include various forms of psychosocial treatment (including outpatient and residential services) and involvement in peer self-help organizations, which often demand

a commitment to abstinence. It is noteworthy that this list does not include detoxification. This is because detoxification, on its own, is not sufficient to support behavior change. Indeed, a significantly increased risk of death has been observed in the period immediately after discharge from detoxification.

This observation, with many others, has informed NIDA's (2012) principles of drug addiction treatment. These also support a range of programs, including abstinence-based and medically assisted treatments, and insist that treatment should be readily available and accessible. A meta-analysis of US studies which relate to these principles (Pearson et al. 2012) supports the majority of them but finds that two NIDA principles which tend to restrict treatment variety (i.e., that treatment outcome is related to length of time in treatment and that treatment should be supported with regular drug testing) are not supported in the meta-analysis. This, again, is consistent with the view that a wide range of treatment modalities can be effective for different people at different stages of their engagement in drug use.

Another form of treatment is missing from the many lists that are available of effective drug treatment. It is compulsory treatment. While NIDA and others suggest that some forms of coercion are not incompatible with effective treatment, this relates to situations where drug users have a constrained choice to enter treatment or to face some other sanction for drug-related crimes. In contrast, programs which compel drug users to enter treatment with no possible alternative – a form of treatment which is prevalent in China and countries of Southeast Asia – have very poor records of effectiveness (in addition to the abuse of human rights and medical ethics which they entail).

79.2.2 The Normative Basis for Service Integration

As Babor et al. (2010) note, judgments on effectiveness of drug treatment depend crucially on the intended outcomes of that treatment. If the aim is to reduce the transmission of HIV and other blood-borne viruses (BBVs), then harm reduction services like needle exchange and opiate substitution treatment may be considered to be most effective. But if the aim is to reduce the prevalence of drug dependence, then treatments which promote abstinence may be judged to have better outcomes. But does providing services to people while they continue to use drugs necessarily conflict with the aim of supporting people to move away from drug dependence? Both the codified standards of human rights and philosophical principles of rationalist ethics (Stevens 2011) would suggest that it is coherent – and even rationally and legally necessary – to provide both harm reduction and abstinence-based services. Pharmacological and other harm reduction services can be provided in ways that support the autonomy of drug users when it has been impaired by addiction. This can be the beginning of a process of recovery and reintegration, not a competitor to it. The right to life is paramount. Services that keep people alive while they are not ready to move away from drug use can also provide a gateway to treatments that can help them define and succeed in their own recovery.

79.2.3 Overcoming the Challenge of Integration

Beyond debates around the evidence base and ethics for integrating services, there are also practical and logistic challenges. These include financial, systemic, and political barriers. Financially, it is likely that different services will be competitors with each other for a slice of the limited budget that is available for the treatment of drug dependence. Money spent on one service is not available to be spent on another. Systemically, it may be very difficult to coordinate services that are managed by different organizations. There may be gaps between services that are run by ministries of health and the criminal justice agencies (e.g., police and prisons) which have most contact with people who are affected by drug dependence. There may be fragmentation and gaps in communication between providers of different services, even when the same individuals are accessing those services simultaneously. Politically, it may be very difficult to generate the support necessary to provide high-quality, integrated services to a group of people who are often marginalized and stigmatized.

Treatment agencies in the UK and elsewhere have increasingly responded to this challenge by pointing to the excellent financial return that drug treatment provides to public investment. Estimates of this vary, and are based on less-than-perfect methodologies, but consistently suggest that treatment provides benefits to society that are of greater monetary value than its costs (e.g., Doran 2008). This enables supporters of treatment provision to argue that investment should be increased, at least until the point where the marginal cost of increasing treatment exceeds the marginal benefit to be gained from it. But there are problems with this approach, besides the need to test these estimates with improved methodologies. One is that the benefits of drug treatment do not always return to the agency that pays for it. For example, much of the benefit of drug treatment is estimated to come in the form of reductions in criminal victimization. The National Treatment Agency for Substance Misuse (NTA, the agency that coordinated drug treatment in England from 2001 to 2013) estimated that £1 million invested annually in drug treatment prevents 9,860 drug-related crimes, with an associated benefit of £1.8 million (NTA 2012). But half of these benefits accrue to potential victims of crime rather than to the state system that pays for the treatment. On the other hand, reduced crime is not the only benefit to arise from drug treatment. An as yet unpublished report by Public Health England (PHE, which took over responsibility for drug treatment from the NTA in 2013) has estimated that the cost of drug treatment per quality-adjusted life year is well above the threshold that is usually used to judge whether investment in a health intervention is worthwhile. However, politicians, despite the desires of many policy analysts, do not make decisions solely on the basis of cost-benefit studies. They have electorates and other parties to satisfy, as well as their own normative preferences to express. Investing money and political capital in the issue of drug dependence may not meet these needs. Perhaps a more politically palatable argument in financially straightened times is that service integration offers ways to save money within the budget that is currently devoted to drug treatment. By reducing duplication of effort,

drug-related deaths, BBV transmission and relapse, integrated services can save money as well as lives.

During years of economic growth, England saw a huge expansion in drug treatment provision between 1998 and 2008. This was delivered through partnership boards, known as Drug Action Teams. These included a range of agencies, such as local authorities (especially housing, youth and social service departments), police, education, and health services. The aim was to develop a more coordinated approach to drug treatment provision. Initially, Drug Action Teams focused on increasing the capacity of methadone maintenance services. But attention has more recently turned to assisting people to leave treatment with their dependency behind them. The current UK drug strategy, published in 2010, recognizes the importance of opiate substitution treatment (including heroin-assisted treatment) but also acknowledges the importance of psychosocial therapy, as well as support for stable housing and employment, in order to help people achieve their aims to live free of dependence.

Another feature of the English system in recent years has been integration between health and criminal justice services for problematic drug users. The government has introduced a growing range of measures to encourage people who have committed crimes and who have problems with drugs to enter treatment. These have ranged from the arrest referral schemes of the 1990s, through the 1998 Drug Treatment and Testing Order (DTTO, a court order which required offenders to enter treatment on a quasi-compulsory basis; the alternative being the usual punishment for the crime), the replacement of the DTTO in 2005 by the Drug Rehabilitation Requirement (DRR), drug testing on arrest, required treatment assessments for those who test positive, and, more recently, alcohol treatment requirements. These have been coordinated through the Drug Interventions Programme (DIP), a centrally funded system of case management that funded workers to build links between criminal justice and treatment agencies. In prisons, the Integrated Drug Treatment Programme has led to a significant expansion of opiate substitution programs, with the aim of reducing the very high rates of death from overdose that have been observed among opiate users in the first few days and weeks after release (Farrell and Marsden 2008). The integration of services has been assisted by the National Health Service taking responsibility for health services in prison (away from the Prison Service itself) in 2003.

When Public Health England replaced the National Treatment Agency in 2013 as the organization responsible for the coordination and integration of drug treatment, the scope for partnership widened. Drug Action Teams have been subsumed into local Health and Wellbeing Boards. The budget for drug treatment has been given to local Directors of Public Health, who are expected to commission services for drug dependence alongside other public health priorities, including alcohol, smoking, violence, communicable diseases, sexual health, and child poverty. This offers the prospect of deeper integration between services but also threatens the budget for drug treatment, which is currently bigger than that for other public health services and may be shifted to these other issues.

England is also moving toward an untested model for the financing of integrated, outcome-focused services for problematic drug users. The idea of the "Payment by Results" approach is that the state will pay service providers for the outcomes that are achieved by the drug users with whom they work. The intention is to create incentives for service providers to deliver outcomes that are both valued by service users and cost-effective for the government. As Humphreys and McLellan (2011) have noted, this strategy is ambitious but untested. Other systems that have attempted to reward service providers principally on the basis of outcomes have been plagued by perverse incentives. One example is the practice of "cherry picking." This happens where the service provider chooses to focus efforts only on those clients who already have the best possibility of achieving outcomes which trigger payments. This creates profit for the service provider but no commensurate benefit to the state or to more problematic clients who may be "parked" and receive little support. Current pilots in England will give more information on the effectiveness of Payment by Results in drug treatment. However, the emerging indications from the application of similar models to services for both unemployed persons and people with criminal convictions are not encouraging.

There is an emerging literature on methods that may help people enter, stay in, and depart from treatment successfully. These include assertive outreach (borrowed from the field of mental health), contingency management (using financial and other incentives to reward retention and progress in treatment), and various forms of case management. However, none has so far proved that it offers a consistently effective approach across different places and target groups. We perhaps have a clearer idea of what does not work. We know that the public stigmatization of drug users does not support abstinence or treatment entry (Palamar et al. 2013; Radcliffe and Stevens 2008). We know that ending treatment prematurely increases risks of death (Hickman et al. 2011). We know that the absence of "recovery capital" (including stable relationships, housing, and employment) is associated with worse outcomes (Laudet and White 2008). Taken together, the evidence suggests that – despite some gaps that need to be filled by more research – we do already have knowledge that we can use to provide integrated services that are able to attract, retain and assist people who have problems with drugs.

79.3 Conclusion

The increasingly integrated English system – at least by the account of the agencies which coordinate it – has been successful in producing health and crime reduction benefits through increased investment in drug treatment; benefits that far outweigh the cost of this investment. There have been encouraging reductions in the estimate of people who have problems with opiates and/or crack cocaine (Hay et al. 2011). But the provision of treatment alone is not sufficient for all treatment entrants to achieve good outcomes. Social dislocation, unemployment, and a lack of stable housing present barriers to the achievement of independent, crime-free lives.

Treatment services can maximize the benefits that they offer by providing a coordinated continuum of care that ranges from low-threshold services – which help to keep people alive while they attain stability – to higher-threshold services that give them the help they may need to make lasting changes to their patterns of dependence. There are evidence-based principles that may help people move along this continuum. These include optimal, sufficient doses for those in medically assisted treatment, as well as the provision of "phased, layered" treatment that supports optimism that people can achieve abstinence (Recovery Orientated Drug Treatment Expert Group 2012). This British report also notes that it is normal for dependent drug users to go through several cycles of drug treatment before they achieve abstinence. Coordinated systems should therefore not disadvantage drug users who have previously "failed" in treatment but should instead offer supportive routes back into treatment. They should recognize that some drug users may not wish or be able to achieve abstinence from their drug of dependence and should provide medical assistance to all categories of drug user. A successful coordinated system is likely to be one that provides a range of points of entry to treatment, a range of options and modalities of treatment and clear pathways between treatment types (e.g., from criminal justice to community services, from detoxification to aftercare, from harm reduction to abstinence – and back again if necessary). Finally, they should provide support for integration into the kind of stable housing and employment which we all need to make good lives.

Addiction Assessment and Treatment Planning: Developing Countries

80

Nicolas Clark and Ambros Uchtenhagen

Contents

Abstract

Lower-income countries sometimes have difficulties assessing the nature and scope of addiction problems in their countries and in planning the treatment system accordingly. Adapting existing services to changing patterns of substance use disorders and related problems can also be a challenge. This chapter provides a public health approach to the development of a health-care response to drug problems, mainly based on the experience of the World Health Organization working with lower-income countries to assess and develop their drug treatment systems. Options for assessing the need for substance abuse treatment, the nature and extent of available resources, and the functioning of existing services are

presented, including an assessment of treatment effectiveness and interactions with the criminal justice system. A detailed example of how to proceed is the WHO project on Substance Abuse Instrument for Mapping Services (SAIMS). A range of useful tools for treatment planning and a checklist on standards of care in addiction treatment are presented in the appendix.

80.1 Introduction

The addiction medicine specialist is often called upon to advice on the development of treatment systems. While Chap. 81, "Screening and Assessment for People with Substance Use Disorders: A Focus on Developed Countries" in this section advises on the issues in higher-income countries, this chapter gives a guide to the development and organization of services in lower-income countries.

According to the WHO ATLAS survey (WHO 2011), lower-income countries typically have less medical staff, less services, less funding reserved for addiction care, and less care provided for special populations like adolescents or prison inmates. Some countries may find themselves with few addiction medical specialists, or in some cases none. Few staff will likely have training in structured psychological techniques.

Funding for health services may be from specific donors such as The Global Fund to Fight AIDS, Tuberculosis and Malaria (GFATM), or may require out-of-pocket contributions which put it beyond the reach of most of those who needs them.

The last 50 years have seen some dramatic changes in the patterns of substance use and related health and social problems, and in many countries, the health-care systems, which often predate these changes, struggle to respond. This is particularly the case in lower-income country settings. Growing wealth and development leads in many cases to a rapidly developing health-care system and brings with it the chance for significant rethinking and reorganization of the health-care system response to substance use and related problems such as HIV, TB, and hepatitis and social problems such as poverty, malnutrition, unemployment, homelessness, and crime.

This chapter is an outline of a public health approach to the development of a health-care response to substance use disorders and related health and social problems, with a particular focus on lower-income countries, based largely on the experience of the World Health Organization work in such countries.

80.2 Planning Steps

80.2.1 Step 1: Defining the Problem (Treatment Need)

It may be the case that there is no good data on the local epidemiology of substance use disorders and the corresponding demand for treatment. In this case a stepwise approach to understanding the problem is proposed. While data on substance use is an important consideration, it is the prevalence of substance use disorders, in particular substance dependence and associated physical and psychiatric disorders, which is the better guide to treatment need.

80.2.1.1 Basic Approach

- ***Check sales data.*** For substances which are legally traded, as is the case for alcohol in most countries, statistics or estimates on national per capita consumption are available either from national sources or from the WHO Global Health Observatory (WHO.int/gho). For illicit drugs it can be more difficult to determine the extent and patterns of substance use disorders.
- ***Ask your patients***. The most basic approach to determining the nature and extent of substance use problems in a country is to ask the patients of different health-care facilities. Addiction specialists practicing in the country can ask their patients not just what substances they are using but also about the availability of substances, the recent trends in the availability of substances, and with which substances the patient has seen other people developing problems with. Asking your patients if it is difficult to get into treatment, i.e., if there is a long waiting list and what proportion of the people they know with substance use problems have received treatment, can be a basic indication of the unmet demand for treatment. If you are a visiting consultant, it is usually possible to ask if you can have an informal conversation with a number of patients.
- ***Ask other people about their patients.*** The next step is to ask other health-care staff about their patients, in the facilities which tend to attract patients with substance use disorders. Ask psychiatric facilities what substances the mental health patients are using; on what substances are people presenting for overdose; with what patterns of substance use are people presenting to the emergency department; what substance use patterns are NGOs providing harm reduction services for drug users seeing; what proportion of HIV patients are injecting drugs, drinking heavily, or using other substances in combination with risky sexual practices; and what proportion of liver patients have hepatitis C, are heavy drinkers, and so on and so forth.

80.2.1.2 Intermediate Approach: Routine Data Collection and Fieldwork

- ***Ask people on the street***. This can be done most easily by engaging a "peer worker," someone who is or who has been in the same situation as the people on the street and with whom you can have a good working relationship.
- ***Analyze data collected from other health-care facilities***, such as drug treatment centers, psychiatric hospitals, emergency departments, and HIV treatment cohorts. Other parts of the health-care system may be collecting data that could be used to indicate what problems there may be due to drug use in the community, such as rates of HIV and hepatitis, the proportion of new infections of HIV and hepatitis that are related to injecting drug use, emergency department presentations due to alcohol, etc. If such data are not currently being collected, it may be possible to introduce one or two key indicators into the routine data collection in these facilities, depending on the circumstances. Ask to see what data they collect, and see if there is a template which can be modified slightly to collect useful data and if there is a way that data can be shared in a way that protects the privacy regulations and confidentiality of the people involved.
- ***Look for data from other sectors*** such as police, prisons, and customs. Data from other sectors can also shed a light on the nature of the drug and alcohol

problem in a community. The type and amount of drugs seized by customs may be publically available in a report. The prison may collect data on what drugs people are using when they come into prison. The police may keep records on what drug-related arrests are made, or the number of people charged for driving while over the legal limit for alcohol.

80.2.1.3 Advanced Approach: Systematic Data Collection

Epidemiological Estimates of Drug Use Disorders and Associated Health Conditions

A detailed description of the various epidemiological techniques for assessing the treatment need is beyond the scope of this chapter, and the reader is referred to Chap. 4, "Burden of Disease: The Epidemiological Aspects of Addiction", Sect. 1 of this textbook. There are a number of points that are worth keeping in mind, however. Firstly, remember that it is the patterns of substance use that are causing the most harm, not prevalence of drug use, that are likely to better correspond to treatment need. People who have used cannabis in the last 12 months, for example, meet most definitions of "drug use" but rarely attend for treatment. Daily patterns of substance use are more correlated to dependence and therefore also treatment need. Secondly, there are some newer techniques for drug epidemiology that are worth considering. Wastewater analysis can be a quick and cheap way to monitor trends in drug use in a city with a wastewater plant. If there is no facility to conduct the analysis in the country, then it can be easily sent by mail to a laboratory that specializes in such assessments (EMCDDA 2008). In communities with high uptake of mobile phones, and where there is a list of mobile phone numbers, or where a random phone dialer can be used to generate a random sample of people in the community, it may be worth considering the network scale-up approach. This approach is based not on the substance use patterns of the person being interviewed but of the other persons in their network of friends and associates. Then by also estimating the size of that person's network, this can be a shortcut to estimating the prevalence of rare or stigmatized behaviors.

Surveys of drug use in school and university students, while not a new technique, can be much easier to conduct than general population surveys and can be conducted often with the assistance of WHO such as the global school-based student health survey (GSHS), which has an optional module on substance use (http://www.who.int/chp/gshs/en/).

80.2.2 Step 2: Look at the Available Resources

The second step is to conduct an inventory of the resources that are currently being used and which could be recruited to tackle the problem of substance use disorders in the country.

This might involve putting together a list of the treatment facilities in the country, including specialized treatment centers and psychiatric facilities with how many staff they have and with what skills.

Treatment facilities can be defined in different ways. The important characteristics to measure are the treatment capacity; whether they are a place where people sleep or not (if yes, the number of beds); the number and qualifications of staff; what medications are available; whether treatment is private, not for profit, or government owned; and the approximate cost of treatment.

Then it is worth noting what services are offered by these treatment services, inpatient and outpatient detoxification, opioid maintenance treatment, counseling, social support, medication for relapse prevention, medical and psychiatric assessment, and treatment of medical and psychiatric comorbidity.

80.2.2.1 What Are the Components of a Substance Abuse Treatment System?

- ***Facilities***
  Hospital beds, nonhospital residential facility (detoxification center, long-term rehabilitation, therapeutic community, supported accommodation), outpatient, and outreach team (few or no fixed facilities). See also Chap. 78, "Treatment Systems for Population Management of Substance Use Disorders: Requirements and Priorities from a Public Health Perspective" of this section.
- ***Human resources***
  Specialist medical, generalist medical, nursing, social work, drug- and alcohol-specific counselors, and lay counselors
- ***Health technologies***
  Medicines, therapeutic techniques, and investigations
- ***Governance infrastructure/financing***
  Government ministry(ies), mechanism of decision making between different parts of the government, public, private, and insurance
- ***Information***
  National substance use observatory, epidemiology, trends, research, and information system
- The ***broader components of a substance abuse treatment system*** include other elements of the health-care system, including the mental health treatment system, drop-in centers, needle and syringe exchanges, and prison health system.
- ***Other systems to which the treatment system relates*** include police, criminal justice, employment, housing support, the social support systems, mutual support organizations, nongovernment organizations, and faith-based organizations.

80.2.3 Step 3: Assess the Functioning of the System

The next step is to consider the functioning of a treatment system. Is treatment available, accessible, affordable, acceptable, of good quality, adequately used, and providing continuity of care? Does treatment adhere to legal and ethical standards of patient care? Do the different components of the treatment system communicate and articulate effectively? Again, this assessment can be made either from

discussions with patients, colleagues, patient representatives, and family members or by more formal data collection such as anonymous questionnaires on treatment quality and measures of treatment effectiveness.

80.2.3.1 Current State of Health-Care Systems

Data from the WHO ATLAS survey (WHO 2011) on the organization of health-care systems for responding to substance abuse highlight that there is no one model of the substance abuse treatment system. Approximately one third to one half use their psychiatric systems, one third have special systems, and the remainder the general health-care system, or sometimes even the criminal justice system plays a role. Regional information systems on Africa, Asia, and Europe are available (WHO.int/gho/substance-abuse/treatment/en/index).

Common problems of drug treatment systems are:

- The ***size of the health-care response is inadequate*** compared to the burden of disease. Often drug treatment systems are only treating a small proportion of those in need, usually due to lack of funding. In many cases, health financiers have been convinced by health economic analyses that it saves the country money in lost productivity, health-care costs, and criminal justice costs to fund substance use treatment at a higher level (NHS 2012; UNODC 2003).
- The ***lack of a home for substance abuse within the health-care system***. The lack of a coherent substance abuse treatment system makes the development of the system difficult, particularly if the place where the treatment is based does not see substance abuse as part of their core business. Whether it is in psychiatry or as a separate entity, having a recognized focal point within the ministry of health, within academia, and within the public health system is vital to improving substance abuse treatment. In many countries this does not exist, as the treatment of substance dependence is a relatively new speciality, and it has developed wherever anyone has shown an interest. While this can be good to get things started, in the long run it is usually necessary to get the political support that is needed to run drug and alcohol treatment services to have a clear focus for those services.
- ***Accessing treatment of medical comorbidities*** such as HIV and TB is a key issue, particularly in the treatment of heroin dependence. The model of receiving the treatment of heroin dependence (with methadone or buprenorphine maintenance) at the same time as receiving the HIV +/− TB medication has shown to be very effective in facilitating good adherence to HIV and TB regimens. Ideally the same pharmacist can provide all three medications at once, and then the patient can also get whatever psychosocial support that they need at the same time. Such models have been set up in many low-income settings around the world (including countries in Africa, Asia, Eastern Europe, and the Middle East) and are the key to improving the very low rates of treatment of HIV in people who inject drugs. In order for such treatment methods to work, sometimes an HIV specialist needs to learn drug treatment, or a drug treatment specialist needs to learn how to treat HIV, or they both need to learn to work together. In any case, such a simple strategy is often difficult to implement in rigid bureaucratic environments.

- ***The role of primary health care***. Almost certainly, it will soon be clear that there are not enough specialist staff to treat all the patients with substance use disorders in the country. The addiction medicine specialist then needs to decide whether or not to allocate some of his or her time to building the capacity of primary care services to manage people with substance use disorders. Most people with substance use disorders already are engaged with a primary care service. Discharge from hospital, detoxification, or other substance misuse service can be an occasion to contact that primary care service and encourage them to continue the care that has been started, particularly if there is a clear role such as the prescription of relapse prevention medication. Primary care services are often happy to collaborate with specialist care services, as long as those specialist services will be able to support them with a difficult patient when the time comes.
- ***The lack of key pharmacological responses***. Despite being around for many years, many services do not provide methadone or buprenorphine treatment. Medication for relapse prevention from alcohol dependence is also often not available. The use of such medication greatly enhances the effectiveness of the service and is a must for any addiction service.
- ***Competing models of care in the criminal justice sector*** including compulsory treatment. Despite substance dependence being a health condition, sometimes treatment is provided by services under the responsibility of the police or justice ministries. Even when the person is in prison, the health-care treatment should be provided under the auspices of the ministry of health.

80.2.3.2 Matching the Treatment System to the Needs

- ***Size and shape*****:** is there proportionate amount of investment overall and in the different components? What treatment services are required? How many specialists, generalists, doctors, nurses, pharmacists, etc.? In the absence of detailed epidemiological data, how can planners know the ideal treatment capacity for their health administrative region?

  For each 500,000 population, a high-income country will typically have (either provided by government, NGO, or private):
  - 10–15 detoxification beds
  - A consultation liaison service that sees patients in the hospital(s) with substance use disorders
  - Three to six addiction specialists
  - Outpatient treatment
  - Psychosocial support
  - Needle and syringe exchange, outreach, and other harm reduction services

  Combining the sources of data should enable a picture of the untreated treatment need to come forward:
- ***Alcohol dependence***

  Need for medical detoxification services, relapse prevention with psychosocial support and medication, and self-help

- ***Binge alcohol use***
  Screening and brief interventions in emergency departments and primary care and referral of the more severe cases to treatment
- ***Heroin dependence***
  Opioid maintenance treatment with methadone or buprenorphine. Psychosocial support and access to sterile injection equipment, HIV and hepatitis testing and treatment, and +/− TB screening and treatment

80.2.3.3 Assessing Treatment Quality

Treatment quality is essential for the acceptability of addiction treatment to patients, to staff, and to the general public, and it is essential for reliable good outcomes.

When you want to assess the quality of treatment services or a service network, the following questions are helpful to identify weaknesses and areas for quality improvement:

- Is there a clear concept about objectives and methods to be used?
- Have staff been trained how to use the therapeutic methods, and do staff get continued education about new evidence on those methods?
- Are staff aware of their respective duties and responsibilities (e.g., are there written procedures and guidelines)?
- Are staff attitudes towards addiction problems and patients favorable?
- Are there good working relationships with other services (e.g., somatic, psychiatric, social)?
- Is the workload of staff acceptable?
- Are the locations and infrastructures of services adequate?
- Are the human and financial resources of services adequate?
- Are services known and acceptable for the target population?
- Are patients satisfied with the treatment they receive?
- Are services accepted by other professionals and in the community?
- Does addiction treatment have adequate political support?
- Is there a system of clinical accountability within the service (in other words, is there someone whose responsibility is to ensure the standard of quality within the service, and to whom other staff must be accountable)?
- Are adverse events documented and discussed regularly?
- Are patients given the opportunity to contribute to the development of the service?

It is highly desirable to use multiple sources of information to find answers to these questions, including staff in various functions, patients and former patients, family members of patients, nontherapeutic services caring for addicted patients, family doctors and hospitals, and law enforcement. When identifying weaknesses and deficits, continue to ask how these could be improved.

In addition, it should be clear that services for the treatment of substance abuse problems are in line with legal requirements for health and social care, as well as with ethical guidelines if available for health and social care.

For a systematic checking of service quality, the WHO questionnaire on standards of care is a useful instrument (WHO 1993). The intention is to look at how adequately the treatment needs of a population are being served. For each standard, it should be checked if it is in place and in adequate form and if not how the situation could be improved. A checklist based on these standards of care can be found in the Annex. There have also been attempts to use business principles to assess and improve treatment quality and efficiency, including a walk-through of the treatment service and looking at the service from the consumer perspective (Ford et al. 2007; Quanbeck et al. 2012).

80.2.3.4 Assessing Treatment Effectiveness

Treatment effectiveness can be measured at different levels: intervention, service, and system (network of services) level. Effectiveness is usually measured by determining treatment outcomes, regarding health status, type and amount of substance use, social integration, and quality of life of patients (EMCDDA 2007, see also Chap. 88, "Monitoring and Evaluation of Addiction Treatment" in this section). Measurements can be made by the degree of goal attainment (reaching a predetermined outcome), or by the nature and size of change in the abovementioned domains.

Effectiveness of ***special treatment approaches and methods (intervention level)*** is measured in clinical trials. Outcomes of such trials are compared in reviews or meta-analytic studies, providing information on the probability of positive results for which drugs, which patients, in which settings, and under which circumstances (EMCDDA 2007). For an assessment of special approaches and methods in your services, you will need to collect baseline and follow-up data, in order to determine change during treatment. It is also worth considering a randomized clinical trial, particularly if you have a significant volume of patients, as this reduces many potential sources of bias that may otherwise make it difficult to interpret the results. In either case, standardized instruments are available for this purpose (WHO/UNODC/EMCDDA 2000; EMCDDA evaluation instrument bank EIB).

Effectiveness of ***treatment programs and services (service level)*** is determined by measuring the same outcome indicators for all patients enrolled in a treatment program or service for a specified period (e.g., annually or biannually). This is made by collecting routinely selected outcome data (monitoring) or by implementing an evaluation research project. Examples for both can be found in the WHO evaluation workbooks (WHO/UNODC/EMCDDA 2000). A useful indicator for service effectiveness is the rate of regular discharges after treatment termination in contrast to premature dropping out and discharge; another is the rate of relapse following discharge (see also Chap. 88, "Monitoring and Evaluation of Addiction Treatment" in this section). Self-evaluation of services needs to be kept to a minimum of data and not measured more frequently than every 3 months. External evaluation is preferable to avoid bias.

Effectiveness of a ***treatment network (system level)*** does measure how well treatment needs in a given country or region are taken care of by the available services (coverage). This is done by comparing the estimated number and type of

substance abuse problems with the documented number and type of treatment populations. A simple method is a routine documentation of waiting lists and waiting time, although those also depend on the quality and acceptability of services. If there is no formal waiting list, new patients can be asked how easy it was to access the service. In addition, satisfaction of treatment populations and other stakeholders is a good indicator for satisfactory outcomes.

80.2.3.5 Interaction with the Criminal Justice System

Legal conflicts and criminal involvement are frequent consequences of substance abuse. The range goes from driving under the influence and violation of traffic rules to property crimes to domestic or public violence, not to mention the involvement in dealing with illegal drugs.

In some countries, such cases can be dealt with in special courts (e.g., drug courts) which can mandate treatment instead of imprisonment (Perry et al. 2008, Mitchell et al. 2012). In many countries, all criminal courts have the possibility to propose treatment instead of imprisonment (if indicated and with patient's consent) (Stevens et al. 2005). Treatments can be provided in regular community-based services, or in special prison institutions. Research has shown that in-prison drug-free residential treatment (therapeutic community type) has good outcomes if including a reentry phase with continued therapeutic contact (Mitchell et al. 2006). The same has been demonstrated for opioid maintenance treatment inside and outside of the prison system (Hedrich et al. 2012; WHO 2009a). Apart from a reduction in addictive behaviors, these treatments result in a remarkable reduction in criminal involvement.

Compulsory referral to reeducation and labor camps without formal treatment and therapeutic staff is not efficient in changing addictive behavior, is followed by high relapse rates to substance abuse and criminal involvement, and is ethically not acceptable (WHO 2009b). Also, compulsory forms of treatment in general have poor outcomes, mostly due to lack of motivation for behavior change (Hiller et al. 2002).

80.2.4 Example from WHO Experience: The SAIMS (Substance Abuse Instrument for Mapping Services)

80.2.4.1 Measuring the Treatment System

The objectives of the SAIMS are to support a standardized method for measuring the extent, quality, and integration of services for substance use disorders, including whether current services are meeting population needs; to demonstrate accountability; and to enable planning based on public health considerations rather than ideology, fads, and personal and professional preferences.

Its other objectives are to inform prevention policy, identify emerging drug epidemics, identify pathways to care, identify barriers to services, and describe the gap between existing service configuration and aggregate distribution of substance use disorders in the population.

The scope of assessment includes:
- Treatment services
- Diagnostic services
- Detoxification
- Medical/psychological/social support
- Therapeutic communities
- Self-help
- Primary prevention
- Health promotion
- Secondary prevention
- Harm reduction

80.2.4.2 Treatment Planning Based on SAIMS

A complete approach to a more comprehensive evaluation of a treatment system based on SAIMS includes some additional steps:
- ***Bring together the key stakeholders in drug treatment***. With the government this may include ministries of health and drug control/security/criminal justice. This might mean the establishment or reactivation of mechanisms of interministerial decision making. Often the prime minister's (or president's) office takes the responsibility to look after this committee itself.
- ***Conduct an assessment and description of the treatment system.***
- ***Analyze the fit with population needs*** for substance abuse services, including gaps in services.
- ***Plan new services***, reallocate resources, and train new staff.
- ***Monitor changes*** as system develops.
- ***Compare analysis*** within and across national boundaries.

80.2.5 Planning for Treatment Development

Once the assessment of the gaps between the current treatment system and the treatment need, a plan for sustainable development of the treatment system should be developed. The nature of this development depends to a large extent on the funding available.

In the absence of further funding, it may still be possible to reorient the treatment system to the areas of unmet treatment need. Further development, even if temporarily funded by foundations such as The Global Fund, will ultimately need sources of funding found within the country, either from government or insurance mechanisms. Since this process can take a long time, it is important to start these discussions early.

Any treatment development will need an increased workforce. Inclusion of elements of substance abuse treatment into the major health curricula in the country will increase the capacity across the whole treatment system. In the meanwhile, many existing practitioners can be assisted to provide substance abuse treatment with mentoring and support, even telephone support, and first-hand exposure to substance abuse treatment, either within the country or abroad.

For rapid expansion in treatment capacity, it may be useful to work with NGOs which focus on substance misuse treatment. In the longer term, for substance abuse treatment to be brought to scale, it will probably be necessary to develop such treatment within the public treatment system.

The addiction medicine physician is often in a unique position to contribute to treatment system development: understanding the nature of substance misuse treatment (including the gaps in current treatment), having the skills to train and mentor the next generation of treatment providers, and also having the capacity to influence funders and decision makers about the structure of the treatment system. When there is a shortage of expertise in a country, the addiction medicine physician will inevitably feel torn between providing patient care and nonclinical activities; however there are many opportunities for a public health impact by supporting the development and orientation of treatment systems for substance use disorders towards public health goals.

