Once the results are known, it should also be discussed what they mean and to whom they might be communicated in order to optimize their potential impact on treatments, on service planning and improvement, on treatment policy, etc.

88.2.3.7 Checklists for Assuring the Evaluation Process

All those involved in planning and implementation of a given project can profit from checklists which help to keep all elements of the project under control. The EMCDDA Guidelines for treatment evaluation present useful checklists for the preparation and implementation, as well as for the evaluation process (EMCDDA 2007, Chap. 5).

88.2.4 Treatment Outcomes: Selected Evidence-Based Guidelines and Systematic Reviews

- Effectiveness of Therapeutic Communities: a systematic review (Malivert et al. 2012)
- Principles of Drug Dependence Treatment. A Research Based Guide (NIDA (2012)
- Guidelines for the Psychosocially Assisted Pharmacological Treatment of Opioid Dependence. (WHO 2009)
- Contemporary Drug Abuse Treatment. A Review of the Evidence Base (UNODC (2002).

88.2.4.1 Cochrane Library (Selected Reviews)

- Psychological therapies for pathological and problem gambling (2011)
- Methadone for non-cancer pain in adults (2012)

- Psychosocial interventions to reduce alcohol consumption in concurrent problem alcohol and illicit drug users (2012)
- Nicotine replacement therapy for smoking cessation (2012)
- Mobile phone-based interventions for smoking cessation (2012)
- Combined pharmacotherapy and behavioral interventions for smoking cessation (2012)
- Psychosocial interventions to reduce alcohol consumption in concurrent problem alcohol and illicit drug users (2012)
- Psychosocial interventions for benzodiazepine harmful use, abuse and dependence (2012)
- Effects of psychostimulant drugs on cocaine dependence (2010)
- Acamprosate for alcohol dependence (2010)
- Opioid antagonists for alcohol dependence (2010)
- Psychosocial interventions for reducing injection and sexual risk behavior for preventing HIV in drug users (2010)
- Psychosocial interventions for people with both mental illness and substance abuse (2010)
- Buprenorphine maintenance versus placebo or methadone maintenance for opioid dependence (2008)
- Psychosocial interventions for cocaine and psychostimulant amphetamines related disorders (2007)
- Alcoholics Anonymous and other 12-step programs for alcohol dependence (2006)
- Methadone maintenance at different dosages for opioid dependence (2003)

Behavioural Addictions and Management Applications: An Introduction

89

Nady el-Guebaly and Hermano Tavares

This section is dedicated to the increasing recognition of the behavioral addictions as a significant component of our field of practice and windows into human nature without the effect of substances. The inclusion of gambling disorder under the new DSM-5 diagnostic code of substance-related and addictive disorders as well as the recognition of Internet gaming disorder as a "condition for further study" are but examples of the awareness of an expanding empirical basis. At the same time, the increasing range of behaviors susceptible to develop from an excessive engagement to a habitual or compulsive pattern behooves us to seek for common as well as distinct features.

Two overview chapters investigate the empirical "state of the science." Drs. Yau, Leeman, and Potenza review the "biological underpinnings of behavioral addictions" including frontostriatal brain imaging findings, the implication of neurotransmitters and genetic heritability, as well as their potential in management.

Drs. Mudry, Stea, and Hodgins conduct a similar analysis of the role of "psychological underpinnings" in the development and perpetuation of the disorders. The comparative evidence of factors such as impairment of control, craving, expectancies, motives, and personality traits is described.

The next seven chapters address common and distinct features of currently recognized clinically significant behaviors.

Dr. Echeburúa's chapter ▶ Chap. 92, "Clinical Management of Gambling Disorder" details the current psychological treatment options including behavioral and

cognitive behavioral therapies, motivational enhancement therapies, and relapse prevention. The role of Gamblers Anonymous is also described. The trials of various pharmacotherapies are reviewed and their challenges described.

It is commonly recognized that only a small proportion of individuals suffering from disordered gambling seek formal treatment. The section includes an encouraging vignette by Drs. Bowden-Jones and Smith describing their National Problem Gambling Clinic in London along with a proposed list of activities to ensure high-quality service delivery.

The next two chapters detail the intertwined investigations of electronic media. Drs. Achab et al. review the screening tools, determinants, and treatment approaches related to Internet addiction. An interesting discussion of the Internet as a vehicle for possible addictive products is included and is of relevance to the expanding social impact of this medium. Drs. Billieux et al. focus next on the dysfunctional involvement in video games and more specifically the prevailing massively multiplayer online role-playing games (MMORPGs). Structural characteristics and their addictive potential are described as well as psychological and neurobiological determinants. Reviews of clinical trials from China and the Western world are identified.