Appendix

Tools for Treatment Planning

Tool for Mapping Treatment Facilities

1. Type of treatment service (select one):
   - General health service (primary care, district hospital)
   - Mental health (including substance use) treatment service
   - Specialist substance abuse treatment service
   - Alcohol only treatment service
   - Drug only treatment service
   - Other (specify)
2. Service setting (select one):
   - Community
   - Hospital
   - Prison
   - Other closed setting (specify)
3. Facilities (multiple answers):
   - Outpatient treatment
     - Number of rooms for seeing patients/clients
   - Inpatient beds
     - Number of beds
   - Outreach
   - Pharmacy
4. Staff time involved in the treatment of substance abuse (in number of equivalents of full-time staff):
   - Medical staff
     - Addiction specialists (addiction medicine or addiction psychiatry)

    - General psychiatrists
    - Internal medicine specialists
    - Other specialist staff (specify)
    - Primary care physician
  - Nursing staff
    - Addiction nurses
    - Psychiatric nurses
    - General nurses
  - Pharmacists
  - Psychologists trained in substance use disorders
  - Social workers trained in substance use disorders
  - Occupational therapists trained in substance use disorders
  - Ex patients – trained in substance use disorders
  - Other (specify)
5. Services provided (approximate number of patients in each category at any given time – choose the one category that best fits each patient):
  - Assessment/diagnosis
  - Outpatient management of withdrawal
  - Inpatient management of withdrawal
  - Individual counseling
  - Group counseling
  - Opioid maintenance treatment
  - Relapse prevention medication
  - Treatment of comorbidity
    - Mental health problems
    - Wound problems
    - HIV/AIDS
    - Hepatitis/liver disease
    - TB
    - Sexually transmitted infections
  - Sterile injecting equipment
6. Does the service have programs specifically for different populations?
  - Pregnant women
  - Adolescents
  - People with mental health and substance use problems
  - People with physical health and substance use problems
  - Men
  - Women
7. Who is responsible for the treatment center?
  - Ministry of health
  - Other government ministry (specify)
  - NGO/FBO (specify)
  - Private company or individual (specify)
  - Academic institution (specify)

Tool for Minimum Data Set of Patients in Treatment Facilities

central Form code (to be filled at the central level):

Annex 1 Substance use treatment information system - examiner report form

1.1 Form code (to be filled at the data collection centre):	1.2 Patient' unique anonymous ID: [ ]
1.3. Staff ID as used at the facility [ ]	1.4 Catchment area name [ ] Catchment area code [ ]
1.5 Centre name: centre code: [ ]	1.6 Reported waiting period: # of days
1.7 Date of first clinical assessment:	Month | Day | Year
2.1 Age (years):_____	2.2 Sex 1☐ male 2☐ female 9☐ other
3.Source of referral: 3.1 self or individual ☐ 3.2 health system referral ☐ 3.3 criminal justice system ☐ 3.4 other[1]☐ [1]please specify: _____	

4. Type of substance (s) involved in current treatment episode	Primary	Non primary	Specify the name of the substance	5. Route of the administration of *primary substance* involved in current treatment episode	Please tick
4.1 Opioids				5.1 Oral	
4.2 Cannabinoids				5.2 Injecting	
4.3 ATS				5.3 Smoking	
4.4 Cocaine				5.4 Inhaling	
4.5 Hallucinogens				5.5 Snorting	
4.6 Solvents				5.6 Unknown	
4.7 Sedatives/hypnotics				6.History: 6.1 Age of first use of the primary substance (years): _____	
4.8 Alcohol					
4.9 Other					
4.10 Number of days the primary substance was used in the last 28 days: _____				6.2 Is this the first ever treatment episode: *Yes* ☐ *no* ☐	

7. Pattern of use (injection and sharing equipment): 7.1 History of injecting over the lifetime: *Yes* ☐ *no* ☐ 7.2 History of Injecting equipment shared over the lifetime: *Yes* ☐ *no* ☐ 7.3 Any sharing of injecting equipment during the last 28 days: *Yes* ☐ *no* ☐	
8. Treatment setting planned for the current treatment episode: 8.1 Inpatient ☐ 8.2 Outpatient ☐ 8.3 Residential ☐	9.1 Opioid maintenance treatment planned for the current treatment episode: *Yes* ☐ *no* ☐ 9.2 Type of medication to be used for maintenance treatment: Methadone: ☐ Buprenorphine: ☐

Tool for Quality of Patient Care (Quality Rights)

http://www.who.int/mental_health/policy/quality_rights/en/

Checklist on Standards of Care

Standards on Access, Availability, and Admission Criteria

A1	Service is easily accessible with regard to location, travel time, and transportation
A2	Services are obtainable without restrictions of time and day
A3	Treatment is available without delays creating risks for patient
A4	A range of treatment settings and treatment options are available (residential, outpatient, day care)
A5	Services are available without the need to undertake laboratory tests, such as tests for HIV
A6	Services are available irrespective of age and gender
A7	Services are available irrespective of ethnic, political, or religious background or beliefs of patient
A8	Services are available irrespective of the type of drug(s), route of administration, and legal status of drug(s)
A9	Patient may continue with prior established treatment of other conditions without prejudice of access to treatment
A10	Service is available irrespective of the somatic or psychiatric condition of patient (including HIV)
A11	Service is available irrespective of the patient's legal status or of past or ongoing prosecutions (including those related to drug use)
A12	Service is available irrespective of the patient's ability to pay, economic or employment status
A13	Professional services are available in custodial settings (e.g., police cells, prisons)
A14	Service is available irrespective of the current drug use of patient
A15	Service is available irrespective of history of prior treatments
A16	Regular contact exists between specialist treatment facilities and general

Standards on Assessment

B1	An initial assessment is made in order to prioritize interventions in a coordinated treatment plan
B2	An assessment is made to detect complicating physical and neurological disorders
B3	A psychiatric/psychological assessment is made to detect complicating disorders (e.g., depression)
B4	An assessment is made of the social circumstances (e.g., family, employment, housing, financial, and legal position)
B5	Methods for the rapid identification of substances used are available through laboratory tests (e.g., urine or blood) or other procedures
B6	Laboratory facilities are available to assist in the assessment of physical and psychiatric/psychological disorders
B7	Standardized instruments for diagnosis are used (e.g., ICD-10)
B8	Detailed records are kept on assessment results at entry

Standards on Treatment Content, Provision, and Organization

C1	Records of patient management, progress, and referral are kept
C2	Treatments are chosen on the basis of drug use, somatic and mental state, and social circumstances

(*continued*)

C3	Treatments are chosen on the basis of somatic and psychiatric disorders and the social situation of patients
C4	Defined protocols exist for prescribing and other interventions appropriate to the specific needs of patients
C5	The protocols are based in research evidence wherever possible
C6	Patients are informed on the range of available treatment options
C7	Whether or not the treatment goal is abstinence, measures are taken to reduce the harm from continued drug use
C8	The least risk-producing treatments are chosen on the basis of a careful risk-benefit assessment
C9	Home-based treatment is available with regular visits by trained staff
C10	Access to self-help and other support groups is available
C11	Information about 24 h emergency facilities is provided
C12	Patients with overdose receive immediate care in-house or through referral to a well-equipped other service
C13	Continuity of care is assured
C14	There is regular evaluation of the service/program
C15	There are links to other services for the care of children or other family members in need of care and support

Standards on Discharge, Aftercare, and Referral

D1	There are defined criteria for the expulsion of patients due to violation of treatment service rules
D2	There are defined criteria for (unvoluntary) retention of patients (e.g., intoxication, suicide risk)
D3	Discharge is based on determination of patient recovery status and on patient's consent
D4	Referral to other services is offered in case of expulsion/discharge
D5	Referral to aftercare and continued support (e.g., social or family support) is offered

Standards on Outreach and Early Intervention

E1	Primary health facilities are informed about your services
E2	Police and the judiciary system (courts, parole, and probation officers) are aware and informed about your services
E3	Counseling of drug users, family members, employers, and other key persons is available in your services

Standards on Patient's Rights

F1	The Universal Declaration of Human Rights applies in your services and is known to staff
F2	Information about the patient's condition, progress, and treatment involvement is not divulged to anybody without the patient's consent
F3	Patients are fully informed about the nature and content of their treatment as well as the risks and benefits to be expected
F4	Prior informed consent is obtained from patients regarding the content, conditions, and restrictions of treatment
F5	A documented complain procedure exists and is made known to patients and their relatives

Screening and Assessment for People with Substance Use Disorders: A Focus on Developed Countries

81

Brian Rush

Contents

Abstract

This chapter outlines the rationale for a more proactive concerted effort to screen for and assess mental health problems and at-risk consumption of alcohol and other drugs and related addictions problems given the evidence concerning the level of under-detection in routine practice and the excellent performance of a host of screening tools and processes. When used for clinical decision-making, best practice calls for a staged approach to maximize efficiency of the overall screening and assessment process and ensure a link to subsequent outcome monitoring. While several specific tools are highlighted, the essential principle for service and system planning is that they must be tailored to the setting and target population for which they are being implemented. Whether working in generic settings such as primary care or specialized settings, a collaborative approach, drawing upon multidisciplinary, multi-provider, and multi-sectoral expertise, is needed across the stages of screening and assessment, along with

a collaborative response protocol for level-of-care placement/referral for treatment and support. The effectiveness of screening is reviewed, and the evidence is quite strong with respect to the ability of screening tools and processes to identify individuals needing brief intervention or other treatment and support. However, the effectiveness literature also tells us that screening is only one part of the process of engagement and the results are more equivocal in terms of the impact of the screening per se on subsequent case management and health outcomes. The literature on SBIRT in the addiction field is an important exception to this finding. Much more research is also needed on the facilitators and barriers to implementing universal or targeted screening and assessment tools and processes at both the level of the individual service provider and within collaborative, shared care arrangements.

81.1 Introduction

The purpose of this chapter is to provide an overview of screening and assessment tools and processes in the context of middle- to high-income (i.e., "developed") countries. In this context, there are important similarities but also differences in the many other books and research papers synthesizing this work from psychiatric (First and Tasman 2006; Greenfield and Hennessy 2008), behavioral (Miller 2006; Tucker et al. 2004), or social work perspectives (Jordan and Franklin 2011). Like previous work, there is an acknowledgement of important principles and practices that can be seen as universal in nature, for example, the need for an evidence-based approach grounded on a comprehensive bio-psycho-social-spiritual model; sensitivity to individual differences in culture, diversity, and developmental age; the critical importance of empathy, listening skills, and therapeutic alliance; and the appropriate involvement of family and significant others. These aspects are critical elements of the interface between clinician and client. Such similarities notwithstanding, this chapter emphasizes more of a systems approach, recognizing that in so-called "developed" countries, the greater resource base offers an opportunity for a collaborative approach to engaging people in need, identifying and assessing their strengths and problem areas, offering a wide range of service options along a continuum of care, and, ideally, following up with post-discharge recovery monitoring. This collaborative approach may involve more than one provider, organization, and service delivery sector – a scenario that professionals working in low-income countries may only dream about in terms of collegial support for their work. Further, many screening and assessment tools that complement clinical skills and experience are not available and validated in many low-income countries. This is another advantage conferred on moderate- to high-income countries that have capacity for research and development.

In short, this chapter acknowledges the value and greater feasibility of a broader systems approach to treatment and support for substance abuse and co-occurring conditions, including screening and assessment (Institute of Medicine 1990). In addition, the underpinnings of collaborative care call for us to aim this chapter

at people working from a range of professional disciplines, for example, psychology, social work, nursing, family practice, psychiatry, and other medical and nonmedical specialists. For this reason, some readers working from an exclusive addiction medicine or psychiatric perspective may benefit from additional discipline-specific, reference texts such as First and Tasman (2006), written for psychiatry. This excellent reference text also provides more details on clinical assessment relevant for particular substances such as alcohol, cocaine, and opiates.

Although there are many important inter-jurisdictional differences in the capacity for screening and assessment, it is important to recognize that many "developed" countries are far from homogonous in terms of community need and capacity to respond. Taking Canada as but one example, there is a tremendous range within the country in terms of rurality/urbanicity, multiculturalism, indigenous versus nonindigenous populations, and substance use patterns and related harms. These and many other factors all influence beliefs about substance use and addiction, the perceived value of treatment, help-seeking behavior, and no doubt cultural interpretation of concepts such as "assessment" or "treatment." There is also wide variation in availability and accessibility of options for treatment and support, an obvious factor critical to screening and assessment considerations. With these caveats in mind, the goal here is to provide guidance to the reader on the screening and assessment of substance abuse risk and harms, primarily from a collaborative care, systems perspective appropriate for many middle- to high-income countries.

81.2 Core Principles and Practices

81.2.1 Rationale for Screening and Assessment

It is widely recognized that only a small minority of people with mental health and addiction-related concerns seek help from either community professionals or less formal services (Urbanoski et al. 2007; Kohn et al. 2004). Reasons behind this are many and varied across communities, including limited access to services or just not knowing how/where to seek help; stigma and discrimination that challenge people to seek help or that impact the attitudes and behavior of the helping agents they encounter; feeling able to manage on their own; and personal challenges related to such responsibilities as work, school, and childcare (Sareen et al. 2007; Urbanoski et al. 2008). Considerable research has also informed us for some time that, among those who seek help, the largest proportion will access a primary health-care provider or other health and social service professional (Shapiro et al. 1984; Kessler et al. 1996; Urbanoski et al. 2007). Although many people with mental health and addiction-related problems, or who are at risk of such problems, are in contact with various service providers, these risks or problems are often not identified (Barnaby et al. 2003; Weaver et al. 2003; Mitchell et al. 2012). These contacts are "teachable moments" and as such are missed opportunities for offering advice, more extended consultation, or referral for additional support.

The focus on improved screening and assessment is a critical element of efforts to "broaden the base" of treatment through a service delivery network that extends well beyond the traditional specialized sector of addiction services (Institute of Medicine 1990; Babor et al. 2008). In particular, there is a need to bring addiction specialists together with primary care physicians and professionals in other health-care settings and community services to deliver collaborative, shared care (e.g., Druss and Mauer 2010; Ivbijaro 2012; Chalk et al. 2011). Models of collaborative mental health care, including addictions, significantly extend the reach of the community-based treatment and support system.

The above trends in service delivery highlight the importance of generic community services such as primary care, hospitals, social services, schools and other education settings, and justice-related services being proactive in asking questions about mental health, substance use, and addiction-related issues in order to identify concerns, increase opportunities for early identification, provide access to more in-depth assessment and other services and supports, and link the person to more specialized services when needed. For people with low-to moderate risk, or less severe mental health and addiction problems, engaging in proactive, opportunistic screening and on-site brief intervention is intended to reduce risks and harms and have a positive impact on health-related outcomes. For those with higher risk, or more severe and complex problems, opportunistic screening is intended to open a pathway to more comprehensive assessment, an appropriate treatment and support response, and improved health outcomes. Savings are also anticipated in future medical-, social-, and criminal justice-related costs.

Service providers differ in their attitudes and beliefs about decision-making with respect to people seeking help at the clinical/service delivery level. These beliefs reflect agency mandate, training, and personal experience. Some professionals may practice without using formal or validated screening and assessment tools; instead they rely on their training and experience to guide problem identification and client-focused decisions. Some may have philosophical and ethical concerns about asking about mental health and addiction issues, considering it to be intrusive or possibly harmful due to potential stigmatization and labeling (e.g., in educational settings). Some may doubt the increased efficacy and efficiency of these tools over their routine decision-making processes. Some may be reluctant to engage in consistent, structured screening due to concerns that they do not have the expertise or resources to address the concerns identified. Research suggests that critically important mental health and addiction concerns are missed when structured tools and processes to prompt thorough questioning are not used (Zimmerman and Mattia 1999). Research also shows that screening is most effective when combined with other staged investigations and matched therapeutic- and motivation-based interventions (Gilbody et al. 2007). Collaborative approaches can serve to mitigate the reluctance of professionals to use formal screening techniques by bringing together complementary services and resources, ultimately building capacity for improved service to individuals who come to them for assistance.

Given the high level of heterogeneity in demographic, cultural, and clinical characteristics of people needing treatment and support for substance use problems,

it is axiomatic that no approach will meet their needs. This calls for a thorough investigation of needs and strengths and a co-constructed matching of this profile to available service options across a continuum of care. The focus on screening and assessment is intended to increase the efficiency of client intake and engagement, improve individual treatment outcomes, and minimize service delivery costs across the system as a whole (Hilton 2011).

Best practices for treatment and support of people with co-occurring disorders who are already engaged with specialized services also call for more proactive screening of these co-occurring problem areas (Rush and Nadeau 2011). This includes screening for mental health problems among people seeking addiction treatment as well as screening for high-risk/hazardous substance use and addiction-related problems among people seeking mental health treatment and support (Health Canada 2001; Rush and Castel 2011). Proactive, systematic screening can identify a wide range of unidentified problems that may impact treatment engagement and outcome among people with co-occurring disorders (e.g., health risks, suicide ideation, chronic health problems, psychosocial challenges). As noted, the screening process must be followed up with more comprehensive assessment, appropriate interventions, and outcome monitoring. A conceptual framework is presented below to help guide tool selection and service planning across this trajectory. Different screening and assessment tools and processes align with the full spectrum of mental health and addiction-related risks and harms and must "fit" with the varied service delivery settings where people are presenting for assistance.

81.2.2 Collaborative Models for Screening and Assessment

Ideally, screening should occur at the point of first contact with the treatment system, which could be a provider at any level of care, and in one of multiple sectors. As such, it is important that providers across sectors have the knowledge and skill to implement appropriate screening processes and tools that are feasible in their context and useful in identifying the person's needs and determining recommendations for further screening, assessment, treatment, and support. Depending on the results of screening and initial assessment, people need to be connected to the level and type of service most suited to their needs, including health promotion and preventive services. In fragmented systems, where collaboration between services and sectors is not well developed, individuals may not get the services they require in a timely manner, if at all, and systematic screening and assessment may facilitate increased access to services.

Many service providers external to the specialized mental health and addiction treatment sector do not have the expertise and resources to identify mental health, addiction, and co-occurring concerns. Further, most specialist service providers do not have the resources to respond to the breadth of complex issues and problems that are identified through many screening tools. Collaborative care models provide the opportunity for various providers to bring together their collective strengths and capabilities to construct a system whereby individuals are screened and can receive

required services in a seamless manner. Screening processes must be connected to fully articulated *response protocols* in order to be useful and effective. These protocols should describe required actions based on positive results on screening tools, including recommendations for more in-depth screening and assessment and follow-up consultation and referrals. In collaborative models, each provider must be clear about their role in screening and assessment, including the response protocols, so that individuals get what they need from the most appropriate resource. There are various models of collaboration that can incorporate screening, assessment, and referral protocols, and these include:

- *Integrated treatment and support for people with co-occurring disorders*, whereby competencies and processes related to screening and assessment are key criteria for defining integrated programs as "concurrent disorder capable" (McGovern et al. 2010).
- *Single assessment process incorporating multidisciplinary assessment* – Single assessment processes reduce the number of assessments between mental health, addictions, and various health and social service professionals in order to enable a seamless care process. Another option is to use common screening and assessment tools across a network of providers and with electronic sharing of the information and joint care planning.
- *Centralized access point to care* – This approach aims to reduce the number of points of entry of care for users, in some cases to a single access point in order to reduce the number of professionals and organizations prospective clients and their families have to deal with.
- *Screening*, *Brief Intervention*, *and Referral to Treatment* (*SBIRT*) – This approach requires health and social service professionals to use brief screening instruments to identify people at risk of, or experiencing, mental health and/or addiction problems and who then receive brief intervention on treatment on-site or who are proactively linked to specialist providers depending on severity.
- *Addiction specialists in generic settings* involves either assigning/hiring an addiction worker to perform in-house screening and brief assessment or colocating a worker from a specialized addiction services into the nonspecialized setting, for example, an emergency department.

81.2.3 Best Practices for Screening and Assessment

Through a treatment system lens, there are many disciplines and service delivery settings potentially involved in the screening and assessment process. An individual situation may require input from a medical, psychiatric, nursing, psychological, psychosocial rehabilitation, social work, and/or spiritual perspective. A collaborative approach to screening and assessment requires mutual interprofessional respect for the unique contributions that each has to offer to a client-centered approach. The uniqueness of the various perspectives notwithstanding, common principles include:

- A "whole-person perspective" on strengths and needs
- A sensitivity to diversity and related equity issues

- A strong emphasis on creating a welcoming, motivation-based, therapeutic interface
- Adherence to an evidence-based approach

An evidence-based approach encompasses several factors including clinician expertise, exploration of person characteristics and contextual variables using psychometrically sound tools, critical thinking skills, personal and collateral input, and knowledge of evidence-informed interventions (Jordan and Franklin 2011). Screening and assessment must be seen as a *process* that continues over time as more information is shared and therapeutic relationships strengthen. A collaborative, longitudinal approach is particularly critical for the assessment of complex, co-occurring disorders (Kranzler et al. 1994) given the need to disentangle etiological sequencing (e.g., depressive symptoms induced by heavy alcohol use). In a collaborative approach to screening and assessment, the *sharing* of information across service providers is also critical. If possible, this should be done through e-health technology, but minimally through telephone, email, or written communication. Interprofessional communication has been shown to be an effective component of collaborative care (Foy et al. 2010).

Best practice entails a staged approach that links screening, assessment, and outcome monitoring with a family of tools and related decision-making processes that are developmentally appropriate and delivered through a diversity-based approach to ensure equitable access and subsequent assessment and treatment. This approach has been articulated in the *Conceptual Framework for Screening and Assessment* described below (Fig. 81.1). This framework is consistent with the emphasis on staged assessment and interventions in the area of mental health assessment for primary care (e.g., Bufka et al. 2002), addictions assessment generally (Carroll 1995; Donovan 1999; National Treatment Agency 2002; Miller 2006), and co-occurring disorders (Drake et al. 1998). It is also consistent with the evidence from the literature on the screening for depression, namely, that screening is more effective if (a) the priority group for getting feedback has been defined on the basis of a predetermined cutoff for "high risk" rather than universally for the whole population screened (Gilbody et al. 2007) and (b) positive screening results need to be followed by concrete steps to further explore strengths and challenges and provide intervention and supports for ongoing client engagement and transitioning to required services (Gilbody et al. 2003). Importantly, guidelines and supporting evidence for SBIRT with respect to alcohol and/or drug use refer to the *overall system* of screening, brief intervention, and referral, not just the screening component.

The framework can assist in choosing the "right" tools and using them with the "right" people at the "right" time. It is recommended that in order to effectively apply the framework, it be considered in the context of a multi-sectoral continuum of care and the specific collaborative models and service delivery settings under consideration. In the application of the framework in specific community contexts, it may be the case that the required level of care is not readily available due to waiting time or the lack of service availability within the jurisdiction or via realistic distance/travel time. Collaborative arrangements with existing services may be

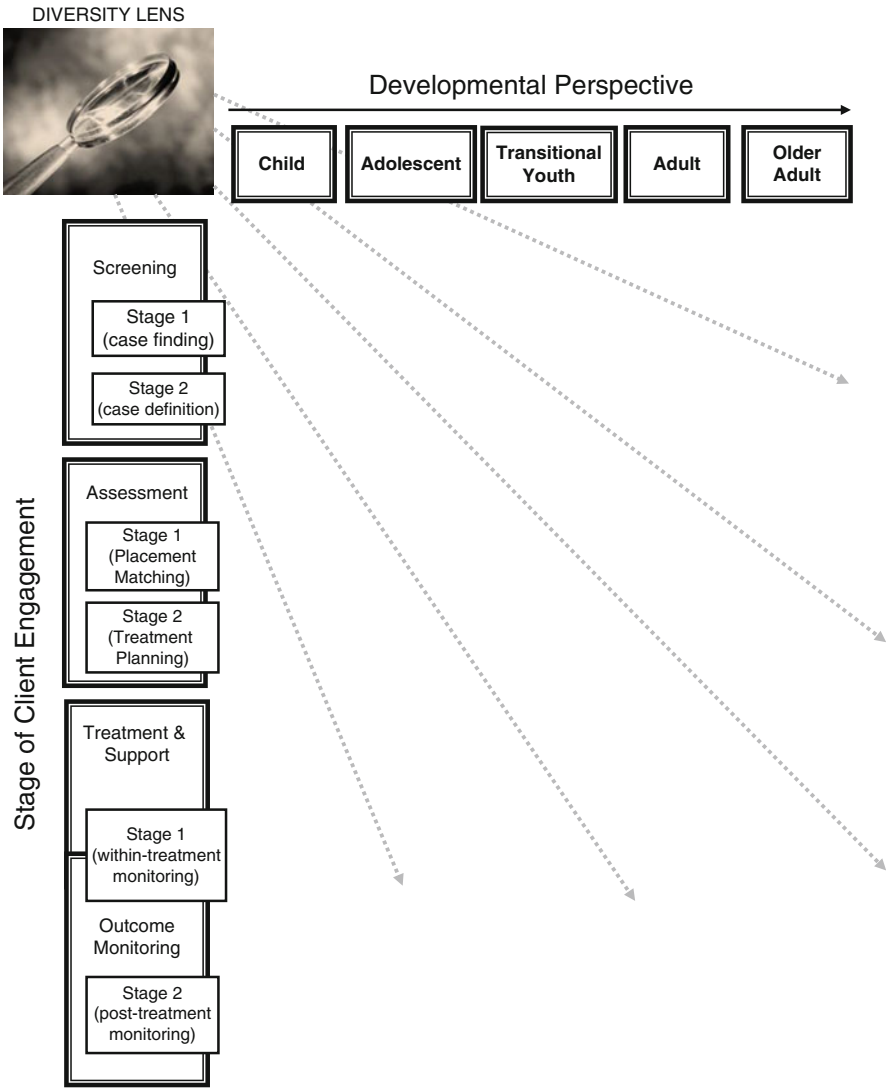

Fig. 81.1 Conceptual framework for screening and assessment in context of collaborative care (Adapted from Rush and Castel (2011))

required in order to offer the best service available at that point in time and to maintain client engagement. Parikh (2008), for example, discusses the types of evidence-based services and supports for mental health problems that can be provided within addiction services following positive results on mental health screening tools. Flynn and Brown (2008) note that, in the case of people with co-occurring disorders, provision of mental health services will often reduce

substance use and ameliorate addiction-related problems. Evidence reviewed by these same authors also suggests the reverse to be true for the provision of addiction treatment and consequent reduction of many mental health-related symptoms and improved functioning.

In short, it is important to work with local resources as best as possible while advocating for additional resources. In rural and remote areas, where resources may be limited, tele-psychiatry may also be an option. Therapist-assisted screening, assessment, and intervention via Internet or mobile-based technology are also an area of high need for more research and development in order to increase service options (see, e.g., Cunningham and Van Mierlo 2009; Andrew et al. 2010; Fjeldsoe et al. 2009).

81.2.3.1 Diversity Lens

Every individual has a unique and complex set of circumstances, perspectives, strengths, and concerns shaped in large part by the social determinants of health and including, for example, gender, sexual orientation, culture, ethnicity, social location, geography, political views, and religious/spiritual affiliation. As such, each component of this framework must be considered through a "diversity lens" when implementing tools, interpreting the results, and providing feedback to individuals in the context of day-to-day service delivery. The diversity lens is also critical when conducting research on screening and assessment tools and processes, for example, working to ensure tools are validated in specific populations and are culturally appropriate.

81.2.3.2 Developmental Perspective

Development stage, an important determinant of health, is a core element of the conceptual framework. The horizontal axis of the framework articulates the developmental trajectory across the lifespan as a frame of reference to also guide the choice of screening and assessment tools and processes. At each stage of this trajectory, there are specific developmental tasks and challenges that an individual must navigate. The diversity lens described above further nuances and elucidates complexity at each life stage. Age cutoffs for each developmental stage may vary for the individual, although most programs and funders allocate services by age rather than stage. Similarly most tools are validated for use with groups of individuals defined by age rather than stage. For example, some transitional age youth in the 18–24 range would be well served by screening and assessment with adult measures and being treated in the adult sector and others, adolescent measures and the youth sector. Therefore, tools and services that can be applied differentially to match developmental stage, rather than being bound by strict age boundaries, are preferred. The GAIN-Short Screener (Dennis et al. 2006) is appropriate for use from age 10 to older adulthood and is, therefore, particularly helpful for collaborative, system-level application (Lucenko et al. 2010).

Developmental stage and consideration of service delivery settings that may be unique to specific stages are also important considerations for determining *when* during the engagement, treatment, and support process to ask different types of

screening questions. For example, for young people being seen on an outreach basis in their school or street environment, it would not be appropriate to begin asking screening questions about sensitive topics such as high-risk sexual behavior, trauma experiences, or illegal behavior before a trusting relationship has been initiated. This will also be the case in many other settings and populations. Interpretation and action in response to screening results also need to be developmentally informed. More attention has been paid to this issue with respect to children, adolescents, and adults, but insufficient attention has been paid to further articulating the role of developmental stages in service transitions for transitional-aged youth and older adults. These developmental stages have been incorporated into the framework to ensure specific consideration is given to individuals in these life stages so that their unique issues and concerns are not overlooked.

81.2.3.3 Stages of Client Engagement

The vertical axis of the conceptual framework describes the stages of engagement that are situated across the continuum of service provision from problem identification or case finding to outcome monitoring. A collaborative approach to screening and assessment can be facilitated by a shared acceptance of this staged approach. As noted above, a staged approach is essential to ensure positive outcome for the individual and to improve the efficiency with which people are engaged in a treatment and support system (Hilton 2011). This staged approach also helps operationalize an "any door is the right door" principle in several treatment system designs. When placed in the context of an integrated screening and assessment *process*, sequentially implemented screening tools work together to ensure progressive but judicious and efficient use of assessment resources to guide the planning of client-centered treatment and support. In addition to screening, there are also two stages of assessment followed by some level of treatment and support and outcome monitoring. Assessment, intervention, and outcome monitoring are all linked to results from initial screening tools at a conceptual and measurement level and ideally through shared information technology. Collectively the resulting information and decision-making processes inform both ongoing treatment and support planning for the individual as well as evaluation and performance measurement at the program and system level.

While the two stages of screening and the two stages of assessment represent a *continuum* of information gathering and decision-making, some helpful distinctions can be made between these groupings nonetheless. It is beyond the scope of this chapter to provide an exhaustive review of the many screening tools that have been developed and tested for work in the substance use area and for application in addictions, mental health, and other settings such as primary care. There are several excellent narrative reviews that cover the large majority of available tools, and it is important to review the relevant literature carefully to assess the available research data on psychometric performance in specific populations (i.e., reliability, validity, sensitivity, specificity, positive and negative predictive power) and factors related to usability such as length, cost, and recommended mode of administration, to name just a few factors. Some of the existing reviews cover tools of particular relevance

to primary care and other health-care settings (e.g., Allen et al. 1995; McPherson and Hersch 2000). Other reviews are more oriented to the area of co-occurring disorders and address the potential applicability of tools for settings such as mental health, addiction services, and criminal justice (Center for Substance Abuse Treatment 2005; Health Canada 2001; Sacks 2008; Savage 2006; Centre for Addiction and Mental Health 2006). Some reviews do not distinguish the settings for application but rather focus on the characteristics of the tools (e.g., Dawe et al. 2002; Tucker et al. 2004). Still others focus on children and youth as opposed to adult populations (Pediatrics 2010; Centre for Addiction and Mental Health 2009; Rush et al. 2009). While there is no shortage of synthesized information about the various options for screening and assessment, it may still be a challenge to sift through the available information as each review often has a particular focus (setting, population, mental health broadly, or addiction specifically).

81.2.3.4 Screening

In the context of addictions, and the broader field mental health, screening is a relatively brief process designed to identify individuals who are at risk of having particular problems or diagnosable disorders that warrant immediate attention, intervention, or more comprehensive review. Identifying the need for further assessment is the primary purpose of screening.

A staged approach to screening involves the sequential use of tools for risk assessment/case finding (Stage 1) and case definition (Stage 2). An important objective of this staged approach is to reserve the tools that require more staff time, resources, and training for those individuals who score above the cutoff on the briefer, more economical tools. The organizational context will dictate whether screening will start at Stage 1 or 2, as further described below.

81.2.3.5 Stage 1 Screening: Risk Assessment/Case Finding

This stage of screening involves the use of psychometrically sound, typically self-report questionnaires that cast a fairly wide net to determine the possibility of a particular problem area or mental/addictive disorder, and which requires further investigation. In the addiction area, Stage 1 tools may also focus on the level of risk associated with alcohol and drug use per se, the AUDIT perhaps being the best known option (Babor et al. 2001).

Having a menu of Stage 1 tools to choose from, ranging from brief 1-3 item instruments to somewhat longer tools that focus on a small number of domains, can facilitate the implementation of systematic screening protocols in emergency rooms, primary care offices, and other service delivery settings where severe time constraints may otherwise preclude a more detailed, systematic screening approach.

Stage 1 tools are characterized by their brevity (typically between 1 and 20 items; completion time less than 5 min) and low-threshold training requirements and scoring algorithms. There have been recent developments toward very brief screeners (1–3 items) for alcohol or other drugs in order to facilitate screening in busy settings such as primary care or emergency departments (e.g., Smith et al. 2010; Ramchand et al. 2009) or with high-need populations that cannot tolerate completion of long

questionnaires (e.g., people with psychosis: Ley et al. 2007). As noted, the AUDIT (Babor et al. 2001) is a Stage 1 tool focused on the level of risk of alcohol consumption. Others are focused on consequences, including substance use/abuse or dependence (e.g., CAGE, Ewing 1984; Dhalla and Kopec 2007; BASIC, Bischof et al. 2007; TWEAK, Russell 1994; and CRAFFT, Knight et al. 1999).

The screening for mental health problems/disorders is also highly relevant for the assessment and treatment of people with identified substance use concerns. With respect to screening for mental health challenges, there is an important distinction between disorder-based tools and those based on a dimensional approach, such as measuring mental distress. Others that are longer such as the Beck Depression Inventory (Beck 1961), the Beck Anxiety Inventory (Beck et al. 1988), or screeners for PTSD (SPAN: Meltzer-Brody et al. 1999) and trauma (Klein et al. 2002) are best considered follow-up Stage 2 tools because of their length and diagnostic specificity. Disorder-based tools that are extremely short, such as those using 1–3 items for identifying depressive and/or anxiety disorder (e.g., the ADD: Means-Christensen et al. 2006), are considered Stage 1 screeners. However, Stage 1 mental health screeners also include brief dimensional measures such as the K6/K10 (Kessler et al. 2002), the five-item mental health component of the SF-36 (Ware and Sherbourne 1992; Berwick et al. 1991); the Psychological Screening Inventory (PSI: Lanyon 2006); and either the Brief Symptom Inventory or the BSRS (Derogatis and Mclisaratos 1983; Lee et al. 2006), both being shorter versions of the Symptom-Checklist 90-R (Derogatis 1983; Benjamin et al. 2006). For children and adolescents, the Strengths and Difficulties Questionnaire serves as a useful Stage 1 mental health screener (Goodman and Goodman 2009).

A small number of Stage 1 screening tools focus on *both* mental health and addictions, and these are highly valued because of their broader coverage and, therefore, their applicability in multiple settings involved in a collaborative care arrangement. The GAIN-SS (Dennis et al. 2006) is one such tool rapidly growing in popularity across North America and now available in multiple languages.

Biological tests for alcohol and drug use may also be helpful and have the advantage of ease of application in medical settings and their utility as a supplement to self-reported information. Limitations include cost, lack of specificity and, in some instances, sensitivity to recent substance use. Biological testing includes alcohol breathalyzer testing, measures of tissue damage from chronic substance use such as reflected in the liver enzyme gamma-glutamyl transferase (GGT) or red blood cell mean corpuscular volume (MCV), and hair, saliva, and urine analysis (see Tucker et al. 2004; Greenfield and Hennessey 2008 for brief reviews).

Time and resources permitting, brief screening across other selected domains is also recommended. Screening for other health problems such as traumatic brain injury, cognitive impairment, fetal alcohol spectrum disorder (FASD), HIV/AIDS, and tobacco use is also of critical importance to treatment and support planning and may be called for in some health-care settings using additional, brief screeners.

81.2.3.6 Stage 2 Screening: Case Definition

This second step in a staged approach to screening involves the use of psychometrically sound tools that are more specific and longer than those used in Stage 1 and which aim to tentatively identify one or more *specific disorders or problem areas*. This may include alcohol or other drug abuse and dependence and other mental disorders such as psychotic disorders, major depressive disorder, a variety of anxiety disorders including PTSD, eating disorders, and ADHD.

Although more specific and detailed than Stage 1 screeners, the information gathered through the tools in this category of the staged approach is still NOT sufficient on which to base a formal diagnosis, although some of the names of the tools can be misleading in this regard. The administration of a Stage 2 screening tool may involve the same or a different service provider than the one undertaking the Stage 1 screening. In any instances involving a transition to a new partner in a collaborative care process, a motivational approach and transition supports to ensure ongoing engagement are critical, especially for people with complex co-occurring conditions.

Screening tools such as the Psychiatric Diagnostic Screening Questionnaire (PDSQ: Zimmerman and Mattia 2001) and the Modified Mini Screen (Alexander et al. 2008) are particularly helpful as diagnosis-based, Stage 2 screeners. Rush et al. (2013) validated the PDSQ, as well as the psychiatric subscale of the widely used Addiction Severity Index for identifying mental disorders among people seeking addiction treatment. Magruder et al. (2005) found both the PDSQ and the Conners' Adult ADHD Rating Scale also performed well in adult substance use treatment settings. For adolescents, the POSIT (Danseco and Marques 2002) is more focused on specific problem areas rather than diagnosis (e.g., substance use, health, school, family) and is a well-validated option for Stage 2 screening in several settings. Others for children and youth are the Child Behavior Checklist (CBCL: Achenbach 1991) and the DISC-R (Lucas et al. 2001) although it covers most mental disorders and substance use. For more discussion on specific screening tools and processes for children and youth, see the narrative review conducted by Rush and colleagues (2009) and synthesized by the Centre for Addiction and Mental Health (2006). As noted earlier tools such as the Beck Depression Inventory (Beck 1961) and the Beck Anxiety Inventory (Beck et al. 1988) are considered to be Stage 2 tools due to their specificity in terms of diagnosis and length. This grouping also includes several mental health screening tools that are dimensional rather than diagnostic in nature such as the longer version of the GHQ-30 and the full SCL-90-R (Derogatis 1983).