The last three chapters are an intriguing exploration of three "required" behavioral needs, i.e., shopping, sex, and food, and the determinants of their evaluation into disorders. Drs. Filomensky and Tavares review the epidemiological challenge, assessment scales, comorbidities, clinical manifestation, and determinants of compulsive buying disorders. The existing pilot treatment trials are identified.

Drs. Amadala and Hertzsprung provide a sensitive review of the evolution of excessive and maladaptive sexual behaviors into the diagnostic syndrome of sex addiction. Available screening and assessment instruments are described as well as a synopsis of etiological determinants and comorbidities. The prevailing psychosocial approaches and a laudable search to validate staff training are outlined as well as the current pharmacological trials.

The section's concluding chapter is an insightful discussion of the association between binge eating, obesity, and addiction. This interaction has come to prominence as a result of the public concern over the epidemic of obesity rising in North America and the identification of addictive features in the development of binge eating. Intriguing common neurobiological and psychosocial features are identified as well as a brand new field of investigation into the phenomenon of food addiction and its optimal management.

This section hopefully conveys the potential for insights of behavioral addictions as windows on human nature without the effect of substances. Each new behavior brings its new insights, but we should beware of the public concern over pathologizing an ever expanding list of behaviors. The section merely makes reference to exercise and work as other candidate behaviors; there are others.

A comprehensive biopsychosociocultural conceptualization of these disorders is critical, and the relative significance of each of these components is yet to be determined. In sum, current or potential candidates for a behavioral addiction have to present solid evidence of the involvement of the brain reward circuitry as

the basis for a shared psychopathology involving a decision-making bias and inhibitory control deficits.

Besides the recognition of gambling disorder as an addiction, the new DSM edition also acknowledges the prominence of craving in the addiction process. As we approach a better model of addiction, we shall be able to depend less and less on a model based upon negative consequences and avoid the perils of a circular logic, i.e., it is an addiction because it is harmful and it is harmful because it is an addiction. Along with craving, the careful reader will notice that the two other implicit concepts crosscutting the chapters from this section are loss of control and compulsion (defined as repetitively performing a behavior as a strategy to deal with an emotional imbalance). Starting with this triad, we may get closer to an evidence-based phenomenological model of addiction, while distancing from a harm-based model, which may be unduly vulnerable to ever changing cultural values and judgment calls (take, e.g., the recent evolution of the gambling perspective from frowned upon behavior to government embraced leisure activity).

That is not to deny the obvious impact of sociocultural factors especially in the determination of new behavioral addictions such as Internet and video gaming. Even in the case of essential behaviors such as sex, eating, and shopping, never before in history have individuals and communities had a wider access to services, products, and credit. Our "information" society suffuses people with news about novel and potentially gratifying behaviors, shortening the time to adequately ponder and decide.

Finally, besides perfecting and broadening the contours of the addiction model, behavioral addictions may challenge previous widely accepted treatment goals such as abstinence. Popular goal posts promoted by 12-step-based programs such as "avoid the first drink" or "avoid the first dose" become unrealistic when expanded to "avoid the first log-on," "avoid the first purchase," and "avoid intercourse," and in the case of compulsive eaters, "avoid the first bite" is an utterly impossible goal! Compulsive eaters anonymous meetings discuss "avoiding the first compulsive bite," which relates to eating when under the influence of an emotional turmoil in an unconscious attempt to deal with it, which will likely lead to loss of control. Clusters of components/symptoms must be identified for each of these behaviors in order to build tailored preventive and treatment strategies more effectively than current broader behavior-focused approaches.

Biological Underpinning of Behavioural Addictions and Management Implications

Abstract

Neurobiological and clinical data indicate that maladaptive engagement in certain behaviors warrants consideration as "behavioral" or non-substance addictions. The present chapter reviews existing neurobiological and genetic/family history evidence for behavioral addictions involving gambling, Internet use, video-game

play, sex, eating, and shopping. At a neurochemical level, behavioral addictions may involve dysregulation of serotoninergic, dopaminergic, noradrenergic, and opioidergic systems. At a neurocircuitry level, findings suggest dysfunction in brain regions associated with the mesolimbic dopaminergic pathway and frontal areas; disruption in these circuits could lead to disadvantageous decision-making, impaired inhibition, and increased cue-induced craving. While a genetic understanding is at an early stage, genetics/family history data support heritability for behavioral addictions and suggest genetic overlaps with other psychopathologies. As this represents an emerging area of research, data remain sparse in multiple domains. An improved understanding of behavioral addictions will help in establishing appropriate nomenclature and enhance the ability to recognize, prevent, and treat these disorders more effectively.