81.2.4 Assessment

In the staged framework, assessment is also conceptualized as involving two phases. Stage 1 assessment is focused primarily on further information gathering and placement/referral to the most appropriate service setting (i.e., level of care). This needs to occur within a stepped-care, integrated systems model that provides

supported transitions across levels of care on an as-needed basis, including multiple sectors of services. Upon engagement in the appropriate setting, Stage 2 assessment goes further in examining strengths and needs across several bio-psycho-social-spiritual domains including health and mental health status, family/social situation, environmental risk factors, etc. One helpful way to conceptualize the distinction between Stage 1 and Stage 2 assessment is that between "placement" and "modality" matching (Mee-Lee and Gastfriend 2008; Gastfriend et al. 2000). Placement matching refers to initial client assignment to a treatment setting with a certain resource intensity and, therefore, important cost implications. Modality matching refers to client assignment on the basis of the optimal clinical approach and intervention(s), including philosophical and goal orientation such as reduced substance use versus abstinence, based on the full profile of client strengths and needs.

The two stages of assessment are further described below.

81.2.4.1 Stage 1 Assessment: Information Gathering and Service Placement

This first step in a comprehensive assessment involves continued information gathering that is optimally done through use of valid tools and structured interviews. There is a gray area between Stage 2 screening and Stage 1 assessment, this being a matter of degree in the level of detail and duration of time for information gathering, case construction, and the initial development of treatment and support plans. However, the essential feature of a Stage 1 assessment, especially in the context of collaborative care across multiple service delivery settings, is the intention to efficiently gather enough information on both strengths and needs, including immediate needs for physical and psychosocial stabilization, to formulate an initial placement/referral in an appropriate level of care.

For addiction services, this would include a determination of the need for withdrawal management which may be initiated in one of the three levels of care: home/mobile, community/medical, or, in the case of complex co-occurring mental and physical problems, a hospital-based service with adequate medical and psychiatric supports. The CWAW-Ar is an assessment tool that supports determination of the need for withdrawal management services (Sullivan et al. 1989). Withdrawal management often needs to be accompanied by a period of stabilization prior to formal engagement in treatment. Aside from withdrawal management, a Stage 1 addictions assessment should also determine the need for community or residential treatment at varying levels of duration and intensity. These levels of care are articulated in considerable detail in the ASAM criteria for placement/referral to addiction services (Gastfriend 2003; Mee-Lee and Gastfriend 2003).

It is critical to reemphasize that the initial placement/referral based on the Stage 1 assessment be undertaken in the context of a stepped care, potentially multiservice model – that is stepping up to a higher level of care if required and stepping down on the basis of progress toward the individual's goals. At moderate-to-high levels of severity and case complexity, this typically requires transition support, including case management and shared e-health information. It also requires monitoring of outcomes, within and posttreatment (see below).

The ASAM model specifies the dimensions across which a clinician must explore strengths and needs in order to make the appropriate placement match (Gastfriend and Mee-Lee 2003). These dimensions include:

- Acute intoxication and/or withdrawal potential
- Biomedical conditions and complications
- Emotional, behavioral, or cognitive conditions and complications
- Readiness to change
- Relapse, continued use of continued problem potential
- Recovery environment

It is highly recommended that these areas be examined with a semi-structured or a structured interview approach facilitated by validated instruments that support the initial placement/referral.

Assessment tools and processes for Stage 1 assessment include the GAIN-Q3 Standard MI or the GAIN-I-Lite – these tools being part of the GAIN "family" of substance abuse screening and assessment tools (www.chestnut.org). As with the GAIN-SS, these brief assessment tools are appropriate for use with individuals from age 10 and up. Another instrument for Stage 1 assessment is the Recovery Attitude and Treatment Evaluation (RAATE: Gastfriend et al. 1995; Mee-Lee 1988; Najavits et al. 1997).

81.2.4.2 Stage 2 Assessment: Case Conceptualization/Comprehensive Treatment Plan

The next stage of the assessment process involves the creation of a case conceptualization, formulation, and/or diagnosis leading to an individualized and adaptable treatment plan. The language around this overall process changes depending on the discipline and service delivery setting. The central idea, however, is to pull together all the information that has been gathered from validated screening tools, undertake additional information gathering as needed through assessment questionnaires, structured and semi-structured interviews, collateral contacts, and case notes from previous service contacts (if available). The resulting case conceptualization or diagnosis informs the treatment plan, including responding to instrumental and clinical needs and providing indicated referrals. The term "modality matching" summarizes the intention of a Stage 2 assessment, although this may also involve revision to the placement decision made at an early stage.

Increasingly, Stage 2 assessment is seen as being grounded in the present context of the person's life situation and problem focused (Jordan and Franklin 2011). This approach, however, should not exclude consideration of critical underlying factors such as trauma, including intergenerational trauma, and neuropsychological mechanisms. A thorough health assessment including a full psychiatric assessment may also be required and is especially indicated for individuals presenting with more complex co-occurring conditions.

It is beyond the scope of this report to delve into all the critical issues involved in the person-clinician interface for purposes of comprehensive assessment and treatment and support planning. There are many excellent reference texts that approach this from various disciplinary perspectives, including psychiatry

(First and Tasman 2006; Greenfield and Hennessy 2008), psychology/behavioral health (Miller 2006; Tucker et al. 2004), or social work (Jordan and Franklin 2011). All such experts acknowledge the role of clinician experience and skills in conducting semi-structured or structured interviews that operationalize core principles and practices such as sensitivity to individual differences in culture, diversity, and developmental age; the need for empathy and establishing therapeutic alliance; and the appropriate involvement of family and significant others. In the addiction field, there is a need for such interviews to cover several areas including, but not limited to, substance use history, including age of first use and onset of negative consequences; severity of substance abuse/dependence; level of insight into past and current challenges; social supports and environment risk factors (e.g., for relapse); medical and psychiatric comorbidity; current phase of use (e.g., intoxicated or in withdrawal); and pressures to seek help and the person's readiness/motivation for change. For many of these areas, the approach is to explore these areas at a deeper level than they have been investigated in Stage 1.

In the addictions field, there have been significant efforts to create integrated assessment packages to support individualized treatment plans and subsequent follow-up determination of outcome. Two well-known comprehensive addiction assessment packages are the Addiction Severity Index (McLellan et al. 1992; version 6) and the GAIN-I (www.chestnut.org). The GAIN-I is now used extensively in North America and has the added advantage of being conceptually and instrumentally linked to the GAIN-SS (Stage 1 screener) and the GAIN-Q3 or GAIN-I-Lite (Stage 1 assessment). Another example with a stronger focus on mental health is the Psychiatric Research Interview for Substance and Mental Disorders (PRISM) which, although designed primarily as a research tool, provides systematic coverage of alcohol/drugs and mental health experiences and symptoms and functional impairment (Hasin et al. 1996). There is also the option to administer the full structured interview for DSM-IV disorders (DSM-IV) (First et al. 1996) although this would need to be supplemented with other addiction specific tools assessing, for example, readiness to change.

81.2.5 Treatment and Support and Outcome Monitoring

These stages of the staged framework will only be briefly summarized as they are somewhat out of the scope of the present focus on screening and assessment. Outcome monitoring is, however, critically tied to these earlier stages because of the need to establish baseline status early in the treatment process and to inform and engage the client in the eventual follow-up processes, for example, obtaining locator information. Importantly, a connection is now made between *within-treatment outcome monitoring* and *posttreatment* outcome monitoring with recovery checkups. Importantly, both within-treatment monitoring and posttreatment outcome monitoring consider the contact for client and program evaluation purposes, an extension of the treatment and support process itself. This is conceptually quite different than a traditional "research" follow-up and much

more likely to engage administrative and clinical staff, as well as clients themselves, in the outcome monitoring process.

81.2.5.1 Stage 1. Within-Treatment Monitoring

Within-treatment outcome monitoring tracks progress on an ongoing basis with very brief but highly relevant clinical tools applied at the front end of periodic therapist-client interactions. This model has evolved from the work of Lambert in the mental health area (e.g., Lambert et al. 1996) and, in the addiction field, McLellan and colleagues (2000). This stage of outcome monitoring occurs at the clinical interface of therapist and client. It is critical that the outcome measures be brief, be implemented within the flow of the clinical encounter, and return feedback immediately in a useful format to further the therapeutic relationship and the client's progress toward goals. Appropriate within-treatment outcome monitoring can be accomplished with repeat application of some screening tools that are sensitive to change over time such as the GAIN-SS. Others such as Lambert et al. (1996) Outcome Questionnaire (OQ) have been designed specifically to assess psychological processes that cut across many types of mental health problems, including addictions.

81.2.5.2 Stage 2. Posttreatment Monitoring

Posttreatment outcome monitoring involves the repetition of selected screening/assessment measures at some interval after program admission, such as 3,6,12, or 24 months, and determination of changes in these measures. In addition, the follow-up contact is an opportunity to re-engage the individual in treatment if indicated, using a guided, motivational return-to-treatment protocol (Dennis et al. 2003; Scott and Dennis 2009). Posttreatment monitoring is useful as an accountability and program evaluation tool and can also be helpful in identifying clients who may be struggling and need further assistance to recoup gains made in treatment.

Ideally, posttreatment follow-up also involves repeat application of one or more assessment tools or sub-scales by phone or face-to-face interview. The GAIN-I and GAIN-Q3-standard (www.chestnut.org) on the Addiction Severity Index (McLellan et al. 1992) are useful measures for outcome monitoring. Locating clients and obtaining good follow-up rates (ideally over 80 %) are the Achilles' heel of posttreatment follow-up for addictions programs. There are protocols for achieving substantially higher follow-up rates (Scott 2004), and these can benefit from collaborative networks working together to locate and engage people in the follow-up process.

81.2.6 Is Screening for Mental Health and Addictions Effective?

The usual approach to answering this question about the effectiveness of screening is to assess whether the screening tool(s) and related process are successful in identifying people with mental health and/addiction problems that would not have been identified through routine care. Although this has rarely been put to the test in

a systematic way (see Gilbody et al. 2007 for a synthesis of the research in the area of depression), the well-documented level of undetected problems combined with the high predictive value of many validated screening tools points to the importance of systematic screening to improve case detection.

There are, however, two additional aspects to the effectiveness question. The first is to ask whether the screening tools and processes, and subsequent review of the results, contribute to the management of the index problem. In other words, does it lead to meaningful action on the part of clinicians that would otherwise not have occurred? Secondly, one must ask if, at the end of the day, the screening and subsequent action have improved the index problem or related challenges. The systematic review on screening for depression by Gilbody et al. (2007) suggests that screening can contribute to better care management and health outcomes if there is some selectivity in providing feedback to only moderate-to-high-risk cases, rather than all people who may score positive according to test guidelines. This highlights the fact that screening *alone* may make little difference without a detailed response plan and follow-up intervention. In the addiction area, there is ample evidence that screening for different levels of risk for alcohol and drug use, accompanied by brief intervention or referral to treatment, is effective in engaging people in both these response options and subsequent outcomes (Babor et al. 2007; Madras et al. 2009; Kaner et al. 2009). More research is needed, however, to tease out the most effective ingredients of the overall SBIRT protocol. More work is also needed on addressing the challenges implementing SBIRT protocols in health care and other settings (Johnson et al. 2010; Williams et al. 2011).

The context in which screening takes place must be carefully considered in both implementation and evaluation of screening and assessment tools and processes. As already mentioned, the role and purpose of screening should be well understood and articulated in the context of the mandate and objectives of the service provider. Organizational policy must also support the implementation of screening and related protocols. Required staff competencies and program design should fit within clear service delivery protocols addressing where, when, and how screening will be administered and how the information gathered will be used. Personnel who are administering the tools must be trained to introduce, administer, score, discuss, and take appropriate action based on the screening results. All of this needs to be clearly conveyed to individuals engaging with the service so that they understand how screening can be helpful and provides fruitful ground for evaluative inquiry.

As noted above, implementing formal screening tools and processes is a logical fit in the specialized substance abuse treatment sector. In these settings, clients have already been identified as needing further screening, assessment, or treatment, and consideration needs to be given to screening for co-occurring concerns beyond the initial presenting problem, such as mental health. In other settings where routine screening and assessment of various health concerns is already taking place (i.e., primary care), the rationale for extending screening to identify addiction problems is also clear. Screening in settings such as schools, employment counseling, and justice settings is important to consider given the evidence that rates of addiction and mental health problems are high and often not identified. While these

settings provide important opportunities for early identification and early intervention, there are a number of potential risks that must be considered, including stigma resulting from identification and labeling, social exclusion, limitation of opportunities, and false-positives consuming scarce treatment resources. Risks associated with identification may be greater for specific individuals, for example, severe sanctions may be imposed on those identified as being involved in substance using activities by some schools, employment programs, shelter and housing providers, residential services in the mental health sector, long-term care facilities, families, and specific ethno-cultural groups and communities.

Models of collaboration within which screening and assessment are core activities provide the field with rich evaluation opportunities, including outcome and process evaluation and an opportunity to monitor trends and performance. Outcomes can be examined at the individual (i.e., client and service provider), organizational, and community level. For example, at the organizational level, outcome indicators could include changes in staff attitudes, skills, and behavioral engagement in screening and assessment practices and change in referral practices as well as client perceptions of care; at the community level, indicators could include increased numbers of new clients referred to treatment and reduced number of emergency visits. It is also of interest to evaluate the extent to which the development of collaborative models of screening and assessment contribute to collaborative processes across agencies/service providers – for example, increased partnership and building of partnership capital to engage in other joint planning and service delivery. Using a consistent screening tool across a collaborative group of service providers provides an opportunity for decision-makers, funders, and researchers to look at presenting needs across settings and monitor trends over time within the collaborative as well as in comparison to the general population (Henderson and Chaim 2013).

81.3 Conclusion

There is a very strong rationale for a more proactive concerted effort to screen for mental health problems and at-risk consumption of alcohol and other drugs and related addictions problems given the evidence concerning the level of under-detection in routine practice and the performance of a host of screening tools and processes. Screening in multiple sectors, along with follow-up assessment and intervention, is one strategy to broaden the base for attending to addiction-related concerns and increasing the scope and reach of treatment and support beyond the traditional sector of specialized addiction services. There are many reasons to engage in more proactive screening, and both individual and collaborating partners need to be clear about how the information will be used, including making improvements at the system level. When used for clinical decision-making, best practice calls for a staged approach to maximize efficiency of the overall screening and assessment process. The specific tools and processes must be tailored to the setting and target population for which they are being implemented. For example, some tools will work best for screening in primary care and other generic health and

social service settings, and others are more appropriate for screening in specialized mental health and addiction settings. That said, whether working in generic settings such as primary care or specialized settings, a collaborative approach, drawing upon multidisciplinary, multi-provider, and multi-sectoral expertise, is needed across the stages of screening and assessment, along with a collaborative response protocol for level-of-care placement/referral for treatment and support.

The evidence is quite strong with respect to the ability of screening tools and processes to identify individuals needing brief intervention or other treatment and support. This evidence underlies the best practice guidelines that call for targeted screening in generic settings such as primary care and universal screening for all clients engaged with specialized mental health and addiction services. However, the effectiveness literature tells us that screening is only one part of the process of engagement and the results are more equivocal in terms of the impact of the screening per se on subsequent case management and health outcomes, the literature on SBIRT in the addiction field being an important exception. Collectively, the literature that cuts across the mental health and addictions area reminds us that screening alone is unlikely to translate into improved outcomes without a concerted response. Collaborative care processes are likely to contribute to this response, and more research is needed to find the active ingredients of collaborative screening, assessment, and treatment and support processes. Much more research is also needed on the facilitators and barriers to implementing universal or targeted screening and assessment tools and processes at both the level of the individual service provider and within collaborative, shared care arrangements.

Stepped Care Models in Addiction Treatment

Ambros Uchtenhagen

Contents

Abstract

Stepped care models aim at matching treatment intensity to defined patient characteristics in a systematic way, thereby avoiding misplacements and making best use of available treatment resources at the same time. In principle, treatment planning for new patients starts with the least intensive care, progressing to more intensive regimes for nonresponders. Such models have been introduced in psychiatry and in other medical fields.

Models of stepwise patient placement in addiction treatment are known from Northern America (Sobell model, model of the American Society of Addiction Medicine, ASAM) for adults and adolescents and special models for dual-diagnosis patients. Another model comes from Europe (the Dutch model for triage and evaluation in addiction treatment MATE; special model for judicial patients). The various elements and procedures of the ASAM and MATE models are described and compared.

An overview on evaluation studies and reviews is presented, concerning feasibility, validity, reliability, effectiveness, and cost-effectiveness of stepped

care models. Outcomes are partly positive, but limitations are mentioned and more research is asked for.

82.1 Introduction

82.1.1 A Concept for Patient Placement

It is normal practice to assign a new patient to an appropriate and readily available treatment and to switch a patient not responding to that treatment to another one, be it another intervention type, another medication, or another setting. The therapist makes his or her choice on the basis of guideline recommendations, scientific studies, or personal experience, eventually also on the basis of patient preference.

The concept of stepped care combines a systematized version of such practice with an attempt at matching treatment intensity to patient characteristics. Screening the new patient for specific characteristics provides the basis for treatment indication and placement, starting with the least intensive intervention and stepping up intensity for nonresponders.

Main principle: Patients should be offered the least intensive and intrusive care at first contact, except in case of emergencies and defined complications which ask for an intensive treatment. Otherwise, only nonresponders should receive care along a scale of increased intensity. This principle is aiming to protect patients from intrusive care they do not need and to make best use of available treatment resources by avoiding misplacements. "Stepped care models represent attempts to maximise the effectiveness and efficiency of decisions about allocation of resources in therapy" (Haaga 2000).

82.1.2 Models of Stepped Care

Approaches to stepped care in addiction treatment have been described repeatedly (Mee-Lee and Gastfriend 2008). By now, stepped care models have been introduced in some fields of psychiatry. Guidelines of the National Institute for Clinical Excellence NICE provide stepped care models in the UK for the treatment of depression and anxiety (Richards et al. 2012). In the USA, such resource allocation issues are mentioned for anxiety disorder, panic disorder, eating disorder, and alcohol dependence (Haaga 2000).

82.1.2.1 From First Line to Intensive Care

In the model proposed by the Sobells (Breslin et al. 1999; Sobell and Sobell 2000), the recommended treatment should start with the least restrictive intervention in terms of cost and personal inconvenience for patients. The first step might even involve facilitating "natural recovery" outside of professional services. Stepping up

requires a decision about patient progress and depends on the type of disorder and the effectiveness of available treatments. The decisions may be made on the basis of guidelines, but should not disregard the risk of inappropriate stepping up and of missed stepping up and should include considerations about costs of treatments at different levels.

82.1.2.2 The ASAM Patient Placement Model

The American Society of Addiction Medicine (ASAM) started to develop the patient placement criteria PPC in 1991, and in 1994 the National Institute of Drug Abuse (NIDA) funded a validity study. Revised versions were published in 1996 (ASAM PPC-2) and in 2001 (ASAM PPC-2R). A further revision will be based on DSM-5 to come.

The basis of the model is a concept of individualized treatment: assessment at intake is made in a range of biopsychosocial dimensions (multiaxial DSM diagnoses); assessment dimensions include also readiness to change, continued problem potential, and recovery environment. This is followed by an identification of priority problems, leading to defining the appropriate model and level of service. Progress assessment is used as a basis for eventual reassignment (Mee-Lee 2001; Mee-Lee and Gastfriend 2008; Mee-Lee and Shulman 2009).

Placement criteria have been set up for adults and for adolescents. Special attention is also paid to co-occurring mental and substance-related disorders, in patient assessment as well as in the specifications of services (Mee-Lee 2006). For dual-diagnosis patient, separate risk dimensions are set up: dangerousness/lethality, interference with addiction recovery efforts, social functioning, ability for self-care, and course of illness.

The criteria also advocate for an adequate availability of treatment; by incorporating more use of outpatient care – especially for those in early stages of motivation for change – the criteria help to reduce waiting lists for residential treatment (Mee-Lee and Shulman 2009).

A supplement was published to delineate specific criteria for the use of pharmacotherapies for alcohol use disorders, for detoxification, and relapse (Fishman 2010).

82.1.2.3 MATE: A Model for Patient Assessment and Referral

The Dutch model for measurement in the addictions for triage and evaluation MATE (Schippers and Broekman 2007; Schippers et al. 2010) is a national project, aiming at constructing and testing of a new instrument for the assessment at intake of all problems and needs in relevant domains in substance abuse treatment; the instrument should also be useful as a framework for the application of existing instruments in selected domains for matching, patient allocation, and treatment evaluation in the addictions. The instrument should help to make rational and transparent decisions about providing which and how much treatment to which patients. It was tested for feasibility, reliability, and validity in a population of heavy users, and in a subproject an instrument was developed and tested for judicial clients.

The assessment of substance use disorders at intake is made on the basis of the international classification systems ICD/DSM. Assessment of personal and social

functioning is made in order to determine which type of services will be needed; this part of the new instrument is based on the WHO international classification system of functioning, disability, and health ICF. Existing instruments are used for the assessment of comorbidities, new modules for treatment history, motivation, and criminality. Overall, the MATE instrument is composed of ten modules. A manual and a protocol with detailed instructions were published in Dutch. A German version of the instrument was tested and implemented (Buchholz et al. 2009).

82.1.3 The Main Elements of Stepped Care Models: A Comparative Overview

Stepped care models use three essential elements: patient indicators used for determining the appropriate level of care, treatment typology in regard to intensity of care, assessment, and referral procedures. The following figures summarize the relevant information on these elements in the ASAM and MATE models (Tables 82.1 and 82.2; Figs. 82.1 and 82.2).

82.1.4 Evaluation Results and Perspectives

A systematic review was made on the efficacy of stepped care models involving different levels of psychosocial treatment for alcohol use disorders and nicotine dependence, with or without medication (Jaehne et al. 2012). Little evidence was found to suggest that stepping up nonresponders to more intensive therapy improved outcomes. In one study, the application of a stepped care approach was found to reduce treatment costs compared with usual care. There was some evidence that the greater differentiation between the intensity of the interventions offered at each step, the better the outcome. Further research is needed to evaluate the efficacy of stepped care approaches to providing psychosocial treatment.

Table 82.1 Patient characteristics used for determining appropriate level of care

ASAM assessment dimensions	MATE patient indicators
Acute intoxication and/or withdrawal potential	Addiction severity
Biomedical conditions and complications	Psychiatric impairment
Emotional, behavioural, cognitive conditions/complications	Social stability
Readiness to change	Treatment history 0–1
Relapse/continued use, continued problem potential	Treatment history 2
Recovery environment	Treatment history 3–5
	Treatment history >5

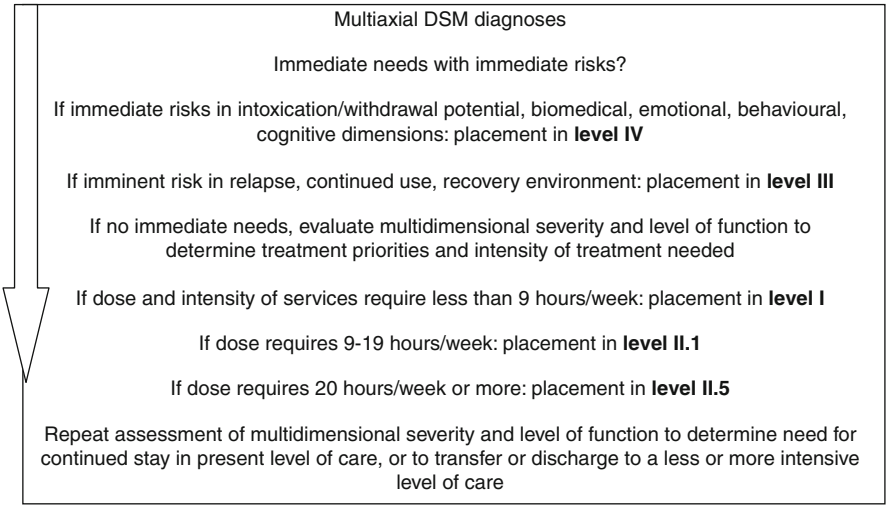

Fig. 82.1 Assessment and referral procedures in ASAM PPC-2r (Source: Mee-Lee and Gastfriend 2008, Fig. 6-1)

Another systematic review of stepped care in psychological interventions was made (Bower and Gilbody 2005). It identified the underlying assumptions on which the benefits of stepped care depend: equivalence in terms of clinical outcomes, efficiency in terms of resource use and costs, and acceptability of "minimal

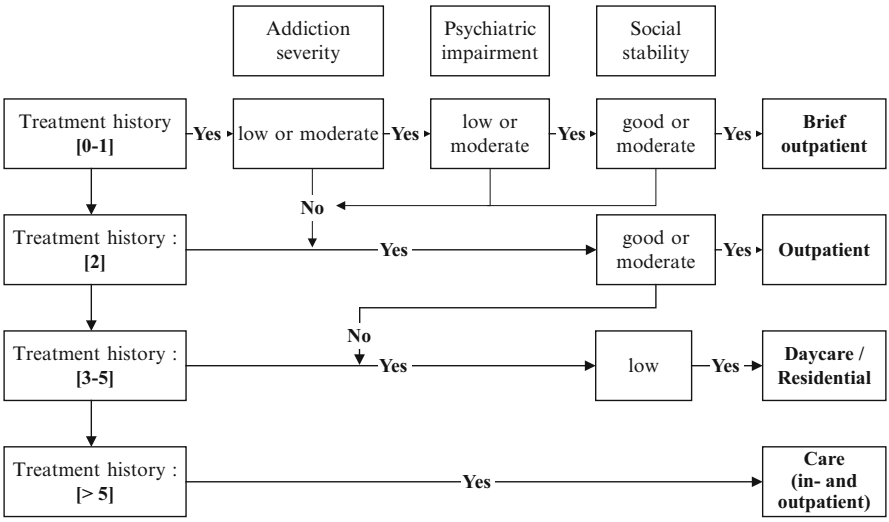

Fig. 82.2 MATE guidance for matching and referral (Source: Merkx et al. 2007, Fig. 2)

interventions" to patients and therapists. The review concludes that more research is needed in terms of rigorous evaluations of the underlying assumptions.

A summary of research on the ASAM patient placement criteria is presented in the Textbook of Substance Abuse Treatment. The authors conclude as follows: "More than a decade of research of the ASAM PPC supports the predictive validity and the cost-effectiveness of the use of PPC. Based on this research, a variety of computer assisted assessment and placement tools are in development" (Mee-Lee and Gastfriend 2008, p. 88). Another overview is presented in the Principles of Addiction Medicine. Nine evaluation studies were performed involving 3,641 subjects; controlled studies found that "treatment based on the ASAM PPC are associated with less morbidity, better client functioning, and more efficient service utilization than mismatched treatment" (Mee-Lee and Shulman 2009, p. 398).

Feasibility and field testing of the MATE in a treatment seeking population was performed in two large treatment settings. Construct validation with related instruments and evaluation of the dimensional structure of modules were performed. Among the results are a satisfactory inter-rater reliability and concurrent validity, indicating the usefulness of the instrument for allocating patients to substance abuse treatment, even in a heterogeneous population (Schippers et al. 2010). However, there were some problems with clinicians not complying with the guidelines, resulting in mismatched patients usually allocated to outpatient treatment instead of early interventions (Merkx et al. 2007).

A comparison of minimal interventions with a stepped care model for patients with alcohol use disorders in the UK evidenced greater cost savings, greater motivation for change, and greater reduction of alcohol consumption for stepped care 6 months after randomization (Drummond et al. 2009).

Further developments: Stepped care models have a considerable potential to improve patient-service matching with improved outcomes and improved use of treatment resources. Stepped care is also considered to be an important element of individualized treatment (Kranzler and McKay 2012). A wider implementation of existing or new models however is slow and may meet problems if not politically supported.

Harm Reduction Interventions

83

Dagmar Hedrich and Richard Hartnoll

Contents

Abstract

The goal of harm reduction is to reduce both the individual and societal harms of drug use through knowledge-based interventions that change risk behaviors and risk settings. ▶ Chapter 84, "Harm Reduction Policies, Settings, and Challenges" in this textbook gives an overview of harm reduction as a public health policy. This chapter describes the main harm reduction interventions implemented in many countries around the world, synthesizes evidence on their effectiveness and risks, and summarizes key lessons learned. The focus is on illegal drugs, especially opioids and central nervous system stimulants. The interventions covered are opioid substitution treatment; needle and syringe programs; supervised drug consumption facilities; drug overdose prevention; outreach, peer education, and health promotion; testing, vaccination, and treatment

of drug-related infectious diseases; interventions for stimulant users; and drug-related sexual risk reduction. Key themes stressed include the following: that harm reduction does not replace the need for treatment but adds to the capacity to respond effectively to the wide range of health and social challenges raised by drug use; that the scientific evidence shows that harm reduction interventions are effective in terms of their stated goals, as long as they are implemented appropriately within their contextual settings; and that single interventions are far more effective when implemented together as part of a broader public health policy, including steps to facilitate healthier living and safer social environments.

83.1 Introduction

The goal of harm reduction is to reduce individual and societal harms of drug use through knowledge-based interventions that change risk behaviors and risk settings. ▶ Chapter 84, "Harm Reduction Policies, Settings, and Challenges" in this textbook gives an overview of harm reduction as a public health policy. This chapter describes the major harm reduction interventions, synthesizes evidence on their effectiveness, and summarizes key lessons learned. The interventions covered are:

- Opioid substitution treatment
- Needle and syringe programs
- Supervised drug consumption facilities
- Overdose prevention interventions
- Outreach, peer education, and health promotion
- Testing, vaccination, and treatment of infectious diseases
- Interventions for stimulant use
- Drug-related sexual risk reduction

This overview draws on a wide range of sources from research and practice. Scientific reviews of experimental studies are valuable for assessing outcomes of single, well-defined interventions. However, they are insufficient regarding multidimensional interventions as implemented in diverse, real-life settings. Experimental designs are not always appropriate, feasible, or ethical and are limited to single types of intervention, thus excluding multiple interventions. Often, it is necessary to draw on a wider body of descriptive studies to obtain a fuller picture. Furthermore, it is essential to understand not only outcomes but also how interventions work (process) and how settings influence outcomes. Clinical, sociological, qualitative, modelling, and ecological studies can provide important evidence not only on the impact of interventions and policies but also on "what works and under what conditions."

The focus is on illegal drugs, especially opioids and central nervous system stimulants. Harm reduction approaches have been applied to other drugs including

alcohol, cannabis, and tobacco and to other user groups such as young recreational drug users (Ritter and Cameron 2006; Rhodes and Hedrich 2010).

83.2 Interventions

83.2.1 Opioid Substitution Treatment

Other chapters in this textbook deal with opioid substitution treatment (OST) as a treatment for heroin dependence. Here, the emphasis is on the role of OST in reducing individual and social harms associated with illicit opioid use. Methadone is the main drug employed, though buprenorphine has become more common since the end of the 1990s. In some European countries, heroin-assisted treatment is provided to long-term refractory heroin-dependent individuals who have not responded well on methadone programs (Strang et al. 2012). OST is usually provided in combination with psychosocial treatment, counselling, and other health and social services.

Within a harm reduction paradigm, OST consists of the (usually long-term) prescription of opioid agonists to prevent withdrawal symptoms and craving, thus enabling users to lead more stable lives and to reduce illicit heroin use, risk behavior, and criminal activity. Apart from reduced illicit heroin use, which has been demonstrated in numerous studies (see ▶ Chap. 28 "Opioid Addiction: Short- and Long-Acting Opioids" in this textbook), specific harm reduction outcomes that are sought include reductions in prevalence and frequency of drug injecting and sharing of drug using paraphernalia, incidence and prevalence of infectious diseases (especially HIV and hepatitis C), rates of drug-related mortality (especially overdoses), and rates of drug-related crime. Reductions in high-risk sexual behaviors, as well as improvements in health status, quality of life, and social functioning, are also objectives, though these are not specific to OST.

83.2.1.1 Evidence on Effectiveness

Three major reviews of multiple studies with robust designs all found strong evidence that OST is effective in reducing self-reported prevalence and frequency of injecting, sharing of injecting equipment, and injecting risk behavior scores (Sorensen and Copeland 2000; Tilson et al. 2006; Gowing et al. 2011). The same reviews found clear, consistent evidence that OST in community settings is effective in reducing HIV transmission, especially among those in continuous treatment and when dosages are adequate. A further review estimated that OST is associated with a 54 % reduction in risk of HIV infection among people who inject drugs (MacArthur et al. 2012).

The effectiveness of OST in reducing HCV transmission has been harder to determine because HCV is more easily transmitted through injecting risk behaviors and because baseline prevalence levels of HCV in drug-injecting populations are

often high. While some reviews report little impact of OST as a single intervention (Wright and Tompkins 2006), other recent studies, including a meta-analysis of UK-based studies and cohort studies of hepatitis C incidence among OST clients, suggest a positive impact of OST on preventing HCV infections (Turner et al. 2011; Kimber et al. 2010; ECDC and EMCDDA 2011). There is stronger evidence that OST combined with NSP for clients who continue drug injecting can be highly effective in reducing hepatitis C incidence, if coverage of both interventions is high (van den Berg et al. 2007; Des Jarlais et al. 2010; Turner et al. 2011).

There is strong, review-level evidence that OST reduces substantially the risk of overdose mortality, as long as doses are sufficient and continuity of treatment is maintained (Amato et al. 2005; Caplehorn et al. 1996; Kimber et al. 2010). A systematic review and meta-analysis of mortality among regular or dependent users of heroin from 58 prospective cohort studies, mostly of OST, found that treatment is clearly protective against mortality (Degenhardt et al. 2011).

There is clear, consistent evidence from many studies that criminal activity, arrest, and incarceration rates decline markedly after patients enter OST and that this effect is stronger the longer they remain in treatment (NIDA 2006). This is particularly true of drug-related criminal activity such as drug-dealing and acquisitive crime. Where sufficient coverage of opioid using populations is achieved, decreases in drug-related crime at individual level are reflected in reduced levels of crime at community level.

A recent systematic review of 21 studies conducted in prison settings concluded that the benefits of OST provided in prison are similar to those obtained in community settings (Hedrich et al. 2012). OST was significantly associated with reduced heroin use, injecting, and syringe sharing in prison if doses were adequate. Prerelease OST was significantly associated with increased treatment entry and retention after release if arrangements existed to continue treatment. For other outcomes, associations with prerelease OST were weaker. While some post-release reductions in heroin use were observed, evidence regarding crime and re-incarceration was equivocal. Due to lack of studies, there was insufficient evidence concerning HIV/HCV incidence, either in prison or post-release. There was limited evidence that prerelease OST reduces post-release mortality. Disruption of OST continuity, especially due to brief periods of imprisonment, was associated with very significant increases in HCV incidence (Dolan et al. 2005). There is also evidence that OST facilitates improved adherence to HIV treatment (Palepu et al. 2006) and modest reductions in high-risk sexual behaviors (Gowing et al. 2004; CDC 2012a).