90.1 Introduction

While the term addiction has traditionally been associated with excessive alcohol and drug use (Maddux and Desmond 2000), the Latin word (*addicere*) from which it is derived was not linked to substance use. Addiction professionals and the public are recognizing that certain behaviors bear resemblance to alcohol and drug dependence, and data have been forwarded that these behaviors warrant consideration as non-substance or "behavioral" addictions (Frascella et al. 2010; Karim and Chaudhri 2012; Potenza 2006). Excessive engagement in behaviors such as gambling, Internet use, video-game play, sex, eating, and shopping may represent addictions (Holden 2010), with a minority of individuals displaying such habitual or compulsive engagement (Brewer and Potenza 2008; Chambers et al. 2007). Some of these behaviors were considered as "Impulse Control Disorders Not Elsewhere Classified" in the *DSM-IV-TR*, a separate category from substance use disorders (SUDs) (American Psychiatric Association 2000). Shaffer et al. (2004) proposed that addiction should be considered as a syndrome with multiple opportunistic expressions (e.g., substance abuse, pathological gambling, and food addictions). Aided by data from neurobiological studies, this view has gained momentum in the past decade and has led to the consideration of categorizing substance and non-substance-related addictions under one diagnostic category, "Substance Use and Addictive Disorders," in the recently published *DSM-5* (American Psychiatric Association 2013). Establishing nomenclature and criteria for behavioral addictions may enhance our capacity to recognize and define their presence.

Biochemical, functional neuroimaging, genetic, and pharmacological research in substance addiction has implicated several neurobiological processes. Multiple neurotransmitters (e.g., serotonergic, dopaminergic, noradrenergic, and opioidergic) are thought to play a role in the pathophysiology of substance addictions (Koob and Volkow 2010; Potenza 2008). For example, dysregulated dopamine systems, which are involved with learning, motivation, and salience of stimuli and rewards, and serotonin (5-HT) systems, implicated in behavioral control, may significantly contribute to addictive disorders (Fineberg et al. 2009; Potenza 2008). Prolonged engagement

in an addictive behavior may lead to a reduction of sensitivity to biological rewards and decrease an individual's perceived control over seeking and eventual engagement in the behavior. At the neurocircuitry level, the mesolimbic dopaminergic pathway (linking the ventral tegmental area (VTA) to the nucleus accumbens (NAc)) and frontal areas are thought to be critical components of the decision-making circuitry in risk-reward assessment (Goldstein and Volkow 2011; Hyman et al. 2006). Preclinical and clinical works suggest that disruptions in these regions could lead to disadvantageous decision-making (e.g., choosing immediate gains versus long-term consequences), impaired ability or willingness to inhibit response to drugs/addictive behaviors when exposed to them, and increased drug- and cue-induced craving (Everitt and Robbins 2005; Goldstein and Volkow 2002; Koob and Volkow 2010; Volkow and Fowler 2000).

Research also indicates genetic effects on the use and misuse of substances (Kreek et al. 2005; Tsuang et al. 1996). Several putative risk genes have been identified. For example, the A1 allele of the Taq1A polymorphism of the dopamine D2-receptor (*DRD2*) gene, which is associated with measures of impulsivity and behavioral inhibition, and the low-transcribing short allele of the serotonin transport gene (*5HTTLPR*), which is associated with moderating the impact of stressful life events on risk of psychiatric conditions such as depression and anxiety (Kendler et al. 2012), have shown associations with addictions in some but not all studies. However, as allelic variants of the *DRD2* are in linkage disequilibrium with another gene (*ANKK1*), the precise biological factors underlying the associations warrant additional study (Leeman and Potenza 2013).