83.2.1.2 Conclusion

Benefits of OST that have been clearly established include reduced illicit heroin use, injecting and risk behaviors, reduced HIV incidence, overdose mortality, and criminal activity. Reductions in HCV incidence, though reported in some studies, are less well established.

In prison settings, OST presents an opportunity to recruit problem opioid users into treatment, to reduce illicit opioid use and risk behaviors in prison, and

potentially to minimize overdose risks on release. If liaison with community-based programs exists, prison OST facilitates continuity of treatment and longer-term benefits can be achieved. For prisoners in OST before imprisonment, prison OST provides treatment continuity, especially important for drug users who are incarcerated for short periods.

There are also limitations. OST is not suitable for users of non-opioid drugs, nor is it appropriate for drug users who have only recently started to use opioids, even though the early stages of use are associated with high risks of becoming infected with HCV through using another person's paraphernalia. Even in countries with high levels of OST provision, it is unusual for coverage of the total opioid-dependent population to rise above 50–60 % (EMCDDA 2012). While other treatment modalities meet some of the shortfall, there remain important populations of problematic drug users who do not come for treatment, or who do not fare well in treatment. Other approaches need to be pursued alongside or in combination with OST.

Specific risks of OST include the possibility of (methadone) overdose during the early stages of treatment indicating the need for caution over dosages and the advisability of supervised consumption during induction. Methadone overdoses also occur in association with careless prescribing or the use of illicit methadone from diversion or thefts. Different challenges arise from the accumulation of ageing, long-term patients on OST, many with multiple comorbidities. A harm reduction approach includes encouraging OST clients to become drug-free when they can but also accepts that for some, this is not possible.

Several important lessons learned should be stressed. Adequate doses are essential. While individual dosage levels vary, positive outcomes are mostly achieved when average program methadone dosages are in the 60–120 mg range (Faggiano et al. 2003; WHO 2009). Continuity too is vital, accompanied by appropriate psychosocial support and health education. Studies comparing methadone and buprenorphine show that while buprenorphine is effective, it is less effective than methadone delivered at adequate doses (Mattick et al. 2008).

83.2.2 Needle and Syringe Programs

Needle and syringe programs (NSPs) are specialized services that distribute sterile injecting equipment to people who inject drugs. They are usually located close to areas where drug injecting is more prevalent. They are almost always part of a wider network of local services. Their primary objective is to facilitate more hygienic injecting practices and to reduce sharing or reuse of needles, syringes, and other injecting paraphernalia in order to prevent injection-related complications, especially transmission of HIV and HCV. In addition, NSPs serve as important contact points for drug users who have little contact with treatment or other health services. Thus a supplementary objective is to deliver health promotion information and to facilitate access to health care, including OST or other treatment. They routinely distribute condoms and offer advice on safer sex. Some offer non-injecting equipment. NSPs may be equipped to provide testing for infectious

diseases and STDs, as well as vaccination for hepatitis B and basic health care. Dedicated NSPs are usually fixed-site, though may also have mobile units or outreach teams. In some countries, NSPs are implemented through national networks of pharmacies. In other settings pharmacy-based programs and vending machines supplement specialized NSPs. In some countries, NSPs have been established in prisons.

83.2.2.1 Evidence on Effectiveness

A broad body of evidence indicates that NSPs are effective, as part of a multicomponent set of responses, in reducing injecting risk behaviors and in limiting transmission of blood-borne infections, without increasing the prevalence or frequency of injecting (WHO 2004a; Tilson et al. 2006; Department of Health and Human Services 2011). There are methodological difficulties in separating the impact of NSPs from that of other interventions and local contextual factors, which means that rigorous studies of the effectiveness of NSPs as a single intervention are limited. Two early studies in Montreal and Vancouver found negative outcomes in settings where NSPs attracted marginalized, high-frequency cocaine injectors while at the same time operating restrictive policies regarding syringe exchange (Tilson et al. 2006). Otherwise, evidence from systematic reviews of NSPs across a range of settings indicates that they are effective in reducing self-reported risk behaviors associated with injecting (Palmateer et al. 2010; Kimber et al. 2010). Review-level evidence regarding their independent impact on HIV incidence is also positive though more tentative and for HCV is considered insufficient (Tilson et al. 2006; Kimber et al. 2010). A larger number of descriptive studies support the conclusion that NSPs as part of a wider package of responses are associated with reduced HIV incidence and, as noted earlier, several studies suggest that the combination of NSPs and OST is effective in reducing HCV, if coverage of both interventions is adequate (WHO 2004a; van den Berg et al. 2007; Des Jarlais et al. 2010; Turner et al. 2011). There is also evidence that NSPs are cost-effective (Jones et al. 2008; The National Centre for HIV Epidemiology and Clinical Research 2009).

There is some review-level evidence to support the effectiveness of pharmacy access to needles and syringes, in addition to dedicated NSPs, in reducing self-reported injecting risk behavior, and weaker evidence regarding reductions in HIV, though not HCV incidence (Kimber et al. 2010; ECDC and EMCDDA 2011). Scientific evidence on the impact of vending machines is limited but suggests that they can complement NSPs in specific locations by providing 24 h coverage (Islam and Conigrave 2007).

Although rigorous review-level evidence is lacking on the impact of NSPs in prison settings, reviews of descriptive studies in different countries report important reductions in injecting risk behaviors, as well as some evidence that they may limit HIV and HCV incidence (Stöver and Nelles 2003; Dolan et al. 2003; WHO et al. 2007).

There is also evidence that NSPs have a positive impact in terms of facilitating entry and retention in drug treatment (Hagan et al. 2000), improved health care, and reductions in sexual risk behaviors (CDC 2012a).

83.2.2.2 Conclusion

Benefits of NSPs, when implemented appropriately, include important reductions in injecting risk behaviors and HIV transmission. They also play a valuable role in health promotion, sexual risk reduction, and facilitation of access to health care including treatment. In combination with other harm reduction interventions, they can make a significant contribution to reducing not only HIV but also HCV transmission. There is no evidence that the establishment of NSPs encourages non-injectors to start injecting, or that the frequency of injection increases among those who attend them (Tilson et al. 2006). There were no reports of adverse events involving syringes in the studies of prison-based NSPs.

Many important lessons have been learned over the past three decades. It is essential to aim for full coverage of clients' injecting needs. Restrictions on the number of needles and syringes distributed, or insistence on returning used equipment, can be counterproductive, especially for high-frequency injectors such as cocaine users, since this can facilitate reuse and sharing. The underlying principle should be at least 100 % coverage of each injection ("one shot, one syringe") and distribution according to need rather than one-for-one exchange. It is also important to achieve wide coverage of local populations of drug injectors. Many NSPs allow secondary distribution, where clients distribute clean needles and syringes to their partners or peers. Mobile units and outreach are valuable to further extend coverage.

Injecting equipment should be appropriate for the local context and take account of factors such as type and preparation of drugs that are commonly injected. Injectors often have preferences for certain types or sizes of equipment. Apart from needles and syringes, it is necessary to provide other injecting-related paraphernalia, including alcohol swabs, sterile water, filters, mixing vessels (e.g., spoons or "cookers"), and acidifiers (e.g., ascorbic acid or citric acid powders) to assist dissolving the substance to be injected (ECDC and EMCDDA 2011).

Health promotion should cover information on viral infections, how they are transmitted and how they can be avoided, practical advice on hygiene and safer injecting, as well as information on STDs and on ways of reducing sexual risks. It should include provision of condoms, information on health and social services, and, when appropriate, referral to drug treatment. While staff can encourage clients to consider entering treatment, or to change to safer routes of administration, this should not be linked to pressure such as implied withdrawal of services. Since NSPs come in contact with out-of-treatment drug injectors, it is valuable if they have the capability to carry out on-site counselling, testing, and monitoring of HIV, viral hepatitis, STDs, and TB, as well as vaccination for hepatitis B. Some NSPs also provide basic health care (e.g., wound dressing) or overdose prevention education, including naloxone.

It is important to distinguish receptive and distributive sharing. While receptive sharing (borrowing) should be strongly avoided, even if the lender is known to be seronegative, it is even more important that distributive sharing (lending) by persons who are seropositive is prevented. There is evidence that drug users reduce their distributive sharing (and also sexual risk behaviors) if they know that they are

seropositive, even if they do not change their receptive sharing behavior (Des Jarlais et al. 2004). Testing and behavior change counselling are essential, not only for those who are seropositive but also for those who test negative, since it is important to avoid complacency.

Despite advice not to reuse syringes, personal reuse does sometimes occur. If this is thought to be frequent, then the availability of syringes and needles needs to be increased. A second-best (and controversial) suggestion is to teach users to sterilize their equipment using bleach. While effective for HIV in the laboratory, there is insufficient evidence of effectiveness in practice because correct disinfection procedures are not or cannot always be followed, especially in settings such as prison or on the street (Small et al. 2005; ECDC and EMCDDA 2011). Another suggestion has been to make available low dead-space syringes (LDSS) in addition to other syringes. LDSS reduce the amount of blood remaining in the syringe after completely pushing down the syringe plunger (WHO 2012; Zule et al. 2013). However, there is a risk that this may appear to accept sharing, in contradiction to the clear message that syringes should not be reused or shared. The provision of fresh equipment for each injection should be a priority.

Safe disposal of used equipment is important. NSPs can facilitate safe disposal by receiving used syringes or by providing puncture-resistant disposal containers to clients. However, if carrying used needles and syringes is a criminal offence or may be used as evidence of drug use, clients may be reluctant to bring used equipment back.

Accessibility and acceptability to target populations are important. This means setting up NSPs in appropriate locations, with easy access and a minimum of bureaucratic entry requirements. Opening hours should include evenings and weekends. Staff should be positive and sympathetic. Qualified nursing personnel are important, and other staff, including peer workers, need to be trained.

NSPs are mostly implemented in urban settings and areas with a higher prevalence of injecting. In smaller towns and rural settings, a pharmacy-based model may be more appropriate.

Apart from (free) distribution through NSPs, needles and syringes can be purchased at pharmacies in many countries, though various formal or informal restrictions can discourage people from using this option, and even a low price may be a disincentive for low income populations.

The distribution of non-injecting paraphernalia has been suggested for people who smoke heroin or cocaine (Leonard et al. 2008). One pilot study suggested that distributing foil and smoking materials from needle and syringe programs helps to promote transitions from heroin injecting to chasing (Pizzey and Hunt 2008).

Despite clear evidence on the benefits of NSPs, opposition from local policy makers, professionals, and community groups can hinder the establishment of NSPs. Consultation with relevant local bodies is essential. Careful planning and coordination with local health and treatment services is important to establish clear procedures for referral links. Agreement needs to be reached with justice and police officials to avoid counterproductive interventions.

83.2.3 Supervised Drug Consumption Facilities

Drug consumption rooms (DCRs) are professionally supervised health-care facilities where drug users can use drugs in safer and more hygienic conditions (Hedrich et al. 2010). DCRs seek to attract hard-to-reach populations of drug users, especially marginalized groups and those who use drugs on the streets or in other risky and unhygienic conditions. They aim to reduce morbidity and mortality by providing a safe environment for more hygienic drug use and by training clients in safer drug use. At the same time, they seek to reduce public drug use and improve public amenity in areas surrounding urban drug markets. A further aim is to promote access to social, health, and drug treatment facilities. Since 1986, more than 90 DCRs have been set up in seven European countries as well as in Canada and Australia (Hedrich et al. 2010) and are planned in several more. They are highly targeted services addressing specific local problems within a wider network of services. Access is typically restricted to registered service users. They usually operate from separate areas attached to existing facilities for drug users or the homeless, though some are stand-alone units. Most target drug injectors, though increasingly cover users who smoke. At times, they have been controversial due to concerns that they may encourage drug use, delay treatment entry, or aggravate problems of local drug markets, and initiatives to establish DCRs have been prevented by political intervention.

83.2.3.1 Evidence on Effectiveness

Evidence shows that DCRs succeed in reaching their target populations and achieve immediate improvements in hygiene and safer use for clients who use the services. There is consistent evidence that DCR use is associated with self-reported reductions in injecting risk behavior such as syringe sharing as well as reductions in public drug use and nuisance such as discarded syringes (Hedrich et al. 2010). Due to a lack of studies, methodological problems of isolating the effect of DCRs from other interventions, or low coverage of the risk population, there is insufficient evidence on effectiveness regarding reduced HIV or HCV incidence (Kimber et al. 2010). There is evidence that use of the facilities is associated with increased uptake both of detoxification and of OST. There is tentative evidence from ecological studies that DCRs may contribute to reducing drug-related deaths at a city level where coverage is adequate (Hedrich et al. 2010; Marshall et al. 2011). There is also evidence that DCRs are generally accepted (or at least seen as the lesser of two evils) by local communities and officials, albeit with some reservations (Hedrich et al. 2010).

83.2.3.2 Conclusion

Benefits of DCRs include improvements in safe, hygienic drug use, especially among regular clients; increased access to health and social services; and reduced public drug use and associated nuisance. The availability of safer injecting facilities does not increase drug use or frequency of injecting, it facilitates rather than delays treatment entry, and does not result in higher rates of local drug-related crime.

DCRs have mostly been established in specific urban settings with problems of public drug use or where there are subpopulations of drug users with limited possibilities of hygienic injection (e.g., homeless, living in insecure accommodation or shelters). In some cases, DCRs are also utilized for various reasons by more socially stable clients, for example, because they live with non-using partners or families. As with NSPs, consultation with local key actors is essential to minimize community resistance or counterproductive police responses.

83.2.4 Overdose Prevention

Although rising overdose deaths often serve as a catalyst for concern over drug use, efforts to develop specific interventions to reduce overdoses have emerged more slowly than responses to other drug-related problems like dependence, crime, or HIV/AIDS. As noted above, OST significantly reduces overdose mortality, and DCRs may make a contribution at the local level. A promising approach to reducing opioid overdose deaths is offered by community-based overdose prevention programs that include peer naloxone distribution (CDC 2012b).

Naloxone (Narcan®) is an opioid antagonist used in medical emergencies to reverse respiratory depression caused by opioid overdose. It has no effect on non-opioid drug overdoses and has a high safety margin. It is available in an injectable form and, in the USA and some other countries, as an intranasal spray.

The aim of naloxone distribution programs is to increase the availability of effective medication in places where overdoses are more likely to occur. The rationale is that overdose is common among opioid users. In some studies, over a third have experienced an (nonfatal) overdose and two-thirds have witnessed one (Lagu et al. 2006). Many people who die from opioid overdose fail to receive proper medical attention because their peers and other witnesses (often other drug users) do not recognize the seriousness of the situation and delay or do not call emergency services for fear of police involvement (Pollini et al. 2006).

Peer naloxone distribution programs work by training drug users and other likely first responders (peers, families) as well as frontline services such as health-care providers, staff in homeless shelters, and in some cases police officers on how to recognize and respond to an overdose, including the administration of naloxone, until emergency medical help is obtained. In the USA, the first program began distributing naloxone in 1996. The number of programs has subsequently risen to at least 50 in 15 states (CDC 2012b). Programs are also reported in other countries including the UK and Australia (Strang et al. 2008; Kerr et al. 2009).

83.2.4.1 Evidence on Effectiveness

Review-level evidence is lacking, but studies indicate that peer naloxone distribution is feasible (Strang et al. 2008; CDC 2012b). Evidence on impact suggests that it can be effective in reducing overdose deaths at community level (Maxwell et al. 2006; Walley et al. 2013). A survey of 48 programs across the USA concluded that distribution of naloxone and training in its administration might have prevented

numerous deaths from opioid overdoses (CDC 2012b). There have been questions of whether nasal administration is as effective, but several studies have found that it can be used safely and effectively outside of hospital settings (Kerr et al. 2009; Doe-Simkins et al. 2009), including on a take home basis (CDC 2012b). A recent study suggests that naloxone distribution is cost-effective (Coffin and Sullivan 2013).

83.2.4.2 Conclusion

Potential benefits include substantial reductions in opioid overdose deaths, if sufficient coverage of risk populations can be achieved. It is recommended by CDC in the USA and by the Global Fund to Fight AIDS, TB and Malaria as a component of a comprehensive package of services for drug users.

In most jurisdictions, naloxone is a prescription only medicine and its use is restricted to medical personnel or to patients to whom it is prescribed. It is thus necessary to change regulations to enable administration by laypeople, as has occurred, for example, in several US states (CDC 2012b). The risks are low as it is a safe drug and there is no evidence that it may encourage risky drug taking. Administration via nasal spray offers advantages for nonmedical responders. Further information is available in a manual developed by the Harm Reduction Coalition (2012).

Even if naloxone distribution is not feasible, increasing risk awareness and response skills among professionals in contact with drug users, and disseminating information to users, their peers, and families, constitutes an important part of a comprehensive program to reduce overdose mortality. Prison release or treatment discharge counselling on overdose risk should be a key component. Crisis intervention and counselling at hospital emergency rooms following admission for overdose have been tried in some countries. New online tools can be used for awareness raising and risk assessment. Precautions over prescribing opioids (especially together with CNS sedatives) are also important, since in the USA a significant proportion of drug overdose deaths are associated with prescription opioids and sedatives (CDC 2013).

83.2.5 Outreach, Peer Education, and Health Promotion

Community-based outreach aims to facilitate improvements in health and reductions in risks and harms for individuals and groups who are not effectively reached by fixed-site services or through traditional health education channels (Rhodes and Hartnoll 1991; Needle et al. 1998, 2005; NIDA 2000; WHO 2004b). It seeks to achieve this through identifying and contacting target groups of drug users in different community settings in order to deliver in situ interventions to hard-to-reach populations, as well as to provide a contact point for increasing access to a range of other services. Depending on the circumstances, interventions may include dissemination of information on drug- and sex-related harms and risk behaviors, provision of advice and counselling on individual behavior change, distribution of sterile injecting equipment and condoms, overdose prevention training including naloxone distribution, and measures to facilitate access to health care, social services, and drug treatment.

Outreach projects may operate from a stand-alone base but are often attached to community health and social services such as NSPs, street-level low-threshold services, treatment centers, etc. Target groups include homeless, migrant or minority group users with limited access to services, street users, sex workers, chaotic stimulant and multiple drug users, or more private, closed groups.

Many variants of outreach have been described (Rhodes and Hartnoll 1991, 1996; NIDA 2000; Needle et al. 2005). Some are based on professional youth or community health workers, others originated from ethnographic research involving indigenous leaders to target at risk networks and individuals, others have focused on promoting peer-driven outreach, and others have developed out of advocacy or self-help organizations. Some concentrate on the individual level (information and awareness raising, referral or support for change), while others give greater emphasis to a network approach involving peer education and modification of peer norms or empowerment of vulnerable groups.

83.2.5.1 Evidence of Effectiveness

A review of over 40 studies of outreach interventions to prevent HIV infection among injecting drug users concluded that outreach is an effective strategy for reaching hard-to-reach, hidden populations of IDUs and provides the means for enabling IDUs to reduce their risk behaviors. A significant proportion of IDUs receiving outreach-based interventions reduced their risk behaviors (drug using, needle and sexual practices) and increased their protective behaviors. Uptake of voluntary testing, counselling, and drug treatment was also increased through referral from outreach teams (Needle et al. 2005). This confirms earlier studies of outreach effectiveness (Stimson et al. 1998).

Peer group social norms about modes of drug use, including the sharing of injecting equipment, have a strong influence on behavior (Grund et al. 1996). In the early stages of the HIV epidemic among injecting drug users in the USA, users were already changing their risk behaviors prior to formal interventions (Des Jarlais et al. 1988). This has encouraged peer-based outreach to focus on changing social norms regarding safer behavior as well as on individual change (Latkin et al. 2003).

Studies of network approaches suggest that, given guidance and nominal incentives, injecting drug users can play a more extensive role in community outreach efforts than the traditional model allows. While both traditional and peer-driven interventions reduce HIV-associated risk behaviors, peer-driven outreach reaches a larger and more diverse set of drug injectors and does so at less expense (Needle et al. 1998).

83.2.5.2 Conclusion

Outreach is a flexible and effective component of local harm reduction strategies. It is essential that outreach workers can establish rapport with target populations and gain acceptance as trusted and knowledgeable sources of information and advice. It is vital to ensure confidentiality and to communicate messages clearly. Outreach workers need adequate training, support, and protection, especially in peer-driven interventions. This is helped by clear guidelines covering objectives,

services offered, responsibilities, and limits (personal, professional, legal, etc.) (NIDA 2000). Concrete procedures with other local agencies are important to maximize the uptake of referrals. Drug users and user organizations should be actively involved as partners in planning and conducting outreach.

83.2.6 Testing, Vaccination, and Treatment of Infectious Diseases

Public health guidelines recommend a comprehensive approach to prevention and treatment of infectious diseases among high-risk populations. This chapter highlights selected key points of relevance to practitioners and managers involved in harm reduction interventions for problem drug use. Extensive information on public health policy, scientific evidence, and clinical practice can be found in reviews and guidelines published by public health institutions (e.g., ECDP and EMCDDA 2011; CDC 2012a; WHO 2012).

Recommended core measures include provider-initiated offer of voluntary, confidential screening for HIV, hepatitis B and C, common STDs, and TB; vaccination for hepatitis A and B and where clinically indicated for tetanus, influenza, and pneumococcus (HIV positive); and antiretroviral treatment (ART) for HIV, as well as treatment for STDs, TB, and hepatitis C. Care should be taken about potential medication interactions, including methadone, especially in the treatment of people with coinfections.

Testing offers the opportunity to provide information and health education to all clients, as well as to identify cases for vaccination or treatment. Knowledge of serostatus provides an informed basis for discussing changes in drug use and sexual behavior with clients and has been found to be associated with positive behavior changes (Des Jarlais et al. 2004, 2010). A study in 20 cities across the USA in 2009 reported 9 % prevalence of HIV among people who inject drugs, of whom 45 % did not know that they were positive (CDC 2012c). Testing of clients can also provide opportunities to encourage partners to be tested and to participate in changes needed to reduce risks. Periodic health checks and monitoring of seronegative individuals can help reinforce protective behaviors. It also contributes to monitoring program effectiveness.

Antiretroviral treatment (ART) is now a highly effective treatment for HIV. It not only benefits individuals but has important preventive effects, since it reduces infectivity and thus the risk of transmission to others (WHO et al. 2013). ART during pregnancy sharply reduces viral load and risk of mother to child transmission of HIV (WHO 2010). When used consistently, ART preexposure prophylaxis has been shown to be effective in men who have sex with men (MSM) and heterosexually active men and women. Trials are under way to assess its effectiveness for drug injectors (CDC 2012a).

Treatment of hepatitis C is effective though expensive. Drug use per se is not now considered to be an exclusionary criterion (WHO 2012). Adherence to treatment is improved through accompanying OST and social-psychological support (this applies to ART also) (ECDC and EMCDDA 2011). Given the challenges of

preventing HCV, treatment of hepatitis C offers an alternative long-term preventive approach. The development of new drugs may make treatment as prevention a realistic goal in the future.

Universal vaccination of children for hepatitis B and vaccination campaigns targeting high-risk groups mean that hepatitis B should become increasingly rare in the future (the USA and the EU have eradication plans). Meanwhile, it is valuable to continue screening for HBV and where appropriate offer vaccination using the Accelerated Schedule (WHO 2012).

STDs increase the risk of sexual transmission of HIV by a factor of 2–5 (CDC 2010). Thus identification and treatment of common STDs is one of the principle HIV prevention strategies among sexually active individuals, especially in high-risk populations (Tilson et al. 2006).

Access to and uptake of testing and treatment of infectious diseases and STDs can be increased by developing on-site screening at services for drug users such as drug treatment centers or NSPs. Rapid testing techniques now make this feasible in a variety of contexts, including low-threshold services and outreach. Where possible, treatment delivery should take place at the same sites to improve uptake. If this is not possible, then active referral pathways to public health facilities should be established. Rapid HIV testing kits (OraQuick) for home use have now been approved by the FDA in the USA and are available from major pharmacies. This further extends prevention possibilities.

83.2.7 Interventions for Stimulant Use

There is a substantial literature on harms that can arise from heavy use of cocaine or amphetamine-type stimulants (Grund et al. 2010). However, many harm reduction interventions are based on models developed in response to opioid use. Less information is available on interventions that specifically target harms of stimulant use.

Apart from dependence, harms associated with chronic stimulant use include a variety of cardiovascular, pulmonary, or neurological damages; mental health problems such as acute psychotic episodes; chaotic behavior, including higher rates of needle sharing associated with intensive, high-frequency injection; increased risk of HIV and STDs linked to high-risk sexual activity (Colfax and Shoptaw 2005); and increased risk of HIV and HCV associated with cocaine smoking, both through sharing paraphernalia and through sexual contact. In high cocaine prevalence areas, significant numbers of acute cocaine episodes are seen by medical emergency services, and cocaine (injected or smoked) is reported in a majority of overdose deaths, often in combination with opioids (CDC 2012a).

The likelihood of harm varies according to context. For example, crack cocaine use is most likely to be found among highly marginalized groups and is associated with elevated levels of risk of transmission of HIV, especially for women who trade sex for money or drugs (Booth et al. 2000). Crack is sometimes injected as well as smoked, adding a further risk dimension (Rhodes et al. 2006). Transmission of

HCV may also occur through sharing of crack pipes via oral sores and cracked lips (Fischer et al. 2008). Methamphetamine use, especially by men who have sex with men (MSM), is associated with high levels of sexual risk behavior (Shoptaw and Reback 2006; CDC 2012a). High levels of cocaine use may also be found among more socially integrated users who sniff rather than inject or smoke the drug. While health risks associated with this route of administration are lower, they still remain, especially through higher sexual risk behavior and possibly through sharing straws. The social networks and economic resources of more socially integrated cocaine users may enable them to resolve problems without contacting services (Decorte 2000). For the most part, problem stimulant use seen at public services is associated with lower socioeconomic status and a range of social and legal problems, in addition to a variety of psychiatric comorbidities (Grund et al. 2010).

Harm reduction interventions available for stimulant users include psychosocial treatment, NSPs, outreach and peer-driven programs, sexual risk reduction education, information campaigns including web-based dissemination, crack kits, assertive community treatment, environments to reduce anxiety and increase control over use, as well as approaches based on alternative medicine. ART preexposure prophylaxis may also be relevant for high-risk sexual behavior.

83.2.7.1 Evidence on Effectiveness

Apart from treatment evaluations, there are few high-quality scientific studies of interventions to reduce specifically the harms of stimulants. Systematic reviews indicate that outpatient treatment including contingency management, cognitive behavior therapy, or motivational interviewing offers modest improvements, more so when interventions are multimodal and intensive (De Lima et al. 2002; Knapp et al. 2007; EMCDDA 2010). Retention rates in treatment tend to be low, reducing the potential for systematic efforts to reduce risk behaviors.

Existing interventions that partially cover stimulant-using populations (mostly of cocaine) include OST for those who also use opioids. While many clients benefit from OST in terms of reduced cocaine use, continued cocaine use has a disruptive effect on OST outcomes (Williamson et al. 2006). Research has yet to confirm effective specific pharmacological treatments, and work on a cocaine vaccine progresses slowly. There is no established equivalent of OST for stimulant users. There have been preliminary studies of substitution treatment with dexamphetamine or modafinil (Castells et al. 2010), and a recent translational review suggests that agonist replacement therapy, especially monoamine releasers, may be effective for managing cocaine dependence (Rush and Stoops 2012), especially if novel compounds or formulations that have less misuse and diversion potential can be identified.

NSPs can be effective for injecting stimulant users as well as for opioid users. As noted earlier, stimulant injectors inject frequently and need a plentiful supply of sterile syringes and needles. Given the chaotic lifestyle, frenetic drug using behaviors, and disturbed sleep patterns often seen in compulsive stimulant injectors, providing adequate coverage of injecting needs, potentially for up to 24 h per day, is a challenge for any service. Mobile units and syringe dispensing machines can help extend coverage in terms of times and places.

Most DCRs were initially established for heroin injectors and often did not admit cocaine injectors or smokers. Increasingly, these facilities adapt to client needs and have set up separate rooms for smokers of cocaine or heroin. This has proved to be feasible, attracting important subgroups such as crack-using sex workers, and appears to provide benefits similar to those that obtain for heroin users (Hedrich 2004; Grund et al. 2010).

It has been suggested that traditional harm reduction services fail to reach problem stimulant users due to opiate-centered services and social barriers to young or female users (Grund et al. 2010). Greater emphasis needs to be placed on outreach and peer education approaches (see above), especially for younger users. For example, a peer-run, all night street NSP in Vancouver was able to deliver harm reduction services to the city's most vulnerable cocaine injectors (Wood et al. 2003). An unpublished PhD thesis by Henskens on a randomized controlled trial of Assertive Community Treatment for marginalized crack users in Rotterdam indicated good program compliance and improvements in physical and mental health (Grund et al. 2010).

In response to the risks associated with smoking crack, some programs in the USA, Brazil, Canada, and France have developed "crack kits". These include a Pyrex tube, plastic tips, filters, lip balm, sterile compresses, chewing gum for salivation, and condoms. Initial results suggest that sharing of crack pipes decreased dramatically, while crack users reduced injecting and more often smoked cocaine (Leonard et al. 2008). However, crack kits are controversial and rarely funded.

Regarding crack, there is some evidence that the severity of mental health harms associated with cocaine is related more to the intensity and context of use than to the specific form of cocaine used (Haasen et al. 2005). Harm reduction measures aimed at safer, more controlled, less intensive use of cocaine together with steps to stabilize the social situation may help to decrease mental health problems.

Other approaches include acupuncture as an adjunct to treatment to reduce craving, though a systematic review of controlled trials found no evidence of effectiveness (Gates et al. 2006), or providing accessible and flexible walk-in calming environments to reduce agitation and anxiety levels (Grund et al. 2010). Advice, counselling, and treatment services for socially integrated users may be more attractive if separated from services for opioid users and drug injectors and if they operate at appropriate hours, for example, evenings. Interventions for less intensive users include information dissemination on managing mental health risks or on stimulant use via flyers or websites, personal messaging via mobile phones, or "pill-testing" in nightlife settings.

83.2.7.2 Conclusion

Patterns of stimulant use and risks can vary greatly from one setting to another. For example, in some former Soviet Union republics, home production of stimulants is associated with specific and highly risky patterns of drug consumption (Grund et al. 2010), and in the UK, groin injection of crack cocaine raises special

challenges (Rhodes et al. 2006). In some settings, women are particularly at risk. This means that interventions need to be thoughtfully planned to take account of local circumstances and vulnerable groups. This should include critical reflection on whether any unintended negative effects might arise. While there is much room for innovative development of harm reduction responses, it should be stressed that all interventions for stimulant users need to give high priority to sexual as well as drug-related risks.

83.2.8 Drug-Related Sexual Risk Reduction

Many harm reduction interventions concentrate on drug-related risks but overlook sexual risks. Since many patterns of drug use, injecting and non-injecting, are associated with elevated risks of contracting or transmitting STDs including HIV, all interventions should if possible include sexual as well as drug risk reduction components. Priority targets for more intensive efforts include sex workers, stimulant users, MSM, female crack users, and partners of HIV-/HCV-positive users. Some of the risk factors and settings associated with elevated sexual risks have been mentioned earlier in this chapter.

Apart from testing and treatment of STDs, interventions to reduce sexual risks include condom distribution and information, education, and counselling. These can be carried out at drug treatment centers, NSPs, STD clinics, and low-threshold services including outreach and peer education. ART preexposure prophylaxis is now also becoming a possible option. The Internet, social media, and mobile phone messaging offer new means of communicating health counselling and advice.

Evidence suggests that condom distribution among young or high-risk populations in general is effective in terms of increasing condom use and reducing STDs (CDC 2012a). Interventions improving the availability of condoms in specific risk settings or increasing their accessibility among risk groups, as well as including additional individual, small-group, or community-level components along with condom distribution, were shown to be efficacious in increasing condom use behaviors. Free distribution facilitates availability and accessibility.

Sex risk education and counselling is also effective (Semaan et al. 2002, 2010; Meader et al. 2010, 2013). Systematic reviews show that significant reductions in sexual risks can be achieved through standard, relatively brief educational interventions and that multi-session psychosocial interventions offer only modest additional benefits. People in formal treatment are more likely to respond to multi-session psychosocial interventions. It also appears single-gender groups may be associated with greater benefit. Generally, brief standard education interventions appear to be a more cost-effective option.

It is important to stress the importance of gender sensitive interventions, given the higher risks and vulnerability of many women problem drug users. More intensive efforts are necessary to empower women to be able to adopt safer sexual practices with partners or clients.

83.3 Conclusion

This chapter has provided an overview of different interventions that contribute to reducing drug-related harms. Harm reduction does not replace the need for treatment but adds to our capacity to respond effectively to the wide range of health and social challenges raised by drug use. It is clearly established that single interventions are far more effective when implemented together as part of a broader package, including steps to facilitate enabling environments that foster healthier and safer living. Combining interventions into a coherent harm reduction approach is covered in ▶ Chap. 84 "Harm Reduction Policies, Settings, and Challenges" in this textbook.

Harm Reduction Policies, Settings and Challenges

84

Richard Hartnoll and Dagmar Hedrich

Contents

Abstract

Harm reduction has become an increasingly important dimension of drug policy over the past three decades. This chapter describes what harm reduction is and how harm reduction policies take account both of individual risk behaviors and of risky settings in order to promote improvements in individual and public health and societal well-being. Another chapter in this textbook, ▶ Chap. 83, "Harm Reduction Interventions", gives an overview of specific interventions.

Richard Hartnoll has retired.

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment: International Perspectives*, DOI 10.1007/978-88-470-5322-9_63,

This chapter covers the following: what harm reduction is, its history and current status from an international perspective, drug-related harms, risk behaviors, risk settings, harm reduction as a combination intervention, implementing an integrated approach at local level, needs assessment in local settings, enabling environments, epidemiological settings, prison settings, law enforcement settings, overcoming barriers, and promoting health and equality of care. It concludes that harm reduction policies and interventions have been successfully implemented in many countries around the world; that over the past two decades, political and professional opinions have increasingly promoted a "comprehensive approach" that includes harm reduction as a central pillar; and that while heroin use and related problems, as well as HIV among drug injectors, are now largely under control in countries that have implemented comprehensive harm reduction policies, challenges remain in those and other countries, including hepatitis C, problems related to stimulant drug use, and continuing sexual transmission of infectious diseases related to drug use. Apart from client-oriented skills, practitioners need an understanding of the community and public health settings within which drug use and drug-related harms arise.

84.1 Introduction

Harm reduction has become an increasingly important dimension of drug policy over the past three decades. The chapter in this textbook, ▶ Chap. 83, "Harm Reduction Interventions," gives an overview of specific harm reduction interventions. This chapter describes what harm reduction is and how harm reduction policies take account both of individual risk behaviors and of risky settings in order to promote improvements in individual and public health. It also stresses harm reduction as a combined response and the importance of a comprehensive, integrated approach.

84.2 Policies, Settings, and Challenges

84.2.1 What Is Harm Reduction?

Harm reduction is a multidimensional response encompassing interventions, programs, and policies that seek to reduce the health, social, and economic harms of drug use to individuals, communities, and societies (Rhodes and Hedrich 2010). Harm reduction policies are also found in related areas of public health and social policy, for example, alcohol policy, safe sex, or nicotine replacement.