Behavioral addictions frequently co-occur and appear to share important elements with substance-related addictions (Grant and Potenza 2012). In terms of phenomenology, both behavioral and substance addictions may be thematically categorized along four domains: craving, compulsion, diminished control, and persistence of behaviors despite negative consequences (Potenza 2006; Shaffer et al. 2004). Moreover, both have been characterized as disorders of motivation, reward, and decision-making (Chambers et al. 2007; Redish et al. 2008). Growing evidence, particularly in pathological gambling, indicates that behavioral addictions share overlapping neurobiological mechanisms and genetic contributions with substance addictions (Kühn et al. 2011; Potenza 2008; Volkow et al. 2012). However, differences have also been observed, and the extent to which findings from substance addictions extend to individual behavioral addictions may differ.

The present chapter will review existing neurobiological and genetic/family history evidence pertaining to behavioral addictions in attempt to shed light on these emerging mental health problems from a neuroscientific perspective. Specifically, the family history findings relating to pathological gambling, Internet addiction disorder, problematic video-game playing, hypersexual disorder, food addiction, and compulsive shopping. As this is an emerging area of research, data are sparse in some domains. Similarities and differences with substance-addiction findings are highlighted. Epidemiologies are addressed briefly, and more detailed descriptions of clinical features and treatment methods can be found in the following chapters. An overview of the neural systems, neurochemistry, and genetic results can be found in Tables 90.1, 90.2, and 90.3, respectively.

Table 90.1 Overview of neural system results for selected behavioral addictions, with a focus on fronto-striatal findings

Behavioral addiction	Key results	Similarities and differences with key results in substance use disorders
Pathological gambling	*Frontal areas*	Between-group differences observed in SUD and control comparison subjects with many tasks indicating reduced frontal activity, but precise nature of differences warrants additional study
	Cognitive tasks: most findings suggest reduced activity in multiple frontal regions in PG, but also some suggesting increased activity and negative findings	
	Cue-induction studies: suggest differences in activity, but the precise nature of differences warrants additional study	
	Striatal areas	
	Cognitive tasks: reduced ventral activity to reward anticipation	Many findings suggest reduced ventral striatal activity in individuals with SUDs compared to controls
	Cue-induction studies: mixed with some studies showing reduced striatal activity in PG compared to controls	
	Others: ventral striatal activity inversely correlated with impulsivity measures and problem-gambling severity	
	White and gray matter: poorer white matter integrity in multiple regions; no volumetric differences in gray or white matter between PG and controls	Poorer white matter integrity and decreased gray matter volumes in SUDs
Internet addiction disorder	*Frontal areas*	
	Cognitive tasks: EEG studies indicate diminished efficiency of response inhibition	Underactive feedback valence in individuals with SUDs
	Resting state: differences in regional homogeneity in multiple frontal regions, but the precise nature of differences warrants additional study	Preliminary studies suggest reduced regional homogeneity in SUDs
	White and gray matter: lower gray matter density in multiple regions including dlPFC, ACC, and insula; differences in white matter integrity between IAD and controls, but the precise relationship is unclear	Poorer white matter integrity and decreased gray matter volumes in SUDS
Problematic video-game playing	*Frontal areas*	Underactive feedback valence in individuals with SUDs
	Cognitive tasks: EEG studies indicate diminished efficiency of response inhibition	

(*continued*)

Table 90.1 (continued)

Behavioral addiction	Key results	Similarities and differences with key results in substance use disorders
	Cue-induction studies: greater activation of multiple frontal areas including the OFC and dlPFC	Between-group differences observed in SUD and control comparison subjects, but precise nature of differences warrants additional study
	Striatal areas	
	Cognitive tasks: greater activation of ventral striatum among frequent (versus infrequent) gamers	Reduced ventral striatal activity typically reported; however, findings may differ per task
	Cue-induction studies: increased activity in the ventral striatum compared to controls	
	Gray matter: greater striatal gray matter volume among frequent (versus infrequent) gamers	Decreased striatal gray matter volume in SUDs
Hypersexual disorder	*White matter*: higher integrity of lower superior frontal region	Poorer white matter integrity in SUDs
Food addiction	*Frontal areas*: increased OFC activation in response to food cues but decreased activity upon ingestion of food among individuals with high food addiction scores	Between-group differences observed in SUD and control comparison subjects, but precise nature of differences warrants additional study
	Other regions: increased ACC and amygdala activation in response to food cues among individuals with high food addiction scores	Evidence for ACC activity in risky decision-making in SUDs; amygdala activity associated with trait craving in SUDs
Compulsive shopping disorder	*Striatal areas*: increased activity in ventral striatum upon product presentation	Reduced ventral striatal activity typically reported; however, findings may differ by task
	Other regions: reduced activity in insula and ACC during price presentation	Insula activity in response to substance cues; evidence for ACC activity in risky decision-making in SUDs

PG pathological gambling, *SUDs* substance use disorders, *IAD* Internet addiction disorder, *PVG* problematic video-game playing, *EEG* electroencephalography, *dlPFC* dorsolateral prefrontal cortex, *ACC* anterior cingulate cortex, *OFC* orbitofrontal cortex

90.2 Behavioral Addictions

90.2.1 Pathological Gambling

In the last decade, pathological gambling (PG) has developed a strong research base in the wake of worldwide legalized gambling and concerns over gambling's possible health and social impacts. Similar to substance addictions, PG can include preoccupations with gambling, gambling with greater amounts of money to receive the same level of desired experience (tolerance), repeated unsuccessful efforts to control or stop gambling, restlessness/irritability when trying to stop gambling

Table 90.2 Overview of neurochemistry results for selected behavioral addictions

Behavioral addiction	Key results	Similarities and differences with key results in substance use disorders
Pathological gambling	*Dopamine*: dopamine implicated but the precise nature unclear; negative between-group findings for differences in D2-like receptor availability at rest; differential response to dopamine antagonist administration in PG, although findings mixed; individuals differences in dopamine release and function may contribute to impulsivity and decision-making	Dopamine release has been related to substance use; reduced D2-like receptor availability in SUDs typically reported; mixed clinical findings with dopamine antagonists; individuals differences in dopamine release and function thought to contribute to variability in impulsivity and risky decision-making in SUDs
	Serotonin: mixed results with SSRIs; possible individual differences in serotonin function	Evidence suggest between-group differences in serotonergic function; mixed clinical results with SSRIs, suggest possible individual differences
	Opioids: positive clinical findings with opioid antagonist suggests involvement of opioid system	Multiple positive clinical findings suggest role for opioid systems, particularly for opiate and alcohol dependence
	Other neurotransmitters: noradrenergic levels elevated among PG; preliminary positive clinical findings with glutamate antagonist suggest involvement of glutamatergic systems	Findings suggest elevated noradrenergic levels in some SUDs; positive clinical findings suggest role for glutamatergic systems
Internet addiction disorder	*Dopamine*: decreased striatal dopamine transporter expression in IAD; limited findings suggest differential D2-like receptor availability in the striatum – however, results differ between subdivisions	Mixed findings regarding levels of dopamine expression in striatum; reduced D2-like receptor availability in SUDs typically reported
Problematic video-game playing	*Dopamine*: limited and preliminary findings suggest increased dopamine release in ventral striatum during video-game play; the role of dopaminergic activity in PVG has not been directly investigated	Dopamine release has been related to substance use, and most studies indicate between-group differences in dopaminergic activity
Hypersexual disorder	*Serotonin*: positive results from clinical trials with SSRIs	Mixed clinical results with SSRIs with some positive and others negative
	Opioids: initial positive findings for high doses of opioid receptor antagonist; however, positive results not long-lasting	Multiple positive clinical findings suggest role for opioid systems in SUDs
Food addiction	*Dopamine*: dopamine release related to food and food cues; reduced D2-like receptor availability in obese individuals and mice; animal models of food addiction suggest consumption of hyperpalatable	Dopamine release has been related to SUDs, and most studies indicate between-group differences in dopaminergic activity; decreased dopamine release and receptor

(*continued*)

Table 90.2 (continued)

Behavioral addiction	Key results	Similarities and differences with key results in substance use disorders
	foods decreased dopamine release and receptor expression following withdrawal; the role of dopaminergic activity in food addiction has not been directly investigated in humans	expression following substance use withdrawal, particularly in striatal regions
	Serotonin: positive findings in open-label and double-blind studies with SSRIs for BED	Mixed clinical results with SSRIs with some positive and others negative
	Opioids: positive findings for high doses of opiate antagonist in rodents but the precise nature unclear; different nutrients may have different effects on the opioid system	Multiple positive clinical findings suggest role for opioid systems in SUDs
Compulsive shopping disorder	*Serotonin*: some positive results from clinical trials with SSRIs, while controlled results for others have been typically negative	Mixed clinical results with SSRIs with some positive and others negative

PG pathological gambling, *SUDs* substance use disorders, *IAD* Internet addiction disorder, *PVG* problematic video-game playing, *SSRIs* selective serotonin reuptake inhibitors, *BED* binge eating disorder