Harm reduction is based on the concept of harmful drug use. This is wider than, though includes, the concept of dependence. It does not assume that drug use per se is harmful. It can be seen as a pragmatic approach in which the goal is to reduce the harmful consequences of drug use through a package of evidence-based, targeted interventions tailored to local settings and needs. Harm reduction programs

typically work through a hierarchy of goals in which the most pressing needs are addressed first (IHRA 2010).

Drug-related harm refers both to individual consequences such as dependence, overdoses, or infectious diseases contracted through sharing paraphernalia and to social, economic, and public health harms to the community (public nuisance, crime, health-care costs, high HIV prevalence). The underlying public health paradigm is broader than client-centered treatment and involves balancing individual and societal needs.

A harm reduction policy entails a "combination intervention approach" involving a coordinated response from a variety of agencies and services, including treatment, prevention, public health, law enforcement, community groups, and local authorities (Rhodes and Hedrich 2010; ECDC and EMCDDA 2011; WHO et al. 2013). This approach goes beyond interventions for individuals by stressing enabling environments to enhance protective factors, reduce harms, and promote public health.

Harm reduction incorporates an important ethical dimension concerning human rights, equality of access to health and social services, respect of the right to privacy and confidentiality, and efforts to counteract social exclusion and stigma (IHRA 2010; Jürgens et al. 2010).

It also acknowledges that important unintended negative consequences can arise from reactions to drug use (European Commission 2009; UNODC 2009). These include structural factors such as the wider policy and legislative framework as well as risk environments that increase social exclusion of already marginalized sections of the community, foster reluctance to seek help for fear of arrest, or exacerbate the HIV epidemic among drug users (Rhodes 2009; Wood et al. 2009; Degenhardt et al. 2010).

84.2.2 History and Current Status

Early examples of harm reduction include the so-called British System of opiate maintenance for patients who, while capable of "leading a useful and fairly normal life" on a stable dose of the drug of addiction, were unable to do so when the regular allowance was withdrawn. In the early 1970s, various ad hoc harm reduction responses evolved at grass roots level in some western European cities (street agencies, outreach, user-driven organizations, and information dissemination). Methadone maintenance, which had originated in the USA, was introduced in a handful of European countries.

Harm reduction as a policy started to gain wider acceptance in Europe with the emergence and rapid spread of HIV/AIDS among drug injectors in the mid-1980s. For example in Britain, the spread of HIV was seen as "a greater danger to individual and public health than drug misuse" (ACMD 1988). The WHO also endorsed the underlying principles of harm reduction (WHO 1986). From 1985, opioid substitution treatment (OST) expanded to more mostly western European countries, and needle and syringe programs (NSPs) were progressively introduced.

Over the 1990s both OST and NSPs extended, albeit unevenly, to most countries including central and eastern Europe (Hedrich et al. 2008).

Beyond Europe, harm reduction approaches emerged in countries such as Australia and Canada (Pates and Riley 2012). Harm reduction interventions also developed in the 1980s in some US cities such as San Francisco (Watters et al. 1994), Chicago (Wiebel 1996), and New York (Des Jarlais et al. 1988) though opposition from federal government and influential lobbies meant that they were not described as such.

Harm reduction is now a major pillar of drug policy in all EU member states (Hedrich et al. 2008) and globally is supported by at least 97 countries (Stoicescu 2012). It is firmly established as a mainstream systemic response promoted in official declarations by the WHO, United Nations, and European Union as a key element of a comprehensive approach (Council of the European Union 2003; WHO et al. 2013).

Within these overall developments, the range of interventions and scale of implementation vary considerably between and within countries (Mathers et al. 2010; Stoicescu 2012). For example, in Europe OST covers over 50 % of opioid-dependent users across most of the continent, though in a few countries coverage is under 20 %. Syringe distribution by NSPs ranges from under 50 per user per year to over 300 (EMCDDA 2012a).

Harm reduction developed mainly in response to public health consequences of heroin use and drug injecting. In many parts of the world, serious problems arise from heavy stimulant use, especially cocaine and methamphetamine. In Europe, the USA, and other countries, an ageing population of chronic users poses new challenges (EMCDDA 2010; ▶ Chap. 128 "Older People and Substance Misuse").

Strong religious, ideological, and political resistance remains in some countries and within some institutions. Sometimes interventions are implemented but not called "harm reduction." In other cases, evidence-based harm reduction interventions have been blocked, with serious consequences. In Russia, for example, methadone was declared illegal, despite urgings to the contrary (UNAIDS 2005). From 1995, injection-related cases of HIV in Russia rose rapidly and since 2002 account for over 80 % of all cases of HIV (Goliusov et al. 2008). Conversely, the role of user groups and advocacy organizations has been changing from opposition to mainstream policies towards recognized and constructive participation in developing evidence-based interventions to reduce drug-related harm (Stoicescu 2012).

84.2.3 Drug-Related Harms

Much drug-related harm occurs in association with heavy or regular consumption of opioids, central nervous system (cns) stimulants, or multiple drug combinations, including alcohol and other cns depressants. There is also a strong relationship between drug injecting and more severe levels of harm, though problems can arise from other routes of administration.

84.2.3.1 Drug-Related Morbidity

Dependence is the most likely consequence of regular drug use seen by professionals in treatment facilities, criminal justice settings, or general practice. Treatment of dependence is covered in other chapters. It should be noted, however, that levels of risk associated with unsafe injecting and with unsafe sexual behaviors increase with higher severity of dependence (Gossop et al. 1993a, b). It is also important to stress that for people who progress from experimental or intermittent drug use to injecting or more intensive patterns of use, there is usually a time lag of several years before they contact treatment services. During these early stages of a drug-using career, individuals may be especially at risk of contracting viral infections such as hepatitis C (Maher et al 2007). This underlines the importance of efforts to reach recent initiates with effective harm reduction and health promotion interventions. By the time they contact treatment services, it may often be too late.

Blood-borne viral infections such as HIV and hepatitis (especially HCV) constitute an important component of injection-related morbidity (see ▶ Chap. 106, "Substance Use and Co-Occuring Infections: An Overview"; ▶ Chap. 102, "Liver Disorders (Incl. Hepatitis) in IVDAs"). Prevalence and incidence of HIV and viral hepatitis among drug injectors varies considerably between sites and over time. For example, HIV prevalence among drug injectors ranges from under 5 % in most northern European countries to over 35 % in parts of eastern Europe and Russia (Mathers et al. 2010; Jolley et al. 2012). Hepatitis C prevalence is considerably higher among drug injectors, reflecting the greater transmissibility of this virus, and ranges from 40 % to over 90 % depending on location and duration of injecting (Hagan et al. 2008). Compared to HIV infection, hepatitis C infection is characterized by relatively high concentrations of virus in the blood, not only during the initial infection phase, but also in the majority who become chronically infected. In the United States, 9–12 % of all new HIV cases and 50 % of all new hepatitis C cases are associated with injecting illicit drugs (CDC 2012a). Given the long-term burden of disease and the high treatment costs associated with hepatitis C, prevention efforts should be given high priority. Coinfections with more than one type of hepatitis or with HIV and HCV present growing challenges (WHO 2012).

Other morbidity includes vein damage, abscesses, and cellulitis (ECDC and EMCDDA 2011). Rates of tuberculosis (TB) and sexually transmitted diseases (STDs) are also often substantially higher in drug-using populations (CDC 2012a).

84.2.3.2 Drug-Related Mortality

Reviews of studies in different countries on mortality among problem drug-using populations (mostly opioid dependent) suggest that all-cause mortality is between 1 % and 2 % per annum, 10–20 times higher than among the general population of the same age and gender (Degenhardt et al. 2011; EMCDDA 2011). Drug overdoses, often involving opioid-cns depressant combinations, are the most common cause of death, accounting for about one third to a half of all deaths. In some countries, cocaine is commonly reported in fatal overdoses, often in combination with opioids. Disease, suicide, and trauma are the other main causes of death.

Risk of death is several times higher among injectors than non-injectors. Specific contexts associated with dramatic increases in overdose mortality are the weeks immediately following release from prison, discharge from inpatient detoxification, and dropout from OST (Davoli et al. 2007; Merrall et al. 2010). In the USA, drug overdose deaths more than doubled from 16,849 in 1999 to 38,329 in 2010 (Jones et al. 2013). Prescription opioids in particular, as well as cocaine and heroin, were a major component of this (CDC 2013). Among older, chronic users, comorbidities, including alcohol and liver and cardiovascular diseases, become more important (EMCDDA 2010).

84.2.3.3 Drug-Related Crime

Drugs and crime are related in different ways, including offenses against drug laws (possession, production, trafficking), crimes committed under the influence of drugs (violence, driving), revenue raising crimes to finance drug use (theft, drug dealing), "systemic" crimes related to the illicit drug market (corruption of officials, turf war violence, money laundering), and public order offenses related to street drug scenes and public drug use. Studies have attempted to quantify the social and economic costs of drug-related crime (Godfrey et al. 2002). Harm reduction interventions have mainly focused on drug-related crime that harms local communities, in particular revenue raising crime (drug dealing and theft) and public nuisance arising from visible street drug scenes and markets. Crimes committed under the influence of drugs overwhelmingly involve alcohol, which is not covered in this chapter.

Other social and economic harms include impact on families, employment prospects, community well-being, or local economy. While important, these aspects have been less systematically studied and there is no space to cover them here.

84.2.4 Risk Behaviors

Serious health risks (infections, overdoses) are associated with drug injecting. HIV and especially HCV are efficiently transmitted via the sharing of injecting equipment. Risks arise not only through sharing syringes and needles but also through other materials used to prepare drugs for injection, for example, water, spoons, drug solutions, or filters (ECDC and EMCDDA 2011). Measures sufficient to prevent HIV transmission may not be enough to prevent HCV transmission. Risks also accompany non-injecting use, including bridging between injecting and non-injecting drug use populations, transmission through sharing non-injecting materials (pipes, straws), or sexual transmission (Strathdee and Stockman 2010; CDC 2012a).

Drug use, whether by injection or not, is strongly correlated with unsafe sexual practices, including unprotected sex, multiple partners, and, in some cases, selling sex for money or drugs (CDC 2012a, b). The sale of sex for money or drugs is most clearly associated with severe dependence on heroin or crack cocaine. Use of

stimulants, for example, methamphetamine, is associated with increased sexual activity, including unprotected sex and number of partners, as well was with increased rates of HIV and other STDs (Colfax and Shoptaw 2005; Scheinmann et al. 2007). The high risks linked to methamphetamine use by men who have sex with men have been emphasized in several studies (e.g., Molitor et al. 1998, 1999). For all groups, STDs (e.g., genital herpes or syphilis) substantially increase the risk of HIV sexual transmission (CDC 2010).

Comorbidity of drug dependence and mental disorders is common among problem drug users (see ▶ Chap. 117, "Co-Occuring Mood and Substance Use Disorders", ▶ Chap. 119, "Comorbid Anxiety and Alcohol or Substance Use Disorders: An Overview", ▶ Chap. 124, "Personality Disorders and Addiction Disorders"). There is consistent evidence that depression in particular is associated with increased risk behaviors such as sharing injecting equipment (Stein et al. 2003).

84.2.5 Risk Settings

Individual risk behaviors occur within a wider social context. A variety of environmental factors give rise to structural and situational settings that influence differentially not only harms associated with drug use but also access to health and social care (Poundstone et al. 2004; CDC 2012a). The diversity of settings implies a diversity of risks and responses (Hartnoll et al. 2010). Social exclusion and stigma are potent factors linked to a mix of poverty, unemployment, lack of health care, low life expectations, and discrimination. Racial and ethnic disparities persist regarding drug-related harms and utilization of health care and treatment (CDC 2012a). Criminalization and law enforcement policies often disproportionally target marginalized groups and communities. These structural factors can lead to environments that encourage high rates of risk behaviors and infection among drug users (Rhodes et al. 2005; Rhodes 2009; Strathdee et al. 2010). For example, a policy of arresting drug users with syringes can create situations in which there is a high risk of hasty injecting in unhygienic conditions with shared syringes (Werb et al. 2008). Fear of arrest or of children being taken into care can act as powerful deterrents to contacting treatment or social services among communities who already lack equal access to services. Legislation restricting syringe provision or availability of specific treatments can increase risk behaviors, morbidity, and mortality (Wood et al. 2009).

Given the high rates of arrest and incarceration found among heavy drug users, prison and other institutional settings constitute important risk environments. Although the frequency of drug use and injecting usually diminishes during imprisonment, when it does occur it is often under more risky circumstances than in the community, due to a shortage of syringes, need for secrecy, and the higher prevalence of infectious diseases in prison populations (Darke et al. 1998). Other high-risk situations include interruptions to treatment due to short periods of

imprisonment (Dolan et al. 2005) and release from prison or discharge from drug-free treatment (see 63.2.3.1 above).

Women who use drugs are often at higher risk than men due to various factors related to gender, power relations, and sexual risk. Female injecting drug users are doubly at risk for HIV infection via unprotected sex and unsafe injections and have needs that are often not adequately addressed in HIV-prevention strategies (El-Bassel et al. 2010). In some studies, unsafe sex is a more significant risk factor for women than drug use (Strathdee et al. 2001). Women who inject drugs are more likely to require assistance injecting and to engage in sex trading and unsafe sex. They are also more likely than men to have a regular partner who injects or is HIV positive. Intimate partner violence is much more common for female drug users than non-drug users. Women who have experienced such violence are less able to negotiate safe sex, less likely to use condoms, and more likely to share needles, to have more sexual partners, and to trade sex for money or drugs, including unprotected sex with dealers (Shannon et al. 2008; Folch et al. 2013). Higher levels of psychiatric comorbidity contribute to heightened HIV risk (Gilchrist et al. 2011).

Other contextual risk factors include the prevalence of infectious diseases in local drug-using populations (see later), historical or cultural patterns of drug use including routes of administration and risk behaviors pertaining in given communities (Des Jarlais et al. 1988; Grund et al. 1996), and local drug market conditions regarding what products are available, in what form and with what variability in content (de la Fuente 1996; Topp et al. 2003).

84.2.6 Harm Reduction as a Combination Intervention

A recurrent theme in the overview of single interventions in ▶ Chap. 83, "Harm Reduction Interventions" is the importance of combined or multiple intervention approaches as central to the effectiveness of individual responses (van den Berg et al. 2007; Degenhardt et al. 2010; Turner et al. 2011; Kidorf et al. 2011; Hagan et al. 2011). For example, analysis of data pooled from six cities in the UK suggested that exposure to OST or high NSP coverage approximately halved the risk of HCV infection, while the combination of OST and high NSP coverage could reduce HCV incidence by up to 80 % (Turner et al. 2011). Adherence to antiretroviral treatment (ART) or hepatitis C treatment is facilitated by OST together with psychosocial support (ECDC and EMCDDA 2011). Reductions in sexual and drug-related risks among highly marginalized groups are best approached through intensive community outreach backed up by syringe and condom distribution and improved access to health services, treatment, and social support. The central elements of a multiple-intervention approach recommended by international and national guidelines include the interventions described in ▶ Chap. 83, "Harm Reduction Interventions" (ECDC and EMCDDA 2011; CDC 2012a; WHO et al. 2013), though only the European guidelines mention drug consumption rooms (DCRs), which have more localized relevance and are still controversial in some countries.

84.2.7 Implementing an Integrated Approach at Local Level

While comprehensive national drug policies exist in most countries, it is at local level that the interface between drug use, policies, and responses takes place. Responding to a diversity of issues, from public concentrations of heroin and cocaine use and drug markets in specific urban areas to less visible patterns of problematic drug use distributed across different groups in different sections of the population, is a complex task. Coordination of local policies and interventions is essential due to the range of agencies involved, including health, social services, education, housing, police and criminal justice system, politicians, as well as civil society including nongovernmental organizations, community groups, and user organizations.

Optimizing the benefits obtained from combined interventions implies implementing at local level a coherent package of harm reduction approaches to problem drug use. This poses many challenges. It involves achieving understanding and cooperation between different sectors and organizations operating at different levels and with different agendas. Broader issues of health system organization are beyond the scope of this chapter. The remainder of this chapter focuses on practical questions concerning implementation of multiple harm reduction interventions in different settings.

84.2.8 Needs Assessment in Local Settings

There can be large differences between settings in terms of drug use patterns, risk behaviors, HIV or HCV prevalence, health and social consequences, community characteristics, and public and professional perceptions. How does one decide what interventions are needed in a given setting?

Assessment of the local situation and identification of needs, followed by monitoring and evaluation, is essential for providing effective responses. Assessment should cover the following areas:

- Epidemiological situation and trends (problem drug use prevalence, user profiles, patterns of drug use, routes of administration, mortality and morbidity including HIV/HCV prevalence and incidence, risk groups and behaviors, other health and social problems, drug-related crime)
- Response situation (existence of enabling policy environment including coordination strategies and support for harm reduction, services available including criminal justice settings, service policies and practices, geographical coverage, referral pathways, service uptake and utilization, client profiles, services provided)
- Needs assessment (coverage of target populations, gaps in responses, unmet needs, contextual risk factors, barriers to services, professional and community perceptions, drug users' perceptions, engagement of stake holders)
- Recommendations (priorities for action, policy environment development, coordination needs and mechanisms, service development and delivery targets, outcome targets, key indicators for monitoring)

Conducting an assessment involves a combination of methods which can include prevalence estimation, key indicators based on administrative or service data, surveys, ethnographic research, and key informant interviews with professionals, community members, and drug users, including through the internet.

Monitoring should cover trends in the epidemiological situation based on public health surveillance and other key indicators of problem drug use and related harms, as well as trends in service provision, uptake, and utilization based on surveys or routine data from services. There are many aspects of evaluation that are useful including process, outcome, and cost-effectiveness.

Differences between settings often imply different priorities and configurations for local responses. Selected aspects of harm reduction policy in practice are discussed below.

84.2.9 Enabling Environments

Harm reduction is about fostering protective "enabling environments" as well as improving services for individuals. This involves seeking to minimize negative dimensions of risk settings while developing alternative approaches that enable safer and healthier environments for both drug users and the local community.

Early examples of local harm reduction policies are the responses of European cities such as Frankfurt, Liverpool, or Zurich to heroin epidemics and public drug scenes in the 1980s. In Frankfurt, a significant heroin market developed in the city center, attracting drug users from the city and surrounding region. Initial policy was based on strong police intervention and coercive drug free treatment, set within the wider context of a repressive and stigmatizing national policy including strict restrictions on methadone and syringe availability. This policy had the effect of chasing the drug scene around the city. Not only did it fail to solve the problem of public drug use, but it created even riskier conditions for drug injecting, and HIV and overdoses increased. Pressure for an alternative approach led to the adoption of a harm reduction policy, "To live with drug addicts," coordinated through weekly meetings of all key actors and supported by a newly created drug policy division within the municipal council (Hartnoll and Hedrich 1996). In addition to developing a wide network of harm reduction, treatment, and rehabilitation services, the policy aimed to involve public discourse on stigma and marginalization and to promote possibilities for social reintegration. While the police did not renounce responsibility for maintaining public order, they largely stopped confiscating syringes and took part in consultations over strategies to reduce the public drug scene and influx of drug users from neighboring cities. Despite continuing tensions, over time the policy environment shifted significantly, public drug use diminished, and overdoses and new cases of HIV declined.

In this case, the drive for policy change was bottom up and arose from a realization at local level, including the police and public prosecutor, that the prevailing policy was creating social environments that heightened both individual

and community harms. However, it was also important that national policy subsequently changed to include harm reduction as a major pillar of drug policy, including OST, NSPs, DCRs, and increased discretion for public prosecutors over possession of small amounts of drugs for personal use.

More recently, the importance of nurturing enabling environments has been stressed in studies of HIV among people who inject drugs in high-risk environments (Rhodes 2009; Degenhardt et al. 2010; Jolley et al. 2012).

84.2.10 Epidemiological Settings

Scaling up coverage of OST and NSPs to contain the spread of HIV and HCV is recommended in research reports (Tilson et al. 2006; Mehta et al. 2011; Grebely and Dore 2011), drug strategies (e.g., EU drug strategies since 2004), and public health policy guidelines (ECDC and EMCDDA 2011; WHO et al. 2013). What this implies in practice is situation dependent. Some studies have used modelling techniques to project the impact of different levels of coverage in different scenarios (Vickerman et al. 2007, 2012). While this approach has limitations and important margins of uncertainty surround projections, they do support several general conclusions.

The impact of different levels of coverage on incidence and prevalence of HIV and HCV is affected by baseline seroprevalence levels in risk populations as well as by individual and collective patterns of injecting risk behavior (Vickerman and Hickman 2010). Scaling up can have an important impact on containing or reducing HIV incidence and prevalence. However, since HCV transmission probability is much higher than that for HIV, higher levels of coverage and larger changes in risk behavior are needed to make an impact on HCV than HIV. Significant reductions in HIV transmission can be achieved by targeting high-risk drug injectors, while targeting low-risk users brings relatively little additional benefit in terms of HIV prevalence. For HCV, however, failure to cover lower-risk users considerably reduces the potential impact of interventions, so all drug injectors should be covered. In Britain, modelling studies suggest that early scaling up of OST and NSP helped to contain the prevalence of hepatitis C among people who inject drugs to 40 % instead of a projected 65 % that would have occurred without high coverage (Vickerman et al. 2012). In situations where HCV prevalence is already high, long-term reductions in the prevalence of chronic hepatitis C are likely to be modest and require long-term sustained coverage. To achieve large reductions in HCV incidence, it is necessary to target all injecting drug users, to reduce sharing to very low levels, and to reach them within 12 months or so of starting to inject (Vickerman et al. 2007).

In situations with low OST and NSP coverage, which globally is under 20 % in most countries (Mathers et al. 2010), it makes sense to prioritize scaling up of OST and NSPs. This also means relaxing restrictions on syringe distribution and implementing measures to increase recruitment and retention in OST. In situations where high levels of coverage of drug injecting populations have already been

achieved (e.g., 50 % or more), it may not be cost-effective to attempt to increase coverage further. For example, in countries such as the UK, it is estimated that coverage of both interventions would have to increase to 80 % or more in order to halve HCV prevalence over 20 years. It would be very difficult to achieve and sustain such a high level (Vickerman et al. 2012). Additional measures, such as treatment for HCV, may in the longer term have a significant preventive effect (Martin et al. 2011).

84.2.11 Prison Settings

Implementing harm reduction in prison raises particular challenges (see also ▶ Chap. 70, "Treatment in Criminal Justice Settings"). There is tension between the abstinence orientation of penal institutions and harm reduction approaches. Prisons are seen as institutions for punishment for illegal behavior, so interventions such as providing syringes can provoke strong opposition. Prison health services are often part of the prison administration and tend to be detached from community health care. Since security is a priority, service provision for prisoners may be seen as less pressing. As a result, health and other services for prisoners lag behind those for the general population. Further, prison administrations may be reluctant to admit that drug use, same-sex activities, and rape take place. Lack of equivalence of care between prison and community is an important barrier to improving prison-based responses to drug users and others.

Particular health risks in prison compared to the community include higher proportions of problem drug users and levels of comorbidity (psychiatric, HIV, HCV, TB), settings that encourage riskier injecting behavior when it occurs (as well as higher sex-related risks), interruptions to treatment, and post-release risk of overdose deaths.

Experience shows that it is possible to establish harm reduction interventions in a wide range of prison settings. Prison OST is both feasible and effective and has been implemented in all but a handful of European countries, though coverage varies (Hedrich et al. 2012). Equivalence of OST provision between prison and community has been achieved in some countries like the UK and Spain. In others the gap between offer and need is closing, but in some remains substantial (EMCDDA 2012b). Prison NSPs are less common, but have been successfully implemented in prisons in at least nine countries (Obradovic 2012). Evidence of impact is based on descriptive studies showing reductions in risky injecting and sharing (Dolan et al. 2003; Stöver and Nelles 2003; WHO 2007). Modalities of distribution vary and include dispensing machines (which deliver clean syringes when a used one is inserted), prison medical staff, external health workers, and trained peers (WHO 2007). Experience shows that prison NSPs do not lead to increased injecting, that syringes are not used as weapons against staff or other prisoners, that disposal is uncomplicated, and that confidentiality increases participation. Distribution of bleach to disinfect needles and syringes has been suggested, but this is an unsatisfactory alternative, especially in prison settings (Small et al. 2005). Distribution of

condoms and lubricants is feasible and contributes to reduced risk behaviors in prison (WHO 2007). All harm reduction measures in prison need support from officials, prison governors, and prison guards; otherwise interventions will be undermined, for example, by increased searches and confiscation of materials.

Continuity of care (e.g., OST or ART) between community and prison following arrest and incarceration and between prison and community following release is an important means of reducing possible harms such as relapse, disruption of infectious disease treatment, or overdose. This requires establishing clear protocols for throughcare-procedures between community and prison services.

In conclusion, it is feasible to implement harm reduction in prison settings with benefits similar to those seen in community settings. Integration of prison health care into health care for general population facilitates moves towards equivalence of care.

84.2.12 Law Enforcement Settings

Substantial numbers of problem drug users come into contact with the police. Conversely, drug-related issues can take up a significant proportion of police time and resources. Although law enforcement and health policies are not often closely related, drug use is a field where there is considerable overlap and where both sectors can benefit from partnerships that foster mutual understanding and cooperation regarding reducing harms. Examples include support by police for OST (usually because of crime reduction) and agreements over community policing with regard to syringe distribution programs, the role of DCRs in reducing public nuisance, or the status of participants in peer-based outreach. In addition to these agreements, harm reduction interventions in law enforcement settings can include drug overdose prevention, referral schemes, health interventions in police stations, and diversion into treatment (Monaghan and Bewley-Taylor 2013).

Regarding overdoses, fear of police attendance can deter those present from calling emergency services (Pollini et al. 2006). In Vancouver, police procedures were changed so that they no longer responded routinely to overdose ambulance calls, but only attended if requested by ambulance personnel (Thomas 2005). Some US states have passed "good Samaritan laws" that provide immunity from drug possession charges for overdose victims and witnesses who call emergency services in good faith to save a life. A few have implemented programs to train police officers to administer Naloxone (Monaghan and Bewley-Taylor 2013). In Britain, some police authorities have issued directives that police personnel treat drug swallowing following arrest as a medical emergency that requires immediate hospitalization (Monaghan and Bewley-Taylor 2013). Warnings of contaminated drugs detected in the local drug scene may also be valuable if the information is disseminated through acceptable peer-recognized channels.

Drug referral schemes involve specialized workers based in police stations to assess, counsel, and refer drug users to treatment. Data from a national monitoring program in Britain showed that half of those who voluntarily asked for assistance at arrest had never been in treatment (Sondhi et al. 2002), though uptake and retention

rates following referral are variable. Subsequently, drug intervention programs became more directive, involving testing and assessment orders, and rates of treatment entry and retention improved. Apart from formal referral schemes, police discretion can enable referral to local services without arrest (MacDonald et al. 2008).

Health interventions in police stations include provision of methadone or buprenorphine (by police surgeons or external doctors). In some countries this is limited to clients in OST; in others in can be administered on the basis of withdrawal symptoms. In practice many opioid users in police custody do not receive medical intervention (MacDonald et al. 2008). Some police authorities in Britain provide sterile injecting kits on release from custody (Monaghan and Bewley-Taylor 2013).

Diversion into treatment through special drug courts is widely used in the USA (US Department of Justice 2012) and some other countries. Evidence suggests that they can reduce both recidivism and court costs (Mitchell et al. 2012), but evidence of their impact on post-program drug and alcohol use, employment, social relationships, or health is scarce (Wittouck et al. 2013). There are legitimate questions over the role of coercion in harm reduction responses.

All partnerships between local health and social services and police have to overcome substantial barriers before they can operate effectively while respecting the professional responsibilities of each agency. They also have to deal with legal constraints. However, it is important to seek such partnerships, since law enforcement activities can increase the risk of harms such as infections or deaths from overdose and can conflict with harm reduction interventions such as NSPs. Arrest can increase risks, for example, through interruption of OST or ART, but it can also offer opportunities for interventions to reduce harm.

84.2.13 Overcoming Barriers

A variety of barriers can inhibit development of effective harm reduction responses. These range from legal or formal professional constraints to informal obstacles such as resistance from other services and professionals, lack of cooperation from the police, and political or community opposition. While it may be difficult at local level to change formal constraints such as laws, it is often possible to reduce resistance through active consultation and sensitivity to the interests involved.

Barriers also discourage drug users from contacting services. These include administrative barriers (registration procedures, appointments, waiting lists), fear of arrest or of children being taken into care, perceptions that services are unfriendly or cannot be trusted, lack of health insurance or costs of treatment, low accessibility due to location or opening hours, and need to contact multiple agencies for different services at different sites. It is possible to minimize some of these barriers by developing strategies to improve access to and utilization of health-care services (CDC 2012a).

Aim for coordinated services that reduce the need for repeated registration at different services. Where possible, offer multiple services at the same site to reduce the need for referral to other services. Review the geographical distribution and

opening hours of contact points and services in consultation with users. Above all, implement user-oriented policies that explicitly enshrine confidentiality and users' rights to care, and strive to create a sympathetic and supportive service.

84.2.14 Promoting Health and Equality of Care

It is essential that practitioners understand the reasons for barriers to help seeking and the primacy of confidentiality and trust. Quality of services is as important as quantity. Commitment to equality of care and basic human rights does matter (Jürgens et al. 2010).

To summarize, the principles underlying a harm reduction approach (ECDC and EMCDDA 2011) are:

- Pragmatic approach to health promotion
- Public health objectives
- Clients' rights perspective
- Based on scientific evidence and expert experience

The principles of service provision are:

- Ensure confidentiality
- Promote service accessibility
- Create a user-friendly atmosphere
- Engage in dialogue with users and promote peer involvement
- Adopt a practical approach to the provision of services
- Refrain from ideological and moral judgment
- Maintain a realistic hierarchy of goals
- Promote an enabling environment as well as caring services for clients

84.3 Conclusion

Harm reduction policies and interventions have been successfully implemented in many parts of the world. HIV among IDUs is now largely under control in countries which have implemented extensive harm reduction policies. Heroin use and related problems are largely contained in many countries where OST has reached high coverage. Other challenges include stimulants and other drugs, ageing populations of dependent users, hepatitis C, and continuing sexual transmission of infections. Harm reduction strategies will need to adapt to changing priorities.

Almost all the evidence presented in this chapter (and also ▶ Chap. 83, "Harm Reduction Interventions") comes from Europe, the USA, Canada, or Australia. Many challenges for the future lie in other regions such as Central and Eastern Asia, Central and South America, and Africa (Mathers et al. 2010; Strathdee and Stockman 2010; Stoicescu 2012). We believe that the lessons learned so far can be adapted and applied to a wide range of settings.

Over the past two decades, political and professional opinions, as reflected in resolutions and policy documents of institutions and bodies at international,

regional, and national level, have increasingly promoted a "comprehensive approach" that includes harm reduction as a central pillar. A more general trend towards viewing health and social policies on illegal drugs, infectious diseases, alcohol, tobacco, and other issues like obesity, high-risk youth, or crime prevention under a much wider umbrella also pushes towards a broader, multi-level paradigm of risk reduction and health promotion.

Discussions continue on whether harm reduction is oppositional or complementary to drug-free approaches. It is not easy to integrate abstinence-oriented and public health and safety paradigms, nor is it simple to achieve a balance between individual and community needs. However, there is clearly space, within the hierarchy of goals of harm reduction, to encourage moves away from drug use and from dependence on services for those who are able while also providing compassionate, long-term care for those who cannot. At the same time, it is important to implement policies and interventions that protect the health and well-being of communities affected by problematic patterns of drug use.

Apart from skills in dealing with individual clients, practitioners need an understanding of the social, community, and public health settings within which drug use and drug-related harms arise, as well as an awareness of how social responses can have unintended consequences. A willingness and ability to cooperate within a local network of agencies and listen to the concerns of drug users themselves is essential. This all involves a broad vision of drug use, harms, and responses and a willingness to think outside of traditional individual psychiatric and social work casework paradigms.

Good Practice and Quality Standards

85

Marica Ferri and Paul Griffiths

Contents

Abstract

The present chapter is aimed at enabling the readers to master the methods to ascertain whether an evidence-based recommendation is appropriate for real-world patients in specific contexts. Nowadays it is crucial to develop an individual capacity for critical assessment and to know where to search for updated and reliable sources of evidence. The methods, the processes, and the practical meaning of the most popular tools for the promotion of quality are presented with links to current projects and free of cost resources for professionals. The ultimate goal of the evidence-based medicine is to provide the patients with the best possible interventions. To reach this goal, knowledge has to be translated into practice. Guidelines and standards are popular instruments to disseminate and implement evidence-based recommendations. Nevertheless to implement them into specific contexts, some decisions are needed. The chapter includes a description of the main approaches used to adapt or adopt guidelines and standards.

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment: International Perspectives*, DOI 10.1007/978-88-470-5322-9_64,

Quality is never an accident. It is always the result of intelligent effort. There must be the will to produce a superior thing.

John Ruskin

85.1 Introduction

The promotion of quality and the exchange of good practice are recognized as an important strategy both to improve the effectiveness of drug-related interventions and to ensure the efficient use of limited resources. Guidelines and standards in particular are among the most frequently used tools for the promotion of quality through the translation of knowledge into the daily practice of treatment of drug addiction. But it is not always needed to publish new guidelines and standards; often the existing good quality guiding documents can be adapted to suit a specific national or local context. New disciplines have emerged focusing on methods for successful knowledge transfer to action, such as implementation science, translational science, and knowledge mobilization. A common recommendation is that the only way to a successful implementation is the promotion of participation among all the stakeholders, starting with the medical doctors and the health professionals and including the decisions makers, the patients and their families, and the public in general.

It is therefore important that the professionals in the treatment of drug addiction are familiar with the terminology and the methods of the quality promotion as these are increasingly part of their daily activity.

The contents of the evidence base change rapidly as soon as new studies are conducted and contribute with new results. This is why it is important to master the methods to ascertain whether a recommendation is appropriate for real-world patients in specific contexts. It becomes crucial to develop an individual capacity for critical assessment and to know where to search for updated and reliable sources of evidence.

To this purpose the present contribution was conceived. The evolution from evidence base to implementation is described giving some details about the terminology and references for further reading. The methods, the processes, and the practical meaning of the most popular tools for the promotion of quality are also presented with links to current projects and free of cost resources for professionals. In particular it is explained how time and resources can be saved by *adapting* or *adopting* already published evidence-based guidelines to specific needs and contexts. The current initiatives for the development of quality standards in drug addiction treatment at international and at national level are described and compared, and for each of them, the links for free downloading of documents are included. To complement the information on implementation, we included a description and references to some recent initiatives in the medical field in which the participation of drug addiction treatment professionals is crucial but still not sufficient. In fact all those initiatives are studying strategies to effectively communicate with decision makers and patients. In a conclusive part, two examples of use of standards are compared more in depth, in one case as part of an accreditation system and in another as a support for implementation and measuring of quality criteria.

85.2 From Knowledge to Implementation

85.2.1 Knowledge Translation into Practice: From Evidence to Change

The overall aim of good practice sharing and standards development is the achievement of improvement in the quality of treatment. Clearly quality is not an abstract concept but rather an umbrella definition for series of measurable achievements in the health and well-being of the treated patients.

"*Primum non nocere*" – first of all do not harm – the phrase attributed to the Hippocratic Oath, reminds that the first aim of a health intervention is to avoid harm.

And it is exactly with this intention that the pioneers of the evidence-based medicine called the attention on the discrepancies between research results and medical practice, which would have cost human lives (Cochrane 1999). According to their claims the timely application to practice of the results from clinical research would have saved many lives and reduced subsequent costs to the society (Egger and Smith 1997). For example, randomized controlled trials proving the effectiveness of systemic glucocorticosteroids administered to pregnant women at risk of preterm delivery to reduce respiratory distress syndrome in newborn babies were available already in the 1970s, but it took almost 20 years before this intervention became a common practice (Roberts and Dalziel 2006).

The possible effect of the delay in the adoption of this practice was that a significant number of premature babies probably suffered and possibly died and needed more expensive treatment than was necessary (Rennick 2006).

The movement for the systematic collection of scientific results for dissemination outside the restricted circles of researchers and academics became known worldwide at the beginning of the 1990s (Sackett et al. 1996) and was boosted by the foundation of the Cochrane Collaboration, an international organization aimed at helping "healthcare providers, policy-makers, patients, their advocates and carers, make well-informed decisions about health care, by preparing, updating, and promoting the accessibility of Cochrane Reviews" (Chalmers and Glasziou 2004).

In 1998 an editorial group specifically devoted to drugs and alcohol was founded with its base in Rome (Davoli and Ferri 2000), and since then around 70 reviews on the various interventions (including prevention) for drug and alcohol problems were published and updated.

The availability of good quality research on effectiveness of treatment for drug problems has dramatically increased over the last years, even though important gaps still remain to be bridged with evidence (Turner and McLellan 2009). The availability of studies and of systematic reviews nurtured the production of clinical guidelines as a major tool for the dissemination and application of evidence in practice.

For example, a recent survey for the identification of treatment guidelines in Europe identified more than 140 sets of guidelines for the treatment of drug addiction (EMCDDA 2011). Nevertheless the practical effects of such a massive effort to produce clinical guidelines were not clear. When measured, the impact on quality of treatment seemed not impressive. Some surveys performed in the medical

field, not specifically in the drug addiction one, showed that clinical guidelines are applied to practice in only 50–70 % of day-to-day decisions, and the main reason given for not applying them is that they are of limited relevance to patients and healthcare staff (Parchman et al. 2011). Moreover, in a recent debate promoted by the British Medical Journal about the effectiveness of guidelines (Grol and Wensing 2004), it was pointed out that to ensure clinical guidelines have an impact on actual care and practice, activities beyond the mere production and dissemination should be instigated (Ferri and Bo 2012).

This type of considerations along with the need to reduce cost and improve quality and outcomes must be at the base of the evolution towards the *knowledge translation into practice* approach (Brownson et al. 2012). In fact, moving from the concept of evidence to that of knowledge expands an idea already present in the definition of evidence-based medicine. The practice of evidence-based medicine integrates clinical expertise with the best available evidence from systematic research, explained David Sackett (1996). "Without clinical expertise, practice risks becoming tyrannised by evidence, for even excellent external evidence may be inapplicable to or inappropriate for an individual patient" reinforced then. Probably "knowledge" is a better term to put together evidence with expertise. *Knowledge translation* has been defined as a "dynamic and iterative process that includes the synthesis, dissemination, exchange and ethically sound application of knowledge to improve health, provide more effective health services and products, and strengthen the health care system" (Canadian Institutes of Health Research 2012). Knowledge translation is not the only term that has been used to name this tendency towards practical use of knowledge to improve practice. According to Straus and colleagues (2009), more than 90 terms were identified in the literature. According to them, in Europe, preferences are for "implementation science" or "research utilization," whereas the terms "dissemination and diffusion," "research use," and "knowledge transfer and uptake" are more frequently preferred in the United States. The Canadian "knowledge translation" has been adapted by others, including the United States National Center for Dissemination of Disability Research and the World Health Organization (WHO).

The lowest common denominator among the above described different terms is a move beyond dissemination of knowledge into actual use of it to transform practice. "Knowledge creation (i.e., primary research), knowledge distillation (i.e., the creation of systematic reviews and guidelines) and knowledge dissemination (i.e., appearances in journals and presentations) are not enough on their own to ensure the use of knowledge in decision-making" (Straus et al. 2009).

A definition of the "best-practice" concept was recently developed by a group of European experts convened by the EMCDDA. In brief, best practice is the best application of the available evidence to current activities in the drugs field. A number of factors were identified as contributing to making an intervention qualify as "best practice." In summary, a best-practice intervention is based on the most robust scientific evidence available regarding what is known to be effective in producing successful outcomes, and it is tailored to the needs of those it addresses. Methods used will be transparent, reliable, and transferable and can be

updated as the knowledge base develops. With regard to implementation, local contextual factors will be taken into account, and the intervention will be harmonized with other actions as a part of a comprehensive approach to drug problems. Best practice is closely linked to the concept of "evidence-based practice," and it requires the careful integration of both scientific knowledge and implementation expertise in order to appropriately adapt the intervention to the single individual and/or to a specific context. A best-practice intervention should provide better outcomes than other interventions and therefore also allow a rational allocation of resources (Ferri and Bo 2012).

There remain challenges associated with the promotion of best practice through guidelines, standards, and other similar tools. The first is to make sure that they are based on reliable scientific evidence and that they are regularly updated when new systematic reviews are published. The second is to make best use of the currently existing guidelines. Finally, it is important to ensure that guidelines and standards are appropriately implemented.

85.2.2 Quality of Interventions: The Main Tools and Their Life Cycle

Clinical guidelines are the main instrument to disseminate evidence-based interventions via recommendations for practice that are based on a clear methodology for the appraisal, synthesis, and grading of the available evidence (Connis et al. 2000). Evidence-based guidelines are produced by convening multidisciplinary groups of experts who systematically assess the quality of the available evidence and classify the recommendations according to the level of supporting evidence. The level of evidence is determined by a synthesis of relevant studies' design (systematic reviews), number of participants studied, and the number of studies sharing the same results along with the overall measure of effect found by pooling the results of the studies. Each recommendation should have an indication of its strength, which clarifies how and when this is applicable to the patients. Although the level of evidence influences the strength of a recommendation, there are conditions under which, even where there is a lack of evidence from studies, the appointed group of experts may attribute a high strength to some recommendations. This is the case for some interventions, such as hydration for hospital patients or blankets to prevent heat loss in trauma patients, that are supported by practical experience and do not need to be based on experimental evidence. Guidelines may therefore include a statement such as "we recommend that this intervention is offered to most patients, even though there are no studies which prove or refute the effects, and this recommendation is based only on expert opinion." In some milestone manuals for guidelines development, these are indicated as *good practice points* (SIGN 2011).

Another example is where patients cannot be directly studied for ethical reasons (such as exposing newborn babies to different drug therapies). In such cases, the recommendations can be based on the results of studies on other types of patients. In practical terms, this system, which separates level of evidence from

strength of recommendations, produces two separate – but not completely independent – scores. In general, evidence-based guidelines are published by independent organizations that are able to assemble experts who are free from conflicts of interest and who represent different fields and professions. These groups generally involve as many stakeholders as necessary to ensure they appropriately address all the different aspects of a question, including patients' preferences and practical concerns arising from the experience of the carers (EMCDDA 2011).

In 2000, a collaboration was established of people interested in addressing the shortcomings of the grading systems used in guideline development, "the grading of recommendations assessment, development, and evaluation" (GRADE) working group (Guyatt et al. 2011). Over the years, this group has developed and continuously updated a common, sensible, and transparent approach to grading the quality of evidence and the strength of recommendations. This system has been adopted by several international organizations among which the EMCDDA (the Best Practice Portal); the World Health Organization; Agency for Healthcare Research and Quality (AHRQ), United States;and the National Institute for Clinical Excellence in the United Kingdom.

The evidence-based clinical guidelines are meant to facilitate the application of updated evidence to practice, and therefore, they are supposed to be timely revised. An indication of a specific date for revision should be stated clearly, and the choice of this date should be based on an assessment of the time in which new evidence is likely to be available.

This anticipation of a date for the availability of new evidence is in general possible because evidence-based clinical guidelines are based on systematic reviews of studies. These are identified through structured "search strategies" developed on the basis of a list of "clinical questions" that the guidelines should address. On the basis of those questions – which should be relevant to the patients and detailed enough to allow the appropriate search for the available evidence (Schardt et al. 2007) – the methodologists search, identify, and select a number of systematic reviews of evidence. The latter are based on published and unpublished studies and should also identify – in ad hoc created registries (WHO 2013) – the ongoing studies. Those registries collect information from the very beginning of the clinical studies and follow up each step until the publication. The entity (or the individual researcher) registering a clinical trial is requested to include a date of completion. Although these dates can be changed during the study period, they provide an idea when new results can be available.

A number of tools have been developed to assess the quality dimensions in guidelines, the most recent being the "appraisal of guidelines for research and evaluation" (AGREE Collaboration 2003), which was created to address the issue of variability in guideline quality by assessing methodological rigor and transparency. The updated version, "AGREE II" (AGREE Next Steps Consortium 2009), is composed of six domains aimed at assessing whether or not the scope and purpose of the guidelines is clearly indicated; the stakeholders' involvement is sufficient to represent the views of the intended users; the process of development was rigorous; the presentation and text are clear; and the guidelines are fit for purpose and free from conflicts of interest.

Several are nowadays the international inventories of guidelines from all over the world which can be consulted freely to find relevant documents. Among those, the more important are the inventory maintained by the Guidelines International Network (http://www.g-i-n.net/library) containing over 6,000 sets of guidelines for evidence-based healthcare (in multiple languages) and the National Guidelines Clearinghouse (http://www.guideline.gov/), an initiative of the Agency for Healthcare Research and Quality (AHRQ) in the United States, which publishes guidelines from any countries provided they are in English. The website of the National Guidelines Clearinghouse offers an automated function to compare different guidelines upon their main characteristics and to obtain synthesis of guidelines. The main aim of the inventories of guidelines is to avoid duplication of efforts making good quality guidelines available for adoption or adaptation in different contexts.

85.2.2.1 Adaptation of Guidelines to Everyday Practice Under Local Circumstances

Clinical guidelines can be elaborated and published at several levels: international, national, or local level. The World Health Organization and the United Nation Office on Drugs and Crime, for example, published guidelines and principles on the treatment of drug addiction (WHO 2009) (Table 85.1).

Being a very resource-intensive activity, guidelines are in general commissioned to specialized national agencies which have the capacity for convening a number of stakeholders from all the involved parts and reduce the risks of conflicts of interest. Examples of agencies to develop clinical guidelines are the National Institute for Clinical Excellence in the United Kingdom; the Scottish Intercollegiate Guidelines Network; the Finnish STAKES, National Research and Development Centre for Welfare and Health; the French National Health Authority (HAS); the New Zealand Guideline Group (went in voluntary liquidation in 2012); the Canadian Task Force on Preventive Health Care; and many others. An indicative list of organizations which develop and publish guidelines is available in the website of the Guidelines International Network (GIN 2012).

Guidelines which are published at general level may require some further elaboration before they can be effectively applied to the everyday practice. The translation of evidence-based recommendations into practice is the so called "implementation" process.

The implementation activities can follow two general approaches mainly depending from the "distance" between the context where the guidelines were issued and that where they have to be implemented. In some cases it is sufficient to *adopt* the guidelines through the development protocols at service level in which the guidelines' recommendations are broken down into actions and responsibilities, agreed by the healthcare personnel. This type of protocols (which can be also called *clinical pathways*) supplement clinical recommendations with hospital (or service)-specific details and, in some cases, can emend those recommendations which are considered not fitting with the local context (Groot et al. 2008). These

protocols can be disseminated in the realm of some peer-led educational activities; and they can include reminders and other initiatives aimed at reinforcing the application of recommendations in practice (Burgers et al. 2003).

In other cases an *adaptation* process is put in place, where the source guidelines are further analyzed by a group of local experts who draft new contextual-wise recommendations. Customizing clinical practice guidelines to a particular context and involving local stakeholders and the end users of the guideline in this process has been identified as a way to improve acceptance and adherence (Harrison et al. 2010). In general, but not necessarily, the *adaptation* occurs when (inter) national guidelines are to be applied at local level. In this case the adaptation process can be kept into consideration more than one set of guidelines and imply a process similar to the one needed for drafting a new guideline. The major difference lies on the search for source documents that in the case of an *adaptation* focus on guidelines rather than on systematic reviews of evidence (and or primary studies) as in the case of a development of a new guideline.

ADAPTE (www.Adapte.org) is an international organization of methodologists researchers, guideline developers, and guideline implementers who aim to promote the development and use of clinical practice guidelines through the adaptation of existing guidelines. The organization created a resource toolkit that can be freely downloaded in the Guidelines International Network website (www.g-i-n.net).

Quality standards are becoming an increasingly popular tool for ensuring quality of interventions in healthcare. In general terms standards are principles and sets of rules about what to do and what to have (Brunsson and Jacobsson 2000) presented as voluntary to a number of potential adopters. According to one of the most known organization for standards development, a standard is a document, established by consensus and approved by a recognized body, that provides, for common and repeated use, rules, guidelines, or characteristics for activities or their results, aimed at the achievement of the optimum degree of order in a given context (ISO 2004; ISO 2004). Typically the standards proposed in the health field refer to content issues, to processes, or to structural (formal) aspects of quality assurance, such as environment and staffing composition.

Quality standards can be developed by private sector organizations as it is the case for the International Standards Organization (ISO 2013); national private, nonprofit organizations like the American National Standards Institute (ANSI); the Association Française de Normalisations (AFNOR); and the British Standards Institute (BSI). The great majority of these organizations have been founded at the beginning of the twentieth century and some after the Second World War. Standards can also be developed by international governmental organizations like the United Nations, the Organization for Economic Co-operation and Development, and the European Union. In fact standards are a good way to propose harmonization especially by those organizations whose members are sovereign states that cannot be obliged to follow some rules (Brunsson and Jacobsson 2000). Nevertheless there are also several national organizations especially in the health field which develop quality standards. In the case of these organizations, quality standards are intended as sets of rules based on evidence used to implement the interventions

recommended in clinical guidelines. The standards which are developed by the National Institute of Clinical Evidence in the United Kingdom, for example, are typically composed of a general statement and a measure which can be used to assess the quality of care or service provision specified in the statement. "The quality statements are clear, measurable and concise and describe high-priority areas for quality improvement. They are aspirational (they describe high-quality care or service provision) but achievable" (NICE 2012).

Several international organizations are undertaking standards development for health interventions in the drug demand reduction.

The European Commission financed a study on the Development of an European Union Framework for minimum quality standards and benchmarks in drug demand reduction (EQUS), proposing a set of 22 quality standards for treatment (the study included also 33 standards for prevention and 16 for harm reduction).

According to the background paper of this project, in the medical sciences, quality standards are determined by different stakeholders: health authorities, insurance companies, service providers, professionals, and patients. Each of these professional categories brings different goals, interests, and priorities which need to be reflected in the standards in the light of the underlying scientific evidence. The project, whose lead investigator was Ambros Uchtenaghen (Uchtenhagen and Schaub 2011), divided the quality standards into four dimensions:

1. *Structural quality*, e.g., standards relating to the physical environment, staff, training, etc;
2. *Process quality* standards relating to the process of an intervention, e.g., diagnostic assessment;
3. *Outcome quality and economic quality*, e.g., standards to measure the cost-benefit ratio.

The *structural standards for services* cover areas like the physical accessibility of treatment services (which need to be located in places easily reached by public transport) or the environment where the treatment take place which should be adequate (to allow privacy during consultations) and safe. Another important aspect is the need for a documented diagnosis as a basis for treatment choice. Staff education and composition is also mentioned in terms of ensuring the presence of medical and nursing staff along with psychologists or social workers and multidisciplinarity with at least three professions represented.

The *process standards at the service level* included the assessment of substance use history, diagnosis, and treatment history along with the somatic and the social status for each patient including an assessment of the psychiatric conditions.

Each patient should be provided information on the treatment options available and should be provided a treatment plan tailored on his/her individual needs.

Treatment plans, assessments, changes, unexpected events, and any relevant information should be recorded and kept confidential. Each treatment service should promote cooperation with other agencies and services to ensure an appropriate response to the needs of their patients (whenever a service is not equipped to deal with all needs of a given patient, an appropriate other service is at hand for referral) and should ensure continuous education for the staff members.

The *outcome standards proposed at the system level* included the goals of health and social stabilization of patients and the reduction of illegal or non-prescribed psychotropic substances. Monitoring included the level of utilization (each service should provide information on the number of slots or bed utilized) and the ratio of discharges occurred as planned or for different reasons.

Internal and external evaluation of services was also proposed as a standard.

Beyond the list of proposed standards, the project-added value lies on the process adopted to consult the stakeholders and to identify several levels of standards. Namely, the stakeholders were interviewed by rounds of Internet-based consultations about the level of implementation status and acceptability of the proposed standards in their respective countries. Through this strategy it was possible to identify a long list of standards and grade them by priority of implementation. In fact, the EQUS study also included a review, involving experts from 24 European countries, of existing quality standards already implemented at the national level. With regard to drug treatment processes, the standards most frequently reported as already implemented were in the areas of client data confidentiality and assessment of clients' drug use history, whereas the standards concerned with routine cooperation with other services, and those focusing on continuous staff training, were less often implemented. In the area of treatment outcomes, the two types of standard most frequently reported as implemented were those with goals linked to health improvement and reduced substance use. Among the standards less likely to be applied were those focusing on external evaluation and monitoring client discharge; problems related to the implementation of these standards were reported.

This approach may allow the participating countries to set their own goals and to pace the achievement of them on the basis of their own capacity and priority. This process would also be greatly facilitated by the existence of the European Monitoring Centre for Drugs and Drug Addiction (EMCDDA), a decentralized agency whose aim is to provide sound and comparable information on drugs in Europe. Thanks to its impartiality and comprehensiveness of information, EMCDDA can support the countries volunteering for the adoption of the quality standards in setting their goals and measuring their successes.

The European standards have not been formally adopted yet, but the EQUS study represents the beginning of an ongoing process to reach consensus over a minimum set of quality standards in drug demand reduction.

Another initiative at supranational level was undertaken by the African Union which has recently proposed a list of Continental Minimum Standards for treatment of drug dependence as a guide to member states (African Union 2012). In the introduction of these standards, there is a synthesis of the current situation of drug consumption in Africa stating that "the levels of drug consumption continue to grow in Africa while there is a tendency toward stabilisation in North America and Europe"; therefore, "an in-depth revision of current drug policies has become necessary (in Africa) in view of the increasing human and social costs and threats to democratic institutions."

Table 85.2 Processes for guidelines adaptation at local level

Document	Process	Professionals involvement	Output	Definition
Guidelines (national or international)	Adoption	Service personnel	Service protocol/ clinical pathway	A comprehensive set of rigid criteria outlining the management steps for a single clinical condition or aspects of organisation (http://www.openclinical.org/guidelines.html#gandp)
Guidelines	Adaptation	Stakeholders	Locally adapted guidelines	The local adaptation of national guidelines has been proposed as a way of increasing the benefit of local ownership, while maintaining scientific validity (Khunti and Lakhani 1998)

The text supports that "provisions should be made towards treatment of drug users which was instrumental in stabilising drug consumption in the West," while "The criminalisation and marginalisation of drug users has increased drug-related health problems and contravened universal fundamental human rights." In summary those standards are presented as an application of the lessons learned in a different context to change a particular situation. This intention captures the exact spirit of sharing of good practice. A general description of recent initiatives of standards for the treatment of drug addiction is reported in Table 85.2, and some of them will be deeply explored.

In general terms it can be observed that the existing standards (at their different level of implementation) seem to be triggered by several reasons: the harmonization of the existing services, the translation in practice of the evidence-based guidelines, the consistency between policy decisions and service provision, and the need to measure the results of interventions. These reasons are diversely reflected in the mentioned initiatives mainly in relation with the level where the standards are proposed. The life cycle of quality standards depends on the supporting evidence, but not completely. In fact when it comes to human rights or general safety measures, the relevant principles are imperishable.

Clinical pathways are structured, multidisciplinary plans of care designed to support the implementation of clinical guidelines and protocols. In a recent past it was considered that this definition was variedly interpreted by different stakeholders until a recent systematic review (Kinsman et al. 2010) clarified the concept.

The clinical pathways are essential to the translation of evidence-based guidelines at service level. They are in fact meant to "detail essential steps in care of patients with a specific clinical problem" and sequence "the actions of a multidisciplinary team" (De Bleser et al. 2006). In clarifying which actions should be undertaken to practice evidence-based recommendations, clinical pathways "facilitate translation of national guidelines into local protocols" (Campbell et al. 1998) and allow continuous improvement by monitoring and evaluating variances.

Clinical pathways are commonly adopted in the United States where in 2003 it was reported that almost 80 % of the hospitals used this tool (Kinsman et al. 2010). Evidence supports the adoption of clinical pathways at hospital level for the reduction of in-hospital complications (such as infections, bleeding, and pneumonia), improved documentation, and possibly a reduction in the length of stay (Rotter et al. 2010). An experience of integrated clinical pathways in mental health has been reported in Scotland where the National Health Service (NHS) Scotland is taking a national approach to improving the quality and safety of mental health services. The program started with the publication of national standards by NHS Quality Improvement Scotland (NHS QIS), setting out the framework for development at local level.

The emphasis of development and implementation of the ICPs lies with local NHS boards to ensure they are developed with local ownership and to meet the needs of the local population. However, to ensure accreditation by NHS QIS, the local ICPs must incorporate the national standards and evidence improvement to the quality of care provided (El-Ghorr 2010). In Belgium there is the European Association for the development of clinical pathways (http://www.e-p-a.org/about-epa/index.html. Among the objectives of this organization, there is the setup of an international network for pooling know-how on clinical pathways and the promotion and fostering of international cooperation between healthcare researchers, managers, and healthcare providers from European countries and the wider international community. The association has a journal which publishes research results on the development of clinical pathways.

85.2.3 Participation: A Key for Successful Implementation

There are two main elements underlying all the instruments for quality improvement mentioned in the previous paragraphs (evidence-based clinical guidelines, quality standards, and clinical pathways). These two elements are the evidence base and the stakeholders consensus. The last three decades have been devoted to define and share a valid methodology for the identification assessment and synthesis of the available evidence. This activity successfully brought to a general understanding about the terminology and the sources of correct information. Nowadays the role of evidence to base decisions is widely recognized, and the access to good quality sources of evidence is increasingly available.

The new challenge seems to lie on the promotion of an authentic participatory implementation of evidence-based interventions.

The same pioneers of the evidence-based medicine are now exploring strategies to communicating and involving two crucial stakeholders: the decisions makers and the patients (this latter category includes also family members, civil society organizations, community representatives (Deber et al. 2005)). Projects like SUPPORT financed by the European Commission's 6th Framework Programme (Lavis 2009) and the most recent DECIDE (Treweek et al. 2013) co-funded by the European Commission under the Seventh Framework Programme are both aimed at supporting decision makers in the use of evidence.

SUPPORT targets policy makers as a diverse group that includes cabinet members (e.g., Ministers of Health or Finance), elected officials (e.g., chairs of legislative committees), senior civil servants (e.g., directors of primary healthcare programs), and high-level political appointees (e.g., heads of government agencies). In spite of being aware of the differences that can exist among the countries due to the different political systems, the leading project managers of SUPPORT state that what all the decision makers have in common is the authority to take or influence decisions directly. The project encompasses several tools for boosting evidence-based decision making in various settings including low- and middle-income countries and high-income countries. As the other mentioned project, DECIDE, also SUPPORT, sought strategies for the involvement of public in evidence-based decision making (Oxman et al. 2009). In particular DECIDE, whose target is Europe, is composed of eight work packages, three of which devoted to identify best strategies to communicate with specific target groups such as health professionals, policy makers and managers, and patients and public.

The two projects have similar objectives though following different approaches: DECIDE focuses on guidelines and recommendations, while SUPPORT aimed to support policy-relevant reviews and trials. DECIDE on the other hand is developing tools that will help policy makers to make a decision about, say, whether to pay for a particular healthcare innovation in their region. Additionally, it is developing tools to make understanding the research information that forms the basis for guideline recommendations easier for a wide audience, including policy makers and the public. To some extent, DECIDE builds on the work of SUPPORT.

Even though these projects are important, quite often the exercise of knowledge translation brings to the appreciation of huge gaps in knowledge, gaps that are difficult to fill with methods for gathering consensus and taking decisions in the lack of evidence. The only possible way forward to fill those gaps is to propose new studies to find answers. These new studies should rely on mixed methods to get sound evidence from several sources and, of course, to be based on the priorities of the end users of the answers they should provide, such as the patients (Liberati 2011). In the United Kingdom, Sir Iain Chalmers, one of the founders of the Cochrane Collaboration, has undertaken a new initiative for the proactive involvement of patients in the setting of research priorities through the James Lind Alliance initiative (Petit-Zeman S FAU – Cowan and Cowan). The James Lind Alliance brings together patients, carers, and clinicians to identify and prioritize the uncertainties, or "unanswered questions," about the effects of treatments that they agree are most important and makes the list of research questions public and available for researchers and research funders. Not always the area of addiction is represented in these initiatives. The main linkages are granted by the Cochrane Group on Drugs and Alcohol and by the European Monitoring Centre for Drugs and Drug Addiction which are working in partnership to bring the typical problems of this field in the broader perspective of knowledge translation.

Some of the characteristics of the drug addiction field can be shared by other medical conditions. For example, the behavioral component calls for research that cannot be only based on experimental studies. Important aspect of knowledge can

be in fact found on long-term observational studies, and in some cases they require qualitative analysis which is more difficult to be systematically retrieved with the typical search strategies adopted in systematic reviews and even more difficult to be assessed for quality and included in meta-analysis (Gough 2012). Nevertheless there are some added values in the drug addiction field which compensate for those extra efforts. The impact of interventions on public health and security makes drug addiction an important point on every political agenda and need to be based on the best available evidence.

85.2.4 Examples of Frameworks for Quality Standards

Several evidence-based guidelines are currently available for the treatment of drug addiction, in particular for the combined pharmacological and psychological approaches for opioid dependence, and these guidelines are issued at international and national level. Differently, the publication of quality standards for drug addiction treatment is less common, as the majority of the existing standards in drug addiction refer to prevention (UNODC 2013; EMCDDA 2012). Following we will describe two examples of standards for drug addiction treatment at national level, in European countries, namely, in the Czech Republic and in the United Kingdom.

In Czech Republic the implementation of quality standards for treatment of drug addiction dates back to 1995 for initiative of the Interdepartmental National Drug Commission (now Government Council for Drug Policy Coordination). Called minimal standards, these were adopted by the Association of Non-Governmental Organizations (ANO) for Addiction Prevention and Treatment for evaluating the quality of member organizations and newly established facilities. After further elaboration occurred in the subsequent 4 years, those standards became the basis for a certification process, which recognizes that a specific service provider is in line with predefined quality standards. Since 2004 the adherence to quality standards is assessed by specifically trained external evaluators. The current process for the certification of treatment providers was kicked off in 2005, and it included a transition period to allow the treatment provider services to start the certification process. After that period, certification became a prerequisite for applying for state grant programs. The overall aim of the certification process was the improvement of the quality of the network of services including a cost-effective administration of public funds. The certification process brought to the integration of the drug addiction services into the medical and social national system.

The underlying principles are as follows: voluntariness, certification is not required to provide drug services but only to apply for public funds; transparency, the evaluation process is carried out according to published criteria; and objectivity, the actual evaluation of quality is performed by an independent agency who appoints trained evaluators and the facility providers can point out any possible conflict of interest.

The standards are at the base of certification and accreditation process. The core activity of the certification process includes that a group of trained assessors visits the service providers to collect relevant information. Active participants in this

process are the facilities requesting the certificate of quality (those wishing to apply for public funds); the Certification Agency (an independent institution that arranges on-site examinations, communication between the parties of the certification process, and training of certificators); the certification team carrying out on-site examinations (composed by at least three trained certificators); the Certification Board of the Government Council for Drug Policy Coordination (deciding about certification request results and validity of certification ranging from 1 to 4 years); and the Executive Board of the Government Council for Drug Policy Coordination – to which the facilities can address their complaints about, for example, the composition of the certification team. In fact, before the certification can start, the agency and the requesting facility have to agree on the date and the composition of the team of assessors. Subsequently a number of previously identified employees and clients are interviewed with semi-structured questionnaires. The on-site examination in general lasts one day at the end of which the team of assessors drafts a report with a proposal for certification or suggestions for improvement. The report is shared with the interested facility which is given the opportunity to comment in writing.

The report is therefore completed and forwarded by the Certification Agency to the Certification Board of the Government Council for Drug Policy for the final decision.

Overall the process takes around 2 months, and the facilities requesting certification have 15 days to contest the results.

In the United Kingdom the National Institute for Clinical Excellence (NICE) publishes evidence-based clinical guidelines for many different medical disciplines including drug addiction. Sets of quality standards are derived from the best available evidence such as NICE guidance and other evidence sources accredited. They are developed in collaboration with NHS and social care professionals, their partners, and service users. The standards consider issues like evidence of effectiveness and cost-effectiveness, people's experience, safety, equality, and cost impact. The quality standards are considered central to supporting the government's vision for an NHS and social care system focused on delivering the best possible outcomes for people who use services (Health and Social Care Act 2012). This act clarifies that the Secretary of State "must have regard to the quality standards prepared by NICE." The care system should consider those standards in planning and delivering services to secure continuous improvement in quality. NICE quality standards do not provide service specifications but rather define priority areas for quality improvement. Nevertheless those standards are the basis to ensure that the providers of health and adult social care in England meet the standards of quality and safety required to by the Care Quality Commission.

The standards developed by NICE are typically composed of a general statement complemented by a measure. These quality measures are drafted only after the quality statement wording has been agreed and addresses the structure of care or services, process of care or service provision, and, if appropriate, outcome of care or service provision. The majority of measures refer to process and are expressed as a numerator and denominator to define a proportion in which the numerator is

a subset of the denominator population. For example, for the standard "People who inject drugs have access to needle and syringe programmes in accordance with NICE guidance," there is a measure at the structure level, which is "Evidence of local arrangements to ensure people who inject drugs have access to needle and syringe programmes in accordance with NICE guidance," complemented by a measure of outcome: (a) proportion of people who inject drugs who access needle and syringe programs, wherein the numerator is the number of people who access needle and syringe programs and the denominator is the estimated prevalence of injecting drug users, and (b) incidence of blood-borne viruses among people who inject drugs.

To clarify the implications of the standard, a breakdown of meanings of the standard for each stakeholder is included: service providers ensure systems are in place for people who inject drugs to have access to needle and syringe programs in accordance with NICE guidance; needle and syringe program staff ensure people who inject drugs have access to needle and syringe programs in accordance with NICE guidance; commissioners ensure they commission services for people who inject drugs to have access to needle and syringe programs in accordance with NICE guidance; and people who inject drugs have access to needle and syringe programs that are nearby, have suitable opening hours, and provide injecting equipment and advice on reducing the risk of harm. The standards include also that the sources of data should be considered in the measurement. Furthermore, at NICE there is an implementation team to support key audiences and organizations to maximize the uptake of guidance and quality standards. The team assesses the aids and barriers to implementation and provides practical support tools for commissioning, service improvement and audit, education, and learning. The team prepares reports on the uptake of guidance that are used to inform the development of the quality standard. The implementation team collaborates with national bodies and local organizations, through local implementation consultants, to support the use of quality standards and to facilitate shared learning. Overall the process to produce standards at the National Institute for Clinical Excellence lasts indicatively for 42 weeks.

These two examples suggest the possibility of different approaches to the use of quality standards. In the Czech experience in fact, the development of the standards represents an initial effort, whereas the actual focus seems to lie on the certification and accreditation process including several levels of training and a "learning by experience" process. Furthermore, the entire experience initiated around 20 years ago has been conceived and developed specifically in the treatment of drug addiction.

On the other hand the National Institute for Clinical Evidence has created along with the Department of Health and other key partners a core library of topics for quality standard development in health-related topics, among which alcohol dependence and drug use were included. In this case the focus seems to be on the development itself of the standards which *translate the evidence-based guidelines* into general statements and measures of outcomes at the system level including the indication of the sources of data to be used for the assessment of the implementation. Furthermore, NICE offers the support of an implementation team to enhance local adoption initiatives.

85.3 Conclusion

Quality of intervention is entrenched to evidence base, and in the last 20 years, important progress has been made in the availability of good quality systematic reviews of effectiveness in the field of drug addiction treatment. Nevertheless important gaps in knowledge still exist and need to be addressed by further investment in research. To ensure that research answers concrete problems arising from the daily experience of those affected by the drug problems at several level, it is crucial that the end users of research results – such as practitioners, patients, and decision makers – are involved in the selection of priority for investigation.

Currently the attention seems to be focused on how to better communicate evidence to policy makers, patients, and the general public. It is clear that the achievement and maintenance of quality in the treatment of drug addiction need the participation of all the stakeholders. The agencies which provide the data needed to assess the current situation and set the future goals, the organizations producing evidence-based documents, the decision makers at service provider level, and those managing the local, regional, and national level have to collaborate with the practitioners, to offer the best possible treatment to the drug users. The drugs users, the families, and the public have to proactively be involved in any decision and should be able to speak out their needs and problems.

The tools to translate evidence into quality of treatment have to be understandable by all the relevant stakeholders to empower them in a reiterative process of testing and lessons learned.

Quality is a continuous process where each new achievement has to be seen as a step towards new goals.

Glossary of Terms

Accreditation is the process by which an institution delivering a service is independently assessed for quality against some predefined criteria. Accreditation requires a set of minimum standards, which are set by the accrediting body.

Benchmarking is the process of comparing service processes and performance metrics to best practices from other services. Dimensions typically measured are quality, time, and cost.

Clinical pathways are structured, multidisciplinary plans of care designed to support the implementation of clinical guidelines and protocols.

Guidance is a general term that covers documents such as guidelines and quality standards.

Guidelines are "statements that include recommendations intended to optimise patient care that are informed by a systematic review of evidence and an assessment of the benefits and harms of alternative care options" (Institute of Medicine 2011). They are designed to assist carers' and clients' decisions about appropriate interventions in specific circumstances.

Protocols, in general, are documents that specify the procedures to follow to perform some tasks, typically those used to conduct a study or to implement some guidelines at individual service level.

Standards and quality standards are principles and sets of rules based on evidence (Brunsson and Jacobsson 2000), used to implement the interventions recommended in guidelines. They can refer to content issues, to processes, or to structural (formal) aspects of quality assurance, such as environment and staffing composition. In some cases, standards are legally binding.

Ethical and Legal Aspects of Interventions in Addiction Treatment

86

Ambros Uchtenhagen

Contents

Abstract

The UN conventions present the international legal framework; they urge member states to provide treatment and rehabilitation but prohibit consumption and possession of scheduled drugs. This creates problems for providing treatment and harm reduction programs to patients who are not or not yet ready to stop illicit drug use. Other international documents, notably from the World Health Organization and the United Nations Office on Drugs and Crime, are strongly in favor of agonist substitution treatment and harm reduction measures. Within this framework, national legislation has much room for diverse preferences; the International Narcotic Control Board regularly comments the national practices, as well as the European Monitoring Centre for Drugs and Drug Addiction for the EU member states. An international trend gradually prefers therapeutic measures over criminal sanctions for drug users.

The international ethical framework is set by the universal declaration and European convention on human rights, striking a balance between individual rights and societal interests. Less ambiguous guidance comes from medical ethics claiming the full range of patient's rights for addicted persons.

Note: Some of the material is based on earlier work of the author about ethical aspects of treatment and care in addiction (Uchtenhagen & Guggenbühl 2000; Uchtenhagen et al. 2005; Uchtenhagen 2010a, b).

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment: International Perspectives*, DOI 10.1007/978-88-470-5322-9_65,

The respective conduct codes for medical professions are regional or national and include procedures how to deal with ethical conflicts. Conflicting situations frequently occur, e.g., around the principles of autonomy or of confidentiality.

An essential ethical element of treatment is its effectiveness and avoidance of harm, asking for scientific evaluation of therapeutic approaches, services, and systems. The ethical acceptability of agonist substitution treatment and of harm reduction measures is based on rigorous evidence of their effectiveness. Other aspects concern the limits of social acceptability of addictive behavior and the limits of what can be attained for an individual patient by therapeutic interventions; avoidance of harm often is the more immediate objective than full recovery. In a public health perspective, effects at population level rather than at individual level are a priority, aiming at good coverage of treatment needs by good accessibility and affordability of services.

86.1 Introduction

Addiction treatment is historically and until present guided by the basic understanding of addictive behavior. Interventions are shaped accordingly to prevailing paradigms explaining substance use and substance dependence. Legislation is a preferred instrument to limit consumption and addictive behavior, through preventive interventions as well as sanctions. The development of liberal societies caring for individual freedom and responsibility, less interference with lifestyles and personal choices, and the need for ethical standards in human behavior came to the forefront and resulted in various rules guiding interventions and therapist's conduct. This process in the area of addiction treatment has been taken at hand, but with persisting differences in orientation and a need for conflict management.

86.2 International Frameworks and National Diversities

86.2.1 Legal Aspects

86.2.1.1 The International Framework: The UN Conventions

The UN conventions of 1961, 1971, and 1988 have some implications for delivering addiction treatment.

The Single Convention urges "to take all practicable measures for the prevention of abuse of drugs and for the early identification, treatment, education, after-care, rehabilitation, and social reintegration of the persons involved." While this article 38 does not indicate how treatment should be delivered, Resolution II declares that "one of the most effective methods of treatment for addiction is treatment in a hospital institution having a drug free atmosphere," and urges the provision of such facilities (UN 1961).

The Convention on Psychotropic Substances of 1971 (UN 1971) restricts the "use and possession of, substances in Schedules II, III and IV to medical and

scientific purposes," thereby criminalizing patients in treatment who continue sporadically or regularly to use illicit drugs (schedules II, III, and IV include drugs such as barbiturates, benzodiazepines, and buprenorphine). Art. 7 states for schedule I drugs to "prohibit all use except for scientific and very limited medical purposes by duly authorized persons." What the limitations are is open to interpretation. Art. 9 requires "that substances in Schedules II, III and IV be supplied or dispensed for use by individuals pursuant to medical prescription only, except when individuals may lawfully obtain, use, dispense or administer such substances in the duly authorized exercise of therapeutic or scientific functions." Licensed pharmacists however may "supply, at their discretion and without prescription, for use for medical purposes by individuals in exceptional cases, small quantities, within limits to be defined by the Parties, of substances in Schedules III and IV." Art. 20 urges to "take all practicable measures for the prevention of abuse of psychotropic substances and for the early identification, treatment, education, after-care, rehabilitation and social reintegration of the persons involved." Also, treatment may be provided either as an alternative to conviction or punishment or, in addition to punishment, if abusers of psychotropic substances have committed such offences (Art.22).

In the 1988 Convention (UN 1988), preparatory acts for personal use of scheduled substances are criminal offences (Art. 3,2):

> Subject to its constitutional principles and the basic concepts of its legal system, each Party shall adopt such measures as may be necessary to establish as a criminal offence under its domestic law, when committed intentionally, the possession, purchase or cultivation of narcotic drugs or psychotropic substances for personal consumption contrary to the provisions of the 1961 Convention, the 1961 Convention as amended or the 1971 Convention

Implicitly, this includes criminalization of use (no use without preparatory acts).

The International Narcotic Control Board (INCB) was set up in 1968, with the main task to control and facilitate the implementation of the Single Convention at national level. The following conventions have revised and restated the functions of the Board.

In summary, the UN conventions urge the treatment and rehabilitation of drug abusers but prohibit the consumption of narcotics and psychotropic substances (including tranquilizers and sedatives), which creates problems for patients in treatment (continued use is often a reason to exclude patients from treatment) and even more problems for harm reduction approaches designed to diminish the medical risks of substance use (for persons in addiction treatment and outside of treatment). Agonist maintenance treatment is viewed critically by INCB as a potential source of diversion of narcotics to the illegal market (INCB 2011). However, the conventions allow diversion to treatment as an alternative to punishment.

86.2.1.2 Other International Frameworks

Some international documents are mentioned here with relevance to addiction treatment and specifically in regard to agonist maintenance treatment and harm reduction interventions. These evidence-based documents present strong recommendations which are not legally binding.

The World Health Organization (WHO) and the United Nations Office on Crime and Drugs (UNODC) published Principles of Drug Dependence Treatment in 2008. This discussion paper is in strong support of agonist maintenance treatment for opioid dependence: "Opioid agonist pharmacotherapy is one of the most effective treatment options for opioid dependence when methadone or buprenorphine are administered at an individualized dosage for a period of several months to years." The discussion paper also urges to implement legal frameworks which guarantee protection from potential sanctions for those seeking treatment (WHO/UNODC 2008).

The UNODC, WHO, and UNAIDS "Technical Guide for countries to set targets for universal access to HIV prevention, treatment and care for injecting drug users," published in 2009, has a range of preventive measures (e.g., needle and syringe exchange programs) among its recommendations, thereby complementing the treatment recommendations (UNODC/WHO/UNAIDS 2009).

In Europe, the EU Action Plan 2005–2008 (EU 2005) foresaw harm reduction measures as a specific action for the implementation of Objective 14 (prevention of health risks related to drug use) and Objective 15 (availability and access to harm reduction services). The implementation process and the available evidence on outcomes is presented in a monograph (Rhodes and Hedrich 2010).

86.2.1.3 Diversity of National Legislation

At the national level, narcotic laws and policy guidelines mirror a diversity of principles, priorities, and preferences, even when countries have ratified the UN conventions. Treatment of substance abuse is one of the essential elements, but how it is defined, for whom it is available, under which circumstances, and which approaches are officially accepted are all subject to major differences. One example is the national guidelines for substitution treatments of opiate dependence; an analysis of 28 national guidelines found a large variety of indication criteria and practices (Uchtenhagen et al. 2005).

An official source of information on problems with the implementation of the UN conventions is presented in the annual reports of the International Narcotic Control Board (INCB). The 2011 report includes, e.g., information on unacceptable treatment problems, such as diversion of prescribed pain medications or allowing safe injection rooms (INCB 2011, p. 38). The setting up of the lack of aftercare is admonished (p. 59). On the other hand, large compulsory treatment centers are mentioned (p. 78), as well as detoxification, rehabilitation, and counseling services (p. 83); opiate substitution treatment (p. 51, 78); and needle/syringe exchange programs (p. 51), without indicating their acceptability and outcomes.

A complete and updated collection of national drug laws and drug policies is presented by the European Monitoring Centre on Drugs and Drug Abuse (EMCDDA); it includes not only the EU member states but also acceding and candidate countries as well as neighboring and Central Asian countries (EMCDDA 2012). The same source provides a systematic information on treatment approaches and harm reduction approaches in these countries.

86.2.1.4 Sanctions

Use and possession of illegal drugs for personal use are prohibited in a range of countries. For Europe, an analysis of national practices is presented (EMCDDA 2009). Only rarely, prison sentences are handed out in case of infraction. In other regions, imprisonment and compulsory treatment are more common, e.g., in labor camps (WHO 2009).

In some countries, drug possession is an offence which may entail imprisonment or even capital punishment. A systematic overview is not available. In Islamic law, use of any drugs including alcohol is prohibited and sanctioned, but it also provides care of those suffering from medical conditions.

Agonist maintenance therapy is prohibited in Russia (MHR 1995), while a growing number of countries supports and expands this approach, replacing criminal sanctions.

86.2.2 Ethical Aspects

86.2.2.1 Ethical Basis of Interventions: Human Rights

The Universal Declaration of Human Rights (UN 1948) contains a number of relevant conditions, such as no discrimination (art.2), no degrading or inhuman treatment (art.5), and right of equal access to medical care and social services (art.25/1), but also that everyone has duties to the community (art.29/1) and that limitations of rights and freedom are admissible on the basis of "just requirements of morality, public order and the general welfare" (art.29/2).

In view of conflicts this may create, a recent initiative proposes the formulation of meta-rules providing guidance on how to resolve conflicts in human rights (Arosemena 2013).

The European Convention on Human Rights (Council of Europe 1950) further stipulates that a person's liberty may be deprived in case of lawful detention of alcoholics or drug addicts (art.5/1/e), with a right to appeal to a court (art.5/4).

In summary, these statements try to establish a balance between protecting the individual rights of the person and respecting the needs of society for public order, general welfare, and even morality. There is large room for interpretation, so that every society can decide on the compatibility of addictive behavior with the nature and extent of the abovementioned requirements. Compulsory measures against persons with substance dependence may be admissible on the basis of national laws.

86.2.2.2 Ethical Basis of Interventions: Medical Ethics

Medical ethics apply only if and inasmuch as substance dependence is understood as a medical condition. This has been the official position of the leading medical organizations since decades (and brain research has identified it as a "brain disease," thereby giving it a biological basis) (Leshner 1997). The substance-dependent person is a patient and should enjoy the status and all the rights of patients.

The current medical science defines substance dependence as a condition with diagnostic criteria, described in the generally acknowledged diagnostic systems International Classification of Diseases ICD-10 of World Health Organization (WHO 2010) and Diagnostic-Statistical Manual of Mental Disorders DSM-IV TR of the American Psychiatric Association (APA 2000). New editions of both systems are in preparation. The criteria include biological symptoms (tolerance, withdrawal symptoms in case of discontinued use), psychological symptoms (craving, desire to reduce consumption), and behavioral symptoms (loss of control over consumption, consuming in spite of perceived negative consequences).

ICD-10 includes a diagnosis of harmful use (with negative health consequences of use), while DSM-IV includes a diagnosis of abuse. These conditions are also considered to be a medical condition inviting therapeutic interventions.

What are the consequences for the treatment of addiction? Examples of the general conduct codes are the Standards of Conduct of the American Medical Association (AMA 2001) and the Good Medical Practice of the English General Medical Council (GMC 2006). Main issues are the patient's autonomy of decision, informed consent, dignity and confidentiality, nondiscriminatory beneficence, and non-maleficence, but also keeping up professional standards by continued education and networking with other services and colleagues in order to provide the best possible care. In addition, the American recommendations include a responsibility to seek change in official or legal requirements which are contrary to the best interests of the patient. These codes usually acknowledge the occurrence of ethical conflicts and provide links for support in such cases.

In the absence of specific rules for the treatment of substance dependence, the general ethical rules for good medical practice apply. The four major principles are as follows: do no harm, improve the well-being, respect the autonomy, and apply justice. It is obvious that even these few principles cannot be followed without creating conflict (Rust 2000).

Involuntary intervention to prevent harm is in conflict with the autonomy of an unwilling patient. Treating all patients as being equal (principle of justice) is impossible where the resources are limited. Also, confidentiality and data protection often are in conflict with administrative and law enforcement interests in case of illicit drug use. All such conflicts must be carefully examined, in the best interest of all concerned. When the patient's interests collide with those of relatives or other third parties, a common solution must be found to the extent possible. It is advisable to recur to an ethical concilium if major consequences are expected from the decision. The principle of respecting the autonomy of the patient must never be overruled in the name of some abstract societal value without the presence of concrete harm implications for others.

86.2.2.3 Ethical Justification of Interventions

Human rights as well as medical ethics mention the interests of society which may be in conflict with the interests of the individual. In fact, the ethical justification to interfere with a person's substance use or dependence resides in negative societal consequences. In the case of substance dependence, treatment is justified in order to

avoid such negative consequences. Among the appropriate measures are all treatments which help to bring a majority of addicts into treatment, without disregarding their autonomy, and to optimize accessibility of treatment services. In the case of hazardous and harmful use, treatment by early and short interventions (e.g., motivational interviewing) can have positive effects.

As in other medical fields, therapeutic interventions are justifiable if efficient and effective. This principle is part of what is named "consequential ethics," in contrast to dogmatic ethics which call for complying with a given norm whatever the consequences may be.

Substance use is a factor in many social and cultural events, as a facilitator of social contact and a source of emotional well-being but also of destructive or aggressive behavior. The acceptable limits of intoxication and behavior, of substances used and of opportunities for consumption, are cultural specific and are to be respected when dealing with substance dependence (Edwards and Arif 1980). For instance, a major difference between western and Asian cultures is the place of the individual within the family system; while the individual's interests and autonomy are a core concept of most western psychotherapies, the integrity and the interests of the family are the higher value in many Asian societies.

In a paternalistic attitude, substance-dependent persons must be protected against wasting their personal resources and potential achievements. However, such an attitude collides with the present position that interference is only justified on the basis of negative consequences of a person's behavior for others. Also, many people have lived or live a productive life in spite of their substance dependence, and to interfere with their lifestyle would cause more ethical concerns than to respect their autonomy.

Developing one's own resources and shaping one's own life is to be facilitated by education and by societal organization, but it is ultimately in the responsibility of the person itself. Conditional are the freedom of choice – and the freedom of the will. Is addiction leaving any room for choices, is it a negation of free will and therefore the basis for involuntary intervention? This has been debated extensively. At present and on the basis of research evidence, we have a more differentiated view. The decision of many to change their lifestyle and go to treatment (Ekendahl 2007; Bergmark 2008) or to stop the dependence without professional support (the so-called self-healers) (Klingemann and Sobell 2007) demonstrates the ability of many addicts to make a choice and stick to it.

This notion is reinforced by observations of regaining consumption control by former addicts (Kaya et al. 2004) and that not the substance alone but also the personality and the social environment had a role in the development of dependence and that many users keep their consumption under control or regain control under more favorable conditions (Zinberg 1984; Robins 1993).

A basic ambivalence – substance dependence as a medical condition or a moral weakness – is reflected in the opposition of medical and moral treatment. Moral treatment is understood to be educational and admonishing. The medical approach is to help the addict in getting motivated for change by appropriate empathy and information, while confrontation and reproaches risk to reinforce the resistance

against any change. It is important to give the patient the feeling that he is taking the decisions and doing the necessary steps forward himself. Special methods have been developed for enhancing the motivation for change, and they have become an important element in today's treatment of alcohol and other drug problems (Moyer et al. 2002; Gossop 2006).

In summary, treatment of substance dependence is expected to help the individual to make his own choices and to regain self-responsibility, rather than to make the decisions for him.

86.2.2.4 The Goals of Treatment: A Hierarchy of Objectives

The goals to be reached through treatments of substance dependence (and which therefore are the criteria for measuring outcome in treatment evaluation research) have changed over the last decades. While the goal of abstinence was traditionally on top of the list, the present situation can be summarized as follows: the primary goal is the patient's survival, moving to health improvements (or at least prevention of deterioration), to improvements in social integration, to reductions in substance use (moving away from addictive behavior), to improvements in quality of life (as defined subjectively by the patient), and ultimately resulting in a responsible and satisfactory lifestyle. Abstinence is not always needed for reaching these objectives, nor does abstinence guarantee to reach them.

A national example of listing the objectives is given in the report on Models of Care by the UK Department of Health (Department of Health 2002):

- Reduction of psychological, social, and other problems directly related to drug use
- Reduction of psychological, social, or other problems not directly attributable to drug use
- Reduction of harmful or risky behaviors associated with the use of drugs (e.g., sharing injecting equipment)
- Attainment of controlled, nondependent, or non-problematic drug use
- Abstinence from main problem drugs
- Abstinence from all drugs

This document fully endorses the principle of consequential ethics in prioritizing the reduction of the various forms of drug-related harm, including social, medical, legal, and financial problems, until the drug-dependent patient is ready and able to come off drugs.

86.2.2.5 Cure or Care?

Treatment is often identified with cure (in the sense of healing an illness), while care means serving a chronic patient without chances for healing. As such, care is an equivalent to harm reduction, meaning all interventions designed to improve the health and social status of a chronic addict who continues a dependent behavior (harm reduction is more than HIV prevention). The present debate on treatment and harm reduction is often a debate on opposing principles of action which cannot be reconciled. In this debate, harm reduction has been disqualified as an approach to prolong dependence, to make substance use acceptable for young people, and to

undermine the readiness of addicts for treatment. A recent movement to promote recovery as a complete resocialization without drugs disqualifies agonist maintenance treatment which is only accepted as "maintenance to abstinence."

Today, in the light of the updated treatment objectives, harm reduction is considered an ally rather than an opponent of treatment. Accordingly, the treatment system must be an integrated system that enables abstinence and harm reduction services to work together, in order to provide a continuum of care, including:

- Easily accessible low threshold services that meet the immediate needs of continuing drug users
- Clear processes for motivating users to move away from drug-dependent lifestyles
- Clear processes for referring users into structured treatment programmes that promote stabilization or abstinence (quoted from Stevens et al. 2006, p. 6)

86.2.2.6 Tailoring Treatment to Individual Needs

Bearing in mind the diversity of etiology, symptoms, and stages of substance dependence, it becomes obvious that treatment cannot be uniform for all dependent persons. In addition, treatment needs in different age groups and other target groups (gender, ethnicity, comorbidity, etc.) may differ considerably as well. Treatment must respond to the specific needs of an individual patient, on the basis of a comprehensive needs assessment and a treatment planning process where patient and therapist work together on a shared understanding of what is needed and what should be done.

This concept of a needs-based treatment has been intensively researched. I mention two large studies from USA: the National Treatment Improvement Evaluation Study (NTIES) documented the results of needs-based treatment planning and found a significant correlation between 1-year outcomes (measured as drug-free urines) and the number of needs included in the treatment plan (Gerstein et al. 1997). A comparison of basic, average, and enhanced services for heroin dependence evidenced better retention and outcomes in services where psychiatric and social care was available to patients (McLellan et al. 1997). In both studies, covering the needs for psychiatric care and living conditions (housing, jobs) was found to be especially important. This again has consequences for the hierarchy of objectives: a reduction of substance use is facilitated by improved living conditions and not necessarily their precondition. "Matching treatment settings, interventions, and services to an individual's particular problems and needs is critical to his or her ultimate success in returning to productive functioning in the family, workplace, and society" is therefore one of the principles of addiction treatment (NIDA 2012).

86.2.2.7 Public Health Interventions Versus Individual Care

Coverage of treatment needs: Reaching the majority of drug injectors became a primary objective in order to slow down the HIV epidemic. The public health priority is to offer treatment to all persons in need of treatment. Individual care is optimized by high-quality treatment, but public health cannot accept high-quality standards for a few as long as the many are not reached adequately. This principle

includes a monitoring of the treatment needs in a given population and, accordingly, a careful planning of the treatment system as a whole. The responsibilities – ethically and professionally – are well distributed: medical practitioners are responsible for good individual care, service directors are responsible for good practice in their services, and health authorities are responsible for good coverage of treatment needs.

Cost-effectiveness of interventions: When caring for the treatment system as a whole, the next step is to take the responsibility for making best use of the available human and financial resources for treatment. This means to look at how much effective treatment is provided at what costs. It does not suffice to give a priority to treatments with good evidence for effectiveness but to treatments which provide effectiveness at the lowest costs in terms of staff and budget. A recent approach are efforts which intend to make best use of resources through models of stepped care, matching patients to specific treatments, on the basis of their characteristics and needs (see ▶ Chap. 82 "Stepped Care Models in Addiction Treatment" in this section).

Harm reduction: An efficient protection of public health goes beyond providing treatment for substance-dependent persons. It includes all measures which are effective in protecting the health and social status of active users, in the interest of users as well as of the population at large.

Accessibility and affordability of treatment: Neglect of patients in need of treatment can take many forms. For instance, an analysis of national guidelines for substitution treatments of opiate dependence showed a range of restrictive access criteria, such as minimal age, minimal duration of dependence, polydrug use, and lack of confidentiality, and likewise restrictive criteria for a continuation of treatment, such as persistent illicit substance use or bureaucratic limitation of treatment duration (Uchtenhagen et al. 2005). Other examples are the denial of social support and/or medical care to active alcohol or drug users or smokers. Examples are the denial of liver transplants to persons with alcohol problems, in spite of research evidence that survival rates in those who continue to drink are not lower than in other patients (Fireman and Rabkin 2001), and the denial of Hepatitis C treatment with Interferon to active drug injectors on the basis of wrongly presumed lack of compliance (Edlin et al. 2001). Excluding addiction treatment from health insurance and reserving treatment to those who can pay for it are other examples.

In summary, the ethical implications are obvious: without appropriate accessibility and affordability of treatment, there is no way to reach the "health for all" goal of good coverage and of treating all patients as equal.

Quasi-compulsory and compulsory treatment: Is it advisable to force addicts into treatment, when they are not motivated to engage in it by themselves, in view of an objective of optimal coverage? It is a common understanding that addicts do not enter treatment unless there is some external or internal force behind such a decision. The forces are quite different, ranging from health concerns to social pressure by family or employer to legal pressure in order to avoid losing the driver's license or going to prison. This is called the "continuum of coercion" (Weisner 1990). The scientific evidence on the effectiveness of such "coercion" is

contradictory (Gerdner 1998; Wild et al. 2006). A recent multi-country study on quasi-compulsory treatment (QCT, treatment on court order as an alternative to imprisonment, with the consent of the patient) documented that perceived pressure does not translate into higher motivation; no significant differences in outcome were found between QCT patients and control groups of voluntary patients (Stevens et al. 2006).

Coercion through mutually agreed consequences of substance use during treatment (contingency management) is recognized to be helpful, but more so when using positive reinforcers than sanctions (Miller and Flaherty 2000; Schumacher et al. 2007). From an ethical standpoint, it is reluctantly accepted under the term of "Ulysses coercion" (Odysseus wanted to be bound to the mast of his ship in order to resist the temptations of the sirens, Tännsjö 1999).

In summary, the findings indicate that coercion may have a role in supporting patient motivation for change, on the basis of informed consent, but it cannot replace motivation by compulsory measures without consent.

86.2.2.8 The Case of Agonist Maintenance Treatment

Rationale and origins: At first view, prescribing agonists with dependence liability to persons suffering from substance dependence seems to be paradox. One of the main arguments against agonist prescribing refers to a prolongation of dependence, considered to be unethical. How can we understand the rise and successes of this therapeutic approach (also known under the terms substitution or replacement treatment)? The main objective is to replace uncontrolled use of an addictive substance by the controlled provision of a medication acting on the same receptors as the original substance. The secondary objectives to be reached are reduction of the uncontrolled substance use, reduction of adverse health and social effects of uncontrolled use (including a reduction in drug-related delinquency), and normalization of lifestyle (including drug-free social contacts, improved housing, and employment conditions). These objectives are in line with the hierarchy outlined above. The primary objective is reached by prescribing and controlled intake of an agonist, the secondary objectives by eliminating the need to purchase the original substance of dependence and by ancillary care.

The introduction of agonist maintenance treatment is closely linked to the experience of unsuccessful detoxification and abstinence-based treatment. Maintenance without substitution was practiced in Roman times (the emperor Marc Aurel was maintained on opium by Galenus, the eminent physician), and daily dosages of opium were provided to dependent persons in Southeast Asia in the nineteenth century (Westermeyer 1982); ironically, after the ban of opium these persons switched to heroin (Westermeyer 2006). First attempts at substitution were to replace opium by alcohol in the sixteenth century (Elliott 1920), morphine by heroin (Kramer 1977), and morphine by cocaine (Freud 1884) in the nineteenth century. These attempts were far from being successful. A first well-designed and scientifically based model was developed by Dole and Nyswander: the methadone maintenance scheme (Dole and Nyswander 1965). They used oral methadone, a full opiate agonist, with a longer half-life than injected heroin (controlled intake of one

dose per day can block the heroin craving effectively). The model included ancillary care for medical and social conditions of enrolled patients.

Apart from opiate replacement, only nicotine replacement has been introduced into present medical practice, while former alcohol maintenance for alcoholics is discontinued.

Results: Methadone maintenance is one of the most frequently and best researched therapeutic approaches. Extensive reviews of the pharmacological aspects, of service delivery, and of therapeutic outcomes have been published (Arif and Westermeyer 1990; Ward et al. 1998; Uchtenhagen 2003; Farrell et al. 2004; Health Canada 2008). In addition to methadone, buprenorphine and retarded morphine have been introduced and researched as replacement medicines in the treatment of opioid dependence, with similar outcomes. The positive findings in terms of health and social improvements, including a massive reduction of delinquency, were complemented by the fact that agonist maintenance treatment has the greatest potential to bring heroin-dependent persons into contact with therapy and care. It therefore became one of the most welcome instruments for limiting the spread of blood-borne diseases – HIV/Aids and hepatitis – among drug injectors. The reduction of risky injecting behavior and of seroconversion rates in methadone patients became evidenced for community-based programs (Metzger et al. 1993) and for prison-based programs (Stallwitz and Stoever 2007). Economic evaluation documented the cost-effectiveness of methadone and buprenorphine maintenance treatment (Connock et al. 2007).

Based on the evidence, methadone and buprenorphine have been scheduled by the World Health Organization as essential medicines (WHO 2004a, b). Also, international evidence-based scientific guidelines for agonist maintenance treatments have been published (WHO 2008).

Concerns: A major concern was a weakening of the motivation to change and therefore a prolongation of addictive behavior through agonist maintenance treatment. There is no evidence for this claim. A multisite major cohort study showed a relapse rate of methadone maintenance patients to daily opiate use of only 27 % at 12 year follow-up (Marsh et al. 1990). The DATOS study from USA and the NTORS study of the UK, both multisite prospective cohort studies, found comparable outcomes at 5 year follow-up in patients who were enrolled in residential drug-free and in methadone maintenance treatment (Hubbard et al. 2003; Gossop et al. 2003).

In summary, the ethical justification of agonist maintenance treatment in the modern form was to provide otherwise treatment-resistant heroin addicts with an effective approach to improve their health and social situation without asking for total abstinence from narcotic substances.

86.2.2.9 Conflicts in Ethical and Legal Orientation

In numerous concrete situations, human rights and medical ethics are difficult or impossible to respect as well as national or local legal conditions. A number of such situations has been indicated throughout this text. Sometimes, an appropriate conflict management may help, especially if the application of an opportunity

principle is permitted. In other situations, there is no such solution. The way out is indicated by the ethical code of AMA: to engage in an effort to change laws which prove to be incompatible with responsible care for the addicts (AMA 2001).

86.2.2.10 Implications and Recommendations: A Final Statement

The essential ethical message is well summarized in the WHO international guidelines for the psychosocially assisted pharmacological treatment of opioid dependence (WHO 2008):

> When making clinical decisions for the treatment of people with opioid dependence, ethical principles should be considered, together with evidence from clinical trials; the human rights of opioid dependent individuals should always be respected. Treatment decisions should be based on standard principles of medical care ethics – providing equitable access to treatment and psychosocial support that best meets the needs of the individual patient. Treatment should respect and validate the autonomy of the individual, with patients being fully informed about the risks and benefits of treatment choices. Furthermore, programmes should create supportive environments and relationships to facilitate treatment, provide coordinated treatment of comorbid mental and physical disorders, and address relevant psychosocial factors.

There is not much to be added. The statement applies fully as the main recommendation for all treatments of substance dependence. It is a perpetual agenda for future generations.

Contents

Abstract

The three international drug treaties cover many psychoactive substances ("drugs"), although not tobacco (now under a separate treaty) or alcohol. They include a penal regime to enforce the limitation of use to medical or scientific purposes, a trade regime concerning drugs for medical use, and a planning scheme to ensure adequate supplies of medical opiates. The system, initiated in 1912, had shifted its main focus by the 1988 treaty to combating the illicit markets which accompany a prohibitory system. The place of the drug treaties in the United Nations system and the bodies which compose the system are briefly characterized. Nearly every country has signed each treaty, though often with

reservations. The option this involves of denouncing and reacceding with reservations has now been successfully used by Bolivia concerning coca leaves. The system has assured access to pain medication in most high-income countries, but not in much of the world, where the system's emphasis on law enforcement has often indirectly but effectively cut off supplies. In terms of controlling legal medical markets, the system has had mixed success. But the system has mostly failed in cutting off the illicit drug trade. In a system which has been committed to a prohibitory approach, there are recent signs of change, particularly in the Americas, which are briefly discussed.

87.1 Introduction

The United Nations drug control system is organized around three international treaties: the Single Convention on Narcotic Drugs of 1961, as amended by a protocol of 1972; the Convention on Psychotropic Substances of 1971; and the UN Convention Against Trafficking in Narcotic Drugs and Psychotropic Substances of 1988. Their texts and the official commentaries on them are conveniently available online: https://www.unodc.org/unodc/treaties/index.html.

The treaties, of course, do not cover the whole range of psychoactive substances. There is a separate treaty on tobacco, the Framework Convention on Tobacco Control of 2003, negotiated under the auspices of the World Health Organization, and an International Convention Against Doping in Sport (many of the substances covered by it are psychoactive), adopted in 2005 under the auspices of UNESCO. Notably absent from the list of substances under international control is alcohol, although it was actually the subject of the first international drug treaty, controlling "trade spirits" in colonial Africa, negotiated in 1889 but now in abeyance (Bruun et al. 1975). The 2012 WHO Expert Committee on Drug Dependence briefly discussed whether alcohol would qualify for listing under the UN drug conventions and referred this for consideration at a future Expert Committee meeting (WHO 2012, p. 16).

From the perspective of the inherent harmfulness of different psychoactive substances (e.g., Nutt et al. 2010), what is included and what is excluded in the three "drug treaties" are not easily defensible except as reflecting the vagaries of history. But despite the ongoing convergence in scientific thinking about psychoactive substances (Courtwright 2005), it is still true that discussions of international drug control which take account of the whole range of drugs and their regulation are rare (for an exception, see Braithwaite and Drahos 2000).

In this chapter, however, attention remains focused on the three UN drug treaties. We consider the intended functions of the treaties, the institutional arrangements for their implementation, and what evidence is available on effects and impact of the system. As this is written at a moment when change in the system seems increasingly possible, a brief discussion of potential future developments is also included.

87.2 Intended Functions of the Treaties

The treaties have three main functions: as a penal regime to enforce limitation of use of scheduled substances to medical or scientific purposes, as a specialized trade treaty controlling international trade in psychoactive substances for medical use, and as a central planning scheme to ensure adequate supplies particularly of opiates for medical use.

87.2.1 A Penal Regime to Enforce Drug Prohibition

The Single Convention, as its name conveys, replaced an array of treaties and protocols which had accumulated since the first opium treaty, the Hague Convention of 1912. But the Single Convention went well beyond what was in the previous treaties, signaling a change in the system's orientation (Carstairs 2005). Whereas the prime concern of the previous treaties had been with regulating international trade in plant-derived drugs (opiates, cocaine, and cannabis), the 1961 Convention introduced requirements that possession and delivery, along with a wide variety of market-related actions concerning the drugs covered, be criminalized under a country's domestic laws (Bewley-Taylor and Jelsma 2012). What had been a system concerned primarily with controlling international movement of drugs became a system committed to enforcing prohibitions on nonmedical use of the drugs, with each country's criminal laws as means of enforcement. The international prohibition system as it now exists can thus be said to have begun with the 1961 treaty.

The 1971 treaty greatly expanded the scope of the system by including a wide range of synthetic substances, many of them with pharmaceutical uses. The market controls in the 1971 treaty are weaker than those in the 1961 treaty, reflecting the powerful influence of the pharmaceutical industry on the treaty negotiations (McAllister 1991). The requirement concerning criminalization under domestic law is more simply stated than in the 1961 treaty, requiring penalization of "any action contrary to a law or regulation adopted in pursuance of its obligations under this Convention." But since the convention requires a medical prescription to authorize use of a covered drug, any possession or use without a prescription should be criminalized.

The 1988 treaty, as its name reveals, represented a further shift in the system's focus, with more attention focused on combating the illicit markets which had emerged as a by-product of the prohibition system, including for the first time controls on precursor chemicals used in the preparation of controlled drugs. But in an effort to eliminate any remaining ambiguity, it also included a further provision on criminalization at the level of the individual drug user: that a signatory country should "establish as a criminal offence under its domestic law, when committed intentionally, the possession, purchase or cultivation of narcotic drugs or psychotropic substances for personal consumption."

The system of treaties inaugurated by the 1961 Convention, then, has as a main goal the elimination or at least suppression of any nonmedical use of drugs, aiming

to eliminate illicit markets in drugs by a five-pronged approach: (1) particularly for drugs covered by the 1961 treaty, by restriction of the supply of the drugs, limiting production to the estimated medical need for the drugs; (2) by a system of export and import permits, restricting legitimate trade in the drugs in accordance with a receiving country's wishes; (3) by requiring that most substances covered by the treaties be in a prescription system, as a way of confining availability to medical control and use; (4) by criminalizing production, sale, and other market activities outside those permitted for drugs for medical use; and (5) by criminalizing users for purchase or possession of drugs other than for medical purposes.

87.2.2 A Trading and Marketing Control Regime

The treaties also set up a trading and marketing regime, a special kind of trade treaty which aims more to structure and direct international trade, rather than the more usual main aim of trade treaties – to facilitate trade. Requiring that an import permit be issued by the receiving country before drugs can be shipped to it means that a country can control and indeed cut off the legal supply of a drug to its residents.

Although the drug treaty system was established before the formation of the current system of international trade treaties, it has served an informal function of protecting the substances under its jurisdiction from any trade disputes seeking to open up markets for controlled drugs. This contrasts with the situation for alcohol and tobacco (O'Brien 2013; Baumberg and Anderson 2008; Shaffer et al. 2005).

87.2.3 A Central Planning Scheme to Supply Medical Needs

Particularly through the 1961 treaty and its predecessors, and particularly for opiates, the international system is intended to ensure that supplies of opium-derived drugs for medical use are available globally. Each signatory country is supposed to send to the International Narcotics Control Board (INCB) annual data on medical use of opioids and estimates of requirements for the next year. There is a system of permits for countries to grow opium to meet the demand from the medicinal market (around 2010, nearly half the legal supply was grown in Tasmania). Particularly with respect to opium, the aim is a globally controlled system of cultivation, manufacture, and supply which will ensure that medical needs everywhere for opioid medications are met.

87.3 Institutional Arrangements for Implementation of the Treaties

In the United Nations system, the drug treaties come under the jurisdiction of the UN's Economic and Social Council (ECOSOC), which serves as the final deciding body for issues such as the scheduling of drugs under the treaties and determines

whether a conference should be called to consider amendments to the treaties. The political body governing the drug system is the Commission on Narcotic Drugs, with 53 member states elected by ECOSOC but with proceedings open to attendance by other UN member states. The CND meets annually for several days in March in Vienna, in proceedings including plenary sessions, a Committee of the Whole for the discussion of proposed resolutions, and committee meetings. Each year the CND adopts resolutions following discussions which are often lengthy, since its decisions are customarily made by consensus.

The administrative body for the system is the UN Office on Drugs and Crime, which has responsibility also for the two UN crime treaties (on transnational organized crime and against corruption). UNODC has a limited "regular budget" as part of the UN system and relies for 90 % of its funding on "voluntary contributions," mainly from governments. Since these contributions are usually earmarked for specific projects, donor countries have a large say in determining the directions of the UNODC's work. In 2012, UNODC had about 500 employees, spread around the world – a smaller number than the US Drug Enforcement Agency had posted outside the USA (Room and Reuter 2012).

The International Narcotics Control Board (INCB) is a board consisting of 13 individual members elected by ECOSOC, 3 of them from a list of 5 nominated by the World Health Organization. They are supposed to serve as independent experts, not as representatives of any state; a unit within the UNODC serves as the INCB's secretariat. In addition to technical duties such as running the international market for opiate medications, the INCB has regarded itself as the "guardian of the treaties," issuing an annual detailed global report on the state of compliance as the INCB defines it (Bewley-Taylor and Trace 2006).

The World Health Organization also has responsibilities under the 1961 and 1971 treaties for providing scientific and medical expertise, particularly concerning the classification and scheduling of psychoactive substances under the conventions. According to the 1971 Convention, its assessments "shall be determinative as to medical and scientific matters." These responsibilities are primarily assigned to the Expert Committee on Drug Dependence, which is supposed to be constituted every 2 years for a process involving first prereview and then 2 years later a detailed review concerning classification of particular substances. However, due to WHO's limited resources, the Committee did not meet between 2006 and 2012. Recognizing that the present scheduling of many substances had not been reexamined in the light of scientific and other developments for many years, the most recent Expert Committee supported a proposal for each scheduled substance to be rereviewed every 20 years. In an Annex to the Committee's report, it was also pointed out that the language of the conventions does not map easily onto current scientific language concerning drugs (WHO 2012, p. 16, 23–35).

Over a number of years, the drug treaty system and the WHO drifted apart. A signal of this has been the CND's rejection in recent years of WHO recommendations on scheduling (Babor et al. 2010, pp. 213–214). Another signal of the division has been over the place of harm reduction in the treatment of drug problems. In public health in general, the reduction of harm is a central commitment

and strategy, and as the global public health agency, WHO was necessarily committed to its promotion. However, prior to 2009 the USA had insisted that the concept and term "harm reduction" not be used in the work of the international treaty agencies. After 2009, relationships between UNODC and WHO have been revitalized, including joint work on treatment guidelines (Room and Reuter 2012).

87.4 What Can Be Said About the Effects and Impact of the System?

One measure of the success of the system is its near universality, in terms of formal adherence to the treaties. Each year's INCB report notes with some pride the tally of countries which are signed up to each treaty. The desire for universality triumphed in the case of Bolivia's recent denunciation and reaccession to the 1961 treaty, despite disapproval by the INCB and other guardians of the system. Bolivia took this route to add a reservation to the treaty which would then allow Bolivians to chew coca leaves without contravening Bolivia's treaty commitments. Thwarted in an attempt to make this change by international consensus, Bolivia denounced (announced its withdrawal from) the treaty, proposing to reaccede with a reservation concerning coca chewing if the reservation was accepted (Room 2012a). If one-third of countries acceding to the treaty had objected, Bolivia's reaccession would not have gone into effect. It is a mark of the system's commitment to universality that there were only a few objections, despite considerable displeasure expressed by the INCB and others about Bolivia's reservation.

A second measure is in terms of its success in ensuring access to pain medication. For developed countries, this is not generally a problem. But the WHO has estimated that 80 % of the world's population lacks adequate access to effective pain medication (WHO 2007). Part of the problem, of course, is a lack of resources to procure or supply the medication. But another part is the indirect result of the treaty system. In consequence of the system's emphasis on law enforcement, decisions on importation of controlled drugs are often in the hands of police, who may choose to restrict or stop imports in order to impede diversion of the medicine to illicit markets. Reflecting concern about this, the most recent WHO Expert Committee decided that ketamine, a cheap and relatively safe anesthetic widely used in poor countries, should not be brought under the treaties. "Concerns were raised that if ketamine were placed under international control, this would adversely impact its availability and accessibility. This in turn would limit access to essential and emergency surgery, which would constitute a public-health crisis in countries where no affordable alternative anaesthetic is available. On this basis, the Expert Committee decided that bringing ketamine under international control is not appropriate" (WHO 2012, p. 9). Reflecting a greater priority still being placed on prohibition of nonmedical use than on the availability of needed medications, many national delegations and three regional groupings expressed concerns or regret about the WHO decision at the May 2013 meeting of the CND (IDPC 2013, p. 11).

A third measure is in terms of success in controlling legal markets. Here the system can show some success, among mixed results. The pre-Single Convention system succeeded (aided by the Depression) in substantially reducing world consumption of opium in the years prior to World War II. The current system, however, has not impeded the substantial rise in recent years in prescribed use of opioids in North America, which accounts for the lion's share of global use of prescribed opioids. In general, the conclusion of Bruun and colleagues (1975) remains true: the system's successes tend to occur where "it has been the conduct of professions and private enterprise which has been influenced." Large firms and state-licensed professionals have something to gain from cooperation with a control system, and with such levers of influence, drug control systems have had some successes, for instance, in getting chemical industries to control chemical precursors and in changing doctors' prescribing patterns when drugs, such as the barbiturates, prove to be more dangerous than was thought. The lack of any trade disputes about drugs under the system's control, in an era when free-market ideology has been dominant, might also be regarded as an unheralded success for the system.

A fourth measure, of course, is the system's degree of success in eliminating or at least reducing illicit trade, markets, and use. Here the overall result must be viewed as a failure. In 1998, the UN system set a 10-year goal of "eliminating or significantly reducing the illicit cultivation of coca bush, the cannabis plant, and the opium poppy by the year 2008." This goal remained as distant at the end of the period as it had been at the beginning (Reuter et al. 2009).

87.5 Signs and Directions of Change

The failure of the international drug prohibition system in terms of its most public goal, of eliminating or minimizing illicit markets, has been apparent for some decades. At national and subnational levels, there have been initiatives and experiments since the 1960s in moving in other directions, although these initiatives have been greatly hampered by the perceived necessity of operating within the constraints of the international system. Thus, even the Dutch "coffee shop" system for quasi-legal retail sale of cannabis, the most far-reaching attempt to move from an illicit to a regulated market, was handicapped by the "back door" problem – that cannabis which was sold under license at the front door had come in the back door illegally, since no way could be found to reconcile a legal wholesale supply with national obligations under the treaty (Korf 2008).

But there are signs of change in the early 2010s, particularly in the Americas. A diverse array of Latin American countries have shown a growing impatience with the status quo and have been willing to push against the long-standing "Washington consensus" for the status quo on drug policies. First several retired Latin American presidents, and then some sitting presidents, have expressed the need for new directions. The motivations have been diverse. In Mexico and Central America, the primary issue has been the carnage in their populations from a "war on drugs" aimed at cutting off the supply to the insatiable demand from northern neighbors.

In Bolivia, as mentioned, legalization of the folk custom of coca-leaf chewing has been a main concern. In countries like Uruguay, efforts to create a regulated legal cannabis market are aimed primarily at removing a main source of criminalization of young people. With a report from the Organization of American States (OAS) exploring alternative scenarios for the future (OAS 2013), these impulses at national levels have now taken a collective form in the region's intergovernmental agency.

At least as important have been the changes in the USA. In November 2012, votes on popular initiatives for regulated cannabis markets in Colorado and Washington (Room 2014b) began concrete processes of change likely to have lasting effects, no matter how the US federal government eventually reacts. At about the same time, trends in opinion polls among US adults for the first time showed a popular majority for legalizing cannabis (Walsh 2013). Changes in the legal status of cannabis do not, of course, deal with the drug problem as a whole. But, since three-quarters of the illicit drug users in the world use only cannabis, in numeric terms dealing with cannabis will have a large effect.

The direction and extent of any changes are still unclear. The OAS report lays out some alternative scenarios for the future. Other recent reports have laid out options for change in the treaties and have discussed more and less likely scenarios (Room 2012b), including a potential Framework Convention on Cannabis which might supersede the handling of cannabis in the Single Convention (Room et al. 2010). But, at least in the short run, it is more likely that changes will be piecemeal and country specific, rather than at the system level – whether involving changes made within the rules of the system, as in the case of Bolivia, or beyond the rules, as with cannabis buyers' clubs in Spain and other parts of Europe (Jelsma 2011) and the Colorado and Washington initiatives (Room 2014a).

Acknowledgment Dave Bewley-Taylor and Ambros Uchtenhagen are thanked for their suggestions and prompts, but are not of course responsible for the results.

Monitoring and Evaluation of Addiction Treatment

88

Ambros Uchtenhagen

Contents

Abstract

Monitoring and evaluation (M & E) are research activities dedicated to document and analyze the processes and outcomes of addiction treatment. Before starting M & E, some conceptual issues apply, such as considering the objectives of a given treatment or treatment system, the outcome indicators to be used, the characteristics of the target population, and the basic understanding of the nature of addiction.

A range of different goals can be envisaged in M & E projects, from measuring treatment implementation and the use of the available resources to measuring efficacy and effectiveness. The overall goal in general is the improvement of services and treatment systems. The main steps in developing M & E projects are determining the research questions, the appropriate type and design of evaluation, and the resources and partners needed. Also, it is helpful to identify expected problems and obstacles.

Lists of evidence-based guidelines and instruments for evaluation are attached, as well as lists of high-quality publications reviewing the outcomes of evaluation studies.

88.1 Introduction

Monitoring and evaluation (M & E) are essential instruments for an optimal drug demand reduction through treatment and prevention. They serve the commitment to effective interventions, which are based on scientific evidence. Only a good knowledge on the effects of interventions can provide the evidence base for an adequate substance abuse policy.

The main objective of M & E is to assess the available intervention system at country, regional, or local level, to determine its adequacy for covering the treatment needs in the respective population, and to measure its intermediate, short-term, and long-term outcomes. This is instrumental for a targeted improvement of available intervention systems, as well as for an adaptation to new challenges from changes in substance using populations and the health and social consequences of use. Monitoring trends in substance using populations out of treatment is helpful in order to observe such changes, e.g., the arrival of new drugs.

M & E also cover structural and procedural properties of services and systems, as major instrumental elements for outcomes.

M & E can also serve other purposes, such as providing arguments for legitimizing the treatment or prevention approach against repressive approaches.

88.2 Main Aspects of Monitoring and Evaluation

88.2.1 Definitions and Rationale

There are no universally accepted definitions. Monitoring and evaluation are performed in many fields of activities, such as health and education, and the aims and definitions are adjusted to the respective field. For this chapter, the following definitions and rationale apply.

88.2.1.1 Monitoring Treatment

Monitoring is an activity to continuously document defined indicators of treatment implementation and outcomes.

Rationale: to determine the level of service performance and treatment results, as a starting point for improvements and for measuring change as a result of improvements.

88.2.1.2 Process Evaluation of Treatment

Process evaluation is a one-time or repetitive activity to document how therapeutic interventions are implemented, in terms of coping with predetermined rules and criteria.

Rationale: to determine the level of service responsiveness to needs and compliance with expected performance, in order to facilitate the expected results.

88.2.1.3 Outcome Evaluation of Treatment

Outcome evaluation is a one-time or repetitive activity to document the consequences of therapeutic interventions for the target population, in terms of predetermined goals and indicators.

Rationale: to measure the intended and unintended effects of therapeutic interventions, in order to determine the value of a given intervention, a service, or treatment system to serve the expected treatment objectives.

88.2.1.4 Economic Evaluation of Treatment

Economic evaluations are a specific type of outcome evaluation. They measure the proportions of costs and benefits of an intervention, a service, or a treatment system. Costs and benefits are measured at the individual or at society level. In cost-effectiveness evaluation, effectiveness is expressed in terms of costs per unit of outcome. Cost-utility evaluation determines the gains in years and quality of life in relation to costs.

Rationale: to explore satisfaction with the results of investments made.

88.2.1.5 Meta-evaluation

The growing number of evaluation studies and their unequal quality invited an effort to review evaluation studies, on the basis of rigorous methodological analysis, resulting in reliable information about "what works" and "what works for whom."

88.2.1.6 Comparable Terms

Other terms for process and outcome evaluation, especially in the educational field, are formative and summative evaluation. Formative evaluation is typically conducted during the development or improvement of a program or course. Summative evaluation involves making judgments about the efficacy of a program or course at its conclusion.

For other and partly overlapping definitions of terms, see the referenced evaluation guidelines of World Health Organization (WHO 2000) and the European Monitoring Centre for Drugs and Drug Addiction (EMCDDA 2007).

88.2.2 Preparing for Monitoring and Evaluation (M & E)

A detailed M & E project is the key to the feasibility of data collection, to the validity of data, and to the usefulness of results. The following issues and steps must be considered before starting a project. It is recommendable to set up an M & E project in collaboration with an expert.

88.2.2.1 Conceptual Issues

Treatment Objectives

The specific objectives of a given therapeutic method or of a given program determine the type of outcome data to be collected, in order to know how far

Table 88.1 Outcome indicators

Retention rate	Measuring time in treatment
Status at discharge	Regular vs. irregular discharge (drop-out, exclusion)
Addictive behavior	Consumption patterns of legal and illegal addictive substances
Risk-taking behavior	Injecting drugs, needle sharing, unsafe sex
Health status	Changes in somatic and psychological health
Social reintegration	Changes in living arrangements, employment, social networking, criminal activities
Quality of life	Subjective wellbeing

outcome responds to the objectives. Objectives may be reduction of main substance use or any substance use, abstinence from main substance use or any substance use, health improvements, reduction or abstinence of illegal activities, social integration such as gainful employment or participating in a social network, or complete recovery.

Outcome Criteria

If not specific treatment objectives are in place, any M & E project has to determine which type of outcomes are to be measured. This may be those mentioned above, but also others such as the quality of life of patients/clients or the reduction of negative consequences of addiction at population level in terms of substance-related crime and nuisance or blood-borne infectious disease. The following is a catalogue of the most frequently used outcome indicators (adapted from EMCDDA 2007, Table 2) (Table 88.1):

The choice of outcome criteria should meet the interests of all stakeholders including the mandating and/or funding bodies for the project.

Characteristics of the Target Population

Intermediate, short-term, and long-term outcomes of therapeutic interventions are diverse for different target populations. Age, gender, level of education, level of social integration and social support, religious affiliation, health factors such as comorbidity, etc. have a potential to influence how well a person responds to a therapeutic intervention or program. Data collection therefore must be tailored to the specificities of the target groups an intervention or service is meant to serve.

Understanding Addiction

Also, the kind of data to be collected for M & E depends on how addictive behavior is interpreted. Various paradigms apply here: the use of psychotropic substances can be understood as self-medication for symptom relief (Khantzian 1997), as a special variation of self-manipulation, tailoring use to a desired state of mind, or as instrumental for self-enhancement, optimizing function and output (Harris 2007). Or else, substance use is understood as a lifestyle phenomenon, in the sense of "consumerism" or of an expression of subcultural identity. On the other side,

addiction is understood as a brain disease, following repetitive substance use resulting in structural changes (Leshner 1997) or on a vulnerability-stress model focusing on the impact of genetic and environmental factors on the brain changes (Volkow et al. 2004). For each of these paradigms, specific contextual data and patient/client characteristics are of interest in order to explain the value of intervention outcomes.

Also, understanding addiction as a chronic relapsing disorder has consequences for the design and methodology of evaluation studies (McLellan et al. 2000).

88.2.2.2 Goals of M & E Projects

M & E projects are made for a variety of purposes (see also EMCDDA 2007, Chap. 1). The purpose is relevant for the research questions to be answered by the project, the research questions are relevant for the design and methodology to be used as well as for the data which are necessary for answering the questions.

Measuring Program Implementation

A comparison is made between the intended standards of a therapeutic program or protocol and the de facto characteristics of its implementation. It includes structural and procedural aspects. Among the many issues of interest are the indication criteria, staff composition and qualifications, infrastructure and location of service, links with other services, etc. It may also include an estimation of how well the treatment needs in the regional/local population are covered.

Such projects are mainly of the process evaluation type. A recent example is part of the WHO collaborative study on substitution therapy of opioid dependence and HIV/AIDS (Lowrinson et al. 2008). Continuous monitoring of the process has the advantage to document changes made over time in terms of program implementation.

Measuring Use of Resources

In an overall purpose to make best use of available human and financial resources, M & E projects can measure the overall utilization of the treatment capacity or the utilization by the intended target population. They can compare outcomes between services receiving similar investments and serving similar populations. More difficult and demanding are economic evaluations as mentioned above.

Measuring Efficacy and Effectiveness

Efficacy of therapeutic interventions are as a rule determined by clinical trials, using a randomized controlled design. These trials provide us with data showing the relative efficacy of a given intervention or medication in comparison to another intervention or medication, if the treatment is allocated at random and the sample characteristics are comparable.

In contrast, the effectiveness of an intervention or a treatment service is defined by how well an intervention or a service works in practice and produces the desired results. It is usually measured by cohort studies including outcome evaluation with or without elements of process evaluation.

Efficacy and effectiveness studies contribute to a better knowledge on what treatment is best suitable and has the best chances for which patients/clients under which conditions and thereby to improve the indication criteria for patient/client placement.

Legitimation of Treatment

A frequent purpose of evaluation projects is demonstrating the value of a given intervention or service, in terms of desired outcomes, patient/client satisfaction, and positive economic balance of input and outcome. This can be done through a single-service follow-up study or a nonrandomized comparative study. The main issues why it is important to assure the legitimacy must be considered in the research questions and the study design.

Improvement of Services and Treatment Systems

M & E studies can provide data which allow to identify weaknesses, to initiate changes, and – in a repetitive effort – to document the intended and unintended effects of such changes. Process evaluation and qualitative data are most helpful for improvement purposes (Rush and Krywonis 1996).

88.2.2.3 Determining the Research Questions

The questions to be answered by an M & E project depend on the aims and must be made explicit, for an agreement between all stakeholders. The questions determine what kind of samples is needed, which data must be collected, and which study design is most appropriate.

Additional research questions may be included in order to address special interests by staff, funding agency, or other stakeholders. The inclusion of such questions has a potential to enhance cooperation and compliance with the main study.

The following types of research questions can be considered (see also WHO 2000, workbook 1 step 5, and EMCDDA 2007, Chap. 3):

- *Descriptive questions* for precise information about observations made
- *Normative questions* aiming at a comparison between observations and expectations (e.g., standards)
- *Impact questions* exploring the role of interventions or elements thereof for the observed outcomes

88.2.2.4 Typology of Treatment Evaluation

There is no universally accepted typology. The following is mainly based on the types presented in the EMCDDA Guidelines (EMCDDA 2007) and in the WHO/UNODC/EMCDDA Evaluation workbooks (WHO 2000).

Needs Assessment Evaluation

Needs assessment studies are used to determine and improve the coverage of treatment needs in a given population, in order to tailor treatment capacity, mix of services, and networking among services accordingly (WHO evaluation workbook 3).

Structure Evaluation

Evaluation of the appropriateness of infrastructure and other structural elements to facilitate the desired outcomes of treatment. This includes location, safety provisions, financial resources, staff composition and qualification, governance, and organization.

Process Evaluation

Process evaluation documents and analyzes how treatment is delivered. Assessment procedures, indication criteria, treatment planning, programming, qualification and attitudes of staff, continued training of staff, house rules, sanctions, etc. are some of the elements to be considered (WHO workbook 4, extensive list of available instruments for process evaluation on the EMCDDA instrument bank EIB).

Outcome Evaluation

The focus is on the consequences of treatment for patients/clients, their families, and the community. It provides information on which treatment modality has which consequences for which target groups and under which conditions. It may consider the impact on other treatment approaches. It may become relevant for treatment motivation in the target population.

Outcome is measured against predefined behavior norms (normative evaluation), baseline pretreatment status (evaluation of change during treatment), or predefined treatment goals (goal attainment evaluation). Outcome evaluation mainly uses quantitative methods (by RCTs or cohort studies), eventually a combination of quantitative and qualitative methods (WHO workbook 7, instruments on EIB of EMCDDA).

Patient/Client Satisfaction Evaluation

Patient/client satisfaction studies measure to what extent treatment provision and treatment results meet the expectations of patients/clients. They are a major source for service improvement, together with retention rates and drop-out rates (WHO workbook 6, instruments on EIB of EMCDDA).

Economic Evaluations

Various designs are used to describe and analyze economic factors in addiction treatment. Cost analysis measures the cost factors and overall costs of treatment (e.g., per patient day, per treatment episode, per treatment modality, etc.). Cost-benefit evaluation determines the relation between costs and financial benefits (e.g., in terms of reduced health and social costs in a defined posttreatment period as compared to pretreatment values). Cost-effectiveness evaluation measures costs in relation to a specific unit of outcome (e.g., significant health improvement or significant reduction in addictive behavior). Cost-utility evaluation measures the utility of treatment for patients/clients, e.g., in terms of disability adjusted life-years DALYs (Anand and Hanson 1997) or as quality adjusted life-years QALYs (Nord 1992, Whitehead and Ali 2010). For cost evaluations see also WHO workbook 5, for economic evaluations WHO workbook 8, and for instruments EIB of EMCDDA.

Formal Evaluation

This is an assessment of service compliance with professional, ethical, and legal standards.

Meta-evaluation

Meta-evaluation is made on the basis of recognized procedures to combine quantitative results from several studies about the same or similar interventions, in order to establish composite outcome scores. This allows assessing the effectiveness of a given intervention with greater confidence than on the basis of a single study.

88.2.2.5 Evaluation by Whom?

External Evaluation

Outcome or/and process evaluation of treatment services or interventions by research professionals who are independent from the evaluated agency. This is the preferred modality, because eventual bias in collecting client data is avoided and the credibility of the study is enhanced. Disadvantages in comparison to internal evaluation may be the higher costs and resistance or noncompliance of treatment staff.

Internal Evaluation (Self-Evaluation)

This can be used as an internal learning process about the treatment program or in case of restricted funds for evaluation studies. However, internal evaluation is not recommended for outcome studies, because credibility is lower in comparison to external evaluation. Collaboration with an external evaluation specialist is an advantage.

88.2.2.6 Evaluation Level and Timing

Evaluation Level

The target of M & E projects can be a specific type of intervention or therapeutic method. It can also be a specific service or setting for delivering treatment. In contrast to single intervention and service follow-up studies, a comparative evaluation focuses on the functioning and outcomes of a local, regional, or national treatment network of services or of the overall treatment system. Choosing the target implies the choice of an adequate type and design of the project.

One-Time and Repetitive Evaluation

One-time evaluation studies are frequently made for all purposes. More relevant are repeated studies or a continuous monitoring system, allowing for a documentation of specific changes in implementation and outcomes over time. However, such an approach has important cost implications. A possible compromise is the combination of a relatively simple monitoring of routine data with a more extensive evaluation study if indicated by changes in the monitoring data or after important program changes.

88.2.2.7 Resources

Estimations must be made on the amount of funds and type of manpower in order to conduct the planned M & E project, and the availability of these resources must be checked in advance, in order to avoid delays or restrictions during implementation. Also, the infrastructure for data storage and analysis must be made available.

In view of the difference in available resources between high-income and low-/middle-income countries, priority-oriented monitoring and evaluation research as well as transnational collaboration is recommendable.

Financial Resources

If an M & E study is mandated by an external agency (governmental or nongovernmental), the budget available for the study must be identified, in order to design the study accordingly. Or else, the research group planning the study has to present a budget proposal and apply to a funding agency (Research council, Foundation, Health Authority, etc.).

If there are doubts about the feasibility of the study (e.g., access to services and patients/clients), a stepwise procedure may be preferred. In this case, a separate budget for the feasibility study is needed, and the results will determine the budget of the ensuing evaluation study.

Human Resources

Which staff is needed for carrying out a planned project? Various functions must be considered: expert support for setting up the research questions and protocol, for determining the appropriate methods and instruments, for training of interviewers, etc. Staff responsible for data collection, interviewers, staff for data control and entering into a master file, statistician for data analysis, etc. are needed. It is helpful to identify staff in advance, in order to avoid delays in implementation and in order to establish a realistic budget.

Infrastructure

Access to the necessary equipment for staff and for safe storage of data is to be ensured, as well as the disposition of the appropriate software for data handling and analysis.

88.2.2.8 Partners

Most M & E project are a collaborative effort between various partners, especially in case of external evaluation of services and networks. Clear agreements on functions, responsibilities, temporal availability, and costs are recommended, eventually with written contracts.

Funding Partners

Agreements on the overall budget, bookkeeping, financial controls, timing of payments, and financial reports help to prevent misunderstandings and litigations. Such agreements should be made to protect the interests of all parties.

Therapeutic Partners

All projects on external evaluation are based on collaboration between researchers and treatment providers. Agreements are needed on the access to patient/client data and service data, access to patients/clients for external interviewers, responsible person in a given service for organizing and facilitating the research process, ownership of data, and arrangements for publishing the study results. Procedures in case of upcoming problems during project implementation should also be agreed upon in advance.

A special situation is created in case of a systematic evaluation at the system level involving all or selected treatment providers.

Research Partners

In case multiple researchers or research groups are involved, a clear working arrangement should identify the functions, tasks, and responsibilities of the individual persons. If a service provider hires a researcher or research group for an internal or external evaluation or monitoring system, there is also a need to identify the various functions, tasks, and responsibilities.

88.2.2.9 Expected Obstacles

Most problems occurring during project implementation are due to missing or incomplete preparation. However, even a carefully prepared project may meet some obstacles. Some of the frequent ones are mentioned here.

Compliance with Protocol

Staff involved in project implementation may disregard details of the research protocol and thereby weaken data reliability, even if well instructed. This may also happen in case of changes of staff. Tutoring staff activities over the entire duration of the project helps to avoid such failures. Also, efforts to make a strong evaluation culture at the system level acceptable will contribute essentially to overcome this type of obstacle.

Resistance from Patients/Clients

One of the most common problems is the refusal to participate in a randomized study, resulting in an unacceptable degree of sample selectivity. This is especially to be expected if a control group with placebos or other forms of low therapeutic value are used or patients/clients are not confident that their data will be well protected against external parties, for example, in studies involving illicit substance use and/or drug-related criminal activities. Informed consent should cover not only aims and design of the study but also measures taken to guarantee data protection.

External Interference

It may happen that family members of patients/client or other third parties raise opposition against an M & E project, on the basis of ethical concerns. It is advisable to have an explicit permission from an ethical committee, if not already prescribed by law.

88.2.3 Implementation of M & E

88.2.3.1 Available Guidelines and Instruments for Treatment Evaluation

International Guidelines for Treatment Evaluation

From the number of evaluation guidelines, a few are mentioned here, on the basis of their wide international applicability. It is highly recommendable to consult one or more guidelines before starting an M & E project.

WHO/UNODC/EMCDDA Evaluation of Psychoactive Substance Use Disorder Treatment Workbook Series (WHO 2000)

This publication consists of a series of workbooks intended to educate program planners, managers, staff, and other decision-makers about the evaluation of services and systems for the treatment of psychoactive substance use disorders. The objective of this series is to enhance their capacity for carrying out evaluation activities. The broader goal of the workbooks is to enhance treatment efficacy and cost-effectiveness using the information that comes from these evaluation activities.

EMCDDA Guidelines for the Evaluation of Treatment in the Field of Problem Drug Use. A Manual for Researchers and Professionals (EMCDDA 2007)

This publication provides basic information on the options, elements, and procedures of drug-related treatment evaluation. It also contains an overview of European and international evaluation and research networks.

Instruments for Treatment Evaluation

The EMCDDA evaluation instrument bank EIB covers a range of available instruments ready for data collection, including information on the target group specificity, the available languages (mostly English), copyrights, and eventual restrictions for use. Instruments are available for needs assessment and planning, for mediating and risk factors, for process and outcome evaluation, for patient/client satisfaction, and for staff knowledge and satisfaction.

The WHO/UNODC/EMCDDA evaluation workbooks present many instruments in the context of the various steps and approaches of treatment evaluation (WHO 2000).

A recent instrument for assessing and improving addiction treatment at the system level is the WHO Substance Abuse Instrument for Mapping Services SAIMS (ongoing).

88.2.3.2 Adaptation of Guidelines to Special Situations

Recommendations made in guidelines are not always responding to the specificity of a given project. However, major deviations from recommendations should be highlighted and reasons should be given. Special situation may arise from restricted resources or ethical restrictions. While there is some research on how to adapt treatment guidelines to clinical practice (Graham and Harrison 2005), no such systematic effort is known for evaluation guidelines.

88.2.3.3 Meta-analysis and Reviews of Evaluation Studies

Two organizations have been established in order to review and analyze evaluation studies selected for their rigorous methodology: the Cochrane Collaboration and the Campbell Collaboration.

The Cochrane Collaboration (www.cochrane.org) has its focus on evaluation of medical treatments, while the Campbell collaboration (www.campbellcollaboration.org) has its focus on social interventions.

Both organizations make their reviews available in their respective online libraries (www.thecochranelibrary.com, www.campbellcollaboration.org/library/php). A growing number of reviews cover pharmacological and psychosocial treatments in addiction and their outcomes.

88.2.3.4 Study Designs and Protocols

The choice of the appropriate study design depends on the research questions and on the available resources. The most frequently used designs are presented below (Table 88.2) (see also EMCDDA 2007, Chap. 3, Table 1).

Cross-Sectional Studies

One-time studies to compare treatment services, treatment populations, and treatment outcomes at a given moment in time (e.g., intermediate outcomes during treatment or after terminating treatment). Cross-sectional studies cannot describe processes of change over time.

Cohort Studies

Cohort studies describe the course and outcomes of treatment populations which receive their treatment as usual in practice, not allocated by randomization (observational or "naturalistic" studies). Cohort studies use retrospective or prospective data.

Longitudinal Retrospective Studies

Anamnestic data on pretreatment characteristics and outcomes of treatment populations are used to describe the therapeutic results of a given intervention/service alone or in comparison with other interventions/services. This type of study is more economic in comparison to prospective studies, which need multiple, at

Table 88.2 Main types of study designs

Cross-sectional studies	Comparing interventions/services at a given point in time
Cohort studies	Comparing measurements of single interventions/services or several interventions/services at multiple points in time (baseline data, intermediate outcomes, outcomes at follow-up)
Randomized controlled studies RCT	Comparing outcomes if interventions are assigned to patients/clients at random, not as in clinical practice (observational studies)
Quasi-experimental studies	RCT with special randomization procedures

least two measurement points in time; its usefulness however depends on the availability and quality of anamnestic data.

Longitudinal Prospective Studies

Collecting pretreatment, during-treatment, and posttreatment data at different time-points allows a focused and detailed description of the treatment process and results. It avoids biased or missing baseline data and therefore provides for more reliable results of effectiveness. Prominent national studies comparing cohorts from different treatment settings are the DATOS study in USA (Simpson 2003) and the NTORS study in the UK (Gossop et al. 2003).

Randomized Controlled Studies

Randomized controlled studies (RCT) are the "gold standard" for evaluating specific therapeutic modalities and medications in clinical research. Patients are allocated "at random" to an experimental group or to a control group, thereby minimizing selection factors between the two groups. As not all patients are willing to accept randomization, especially if not allocated to their preferred intervention, this design may suffer from refusal to participate or from elevated drop-out rates. Randomized studies allow to identify the effectiveness of a modality or medication, but do not provide results of effectiveness due to their selectivity. An updated collection of RCTs on addiction treatment can be found in the Cochrane library.

Double-Blind Randomized

If assignment to the experimental or the control group is not revealed to patients and therapists, their preferences are better (although not completely) ruled out and the study gets more reliable results about comparative treatment efficacy. This design is mainly used for a comparison of medications; psychosocial interventions cannot be "blinded."

Quasi-experimental Designs

Instead of comparing two or more modalities, the effects of an experimental modality can be compared to the course while waiting to be accepted for that modality. In this case, the control group receives treatment as usual or no treatment while waiting.

In the Zelen design, informed consent is only asked after randomization and only from patients assigned to the experimental group, while those who are randomized to treatment as usual need not to consent to participation in the study (Torgerson and Roland 1998). This design makes it easier for patients to participate, because they do not have to consent to be randomized. Of course, blinding is not possible in this design.

Another design uses different sequences of treatment modalities, e.g., A-B-A compared with B-A-B or B-B-A.

Role of Methodology for the Quality of Results

Grading of Evidence

Treatment evaluation searches for scientific evidence which can be used as a basis for therapeutic recommendations. However, there are grades of evidence,

Table 88.3 Grading of evidence

Grade	Definition
A	Highest degree of evidence: review from multiple randomized controlled studies (RCT) with convergent results
B	High degree of evidence; results from single RCT and controlled clinical studies
C	Moderate degree of evidence: prospective comparative longitudinal studies (observational studies without control design)
D	Low degree of evidence: single intervention/service follow-up studies, case studies
E	Very low degree of evidence: nonsystematic observations
Z	Not known

depending on the type of study design (see also GRADE working group 2004). The following is an adapted version (Table 88.3).

Standards for Consensus Building

Where evidence from quantitative studies is not available or feasible, recommendations for good practice are mainly based on expert opinion. In order to optimize the consensus building process, rigorous rules have been established (AGREE II 2009).

88.2.3.5 Quantitative and Qualitative Methods

Quantitative Methods

Quantitative methods are used for outcome evaluation. They consist in collecting empirical data via standardized instruments (surveys, questionnaires, pre-post tests) for statistical analysis and mathematical modelling and in producing numerical results (statistics, percentages) which answer specific research questions. Data may come from existing databases (secondary data) or are collected directly from treatment samples (face to face, per telephone, or electronic media). Questionnaires may be self-administered or administered by trained interviewers. Sample size and homogeneity, reliability and validity of data, and appropriate statistical methods and models are essential for representative results.

Not all patients/clients who participate in a randomized evaluation study are compliant with the study protocol and available for follow-up data collection. Two concepts are therefore used for statistical analysis: the intention-to-treat concept (ITT) includes all participants who have been randomized, ignoring noncompliance and withdrawal, while the per-protocol concept includes only participants without any major protocol violations (Gupta 2011).

Qualitative Methods

Qualitative methods are mainly used for process evaluation. When indicating problem areas in the provision of treatments, they can also be useful for improvements and for generating new research questions. They provide information for the construction of questionnaires in process and outcome evaluation, and they can be used for the interpretation of quantitative findings (Neale et al. 2005).

The main methods are participant observation, semi-structured interviews, focus groups, and narrative research (see EMCDDA 2007). A standardized method for the selection of interview and focus group partners is the theoretical sampling model, allowing for the broadest possible spectrum of views and perspectives (Glaser and Straus 1967).

88.2.3.6 Use of Results

It is advisable to determine at an early stage of an M & E project how the results will be communicated, by whom and how. This includes issues like data ownership and authorship in publications. In order to avoid later litigations, all agreements should be documented in written.

A first start to communicate evaluation results are intermediate and comprehensive final reports; for recommended components see WHO 2000 (workbook 2, step 4) and the EMCDDA Guidelines for treatment evaluation (EMCDDA 2007, Chap. 6). Reports must at least be accessible to all stakeholders of an evaluation project. On the basis of the final results, a publication plan can help to make the best use of those. The scientific community is best reached by publications in peer-reviewed journals, and a wider audience eventually by books, good practice documents (e.g., UNODC 2008), pamphlets, mass media articles, etc.