(withdrawal), and interferences in major areas of life functioning. PG criteria also include gambling to escape from a dysphoric state, gambling to regain gambling-related losses ("chasing" losses), lying in significant relationships about gambling, and relying on others to fund gambling (American Psychiatric Association 2000). Engaging in illegal activities in order to fund gambling was a criterion in the DSM-IV-TR but was eliminated in DSM-5, thus reducing the threshold of inclusionary criteria from 5 of 10 to 4 of 9, and the disorder has been moved to an "Addiction and Related Disorders" category. High comorbidity rates for PG and substance addictions have been observed, with a recent meta-analysis suggesting a mean co-occurrence of 57.5 % (Lorains et al. 2011).

90.2.1.1 Neural Systems

The basis of PG is likely multifactorial. Changes in processing of gambling cues and gambling decisions, including those relating risk/reward decision-making, reward processing, and impulse control, are likely contributing factors (van Holst et al. 2010). Neuroimaging studies have typically investigated frontal and striatal circuits, although several lines of evidence also suggest the involvement of other regions.

Neuropsychological findings in PG have indicated impaired decision-making and deficits in executive functions compared to controls (van Holst et al. 2010). Functional magnetic resonance imaging (fMRI) studies during cognitive tasks have implicated frontal areas; in particular, multiple investigations have observed

Table 90.3 Overview of selected genetic results for selected behavioral addictions

Behavioral addiction	Key results	Similarities and differences with key results in substance use disorders (SUDs)
Pathological gambling	*Family history*: PG highly heritable; twin studies indicate genetic factors may share similar magnitudes with or contribute more than environmental factors to overall risk for developing PG	SUDs highly heritable; twin studies indicate genetic and environmental factors share similar magnitudes of influence on overall risk for developing a drug use disorder
	Molecular genetics: preliminary findings suggest genetic polymorphisms related to dopamine (DRD2) and serotonin transmission (5HTTLPR, MAO-A); recent genome-wide association study did not identify different contributions to individuals with PG	Associations with polymorphisms related to dopamine and serotonin transmission; genome-wide associations indicate some different contributions to individual SUDs
Internet addiction disorder	*Molecular genetics*: preliminary findings suggest overexpression of SS-5HTTLPR in males with IAD	Associations with serotonin transporter gene polymorphisms
Problematic video-game playing	*Molecular genetics*: preliminary findings suggest presence of Taq1A polymorphism of DRD2 receptor gene and low activity COMT alleles more likely in males with online PVG	Links between SUDs and Taq1A polymorphisms, but not universally replicated; the low activity COMT variant linked to various SUD (e.g., nicotine, methamphetamine, and alcohol)
Hypersexual disorder	*Family history*: more likely to have parent with hypersexual disorder; more likely to have first-degree relative with SUDs	Individuals with SUDs more likely to have first-degree relative with various SUDs and psychopathology
Food addiction	*Family history*: obesity tenfold more likely in people with an obese first-degree relative	Individuals with SUDs more likely to have first-degree relative with various SUDs and psychopathology
	Molecular: obese individuals with BED, compared to non-BED, had lower frequencies of the Taq1A1 polymorphism of DRD2 receptor gene and higher frequencies of the G118 polymorphism of the mu-opioid receptor gene (OPRM1); overexpression of SS-5HTTLPR in overweight adolescent	Associations with polymorphisms related to dopamine and serotonin transmission; OPRM1 polymorphisms may mediate reward effects of drugs of abuse (e.g., opiates, alcohol, and heroin); however, result in clinical populations have been mixed
Compulsive shopping disorder	*Family history*: relationship to parental history of CSD and first-degree relative with SUDs	Individuals with SUDs more likely to have first-degree relative with various SUDs and psychopathology
	Molecular: negative findings for 5HTTLPR polymorphisms	Associations with serotonin transporter gene polymorphisms

PG pathological gambling, *SUDs* substance use disorders, *IAD* Internet addiction disorder, *PVG* problematic video-game playing, *CSD* compulsive shopping disorder, *DRD2* dopamine receptor D2, *5HTTLPR* serotonin transporter-linked polymorphic region, *MAO-A* monoamine oxidase A, *COMT* catechol-O-methyltransferase, *OPRM1* opioid receptor, mu 1

differences in ventromedial prefrontal cortex (vmPFC) function in PG. For example, PG (versus control) subjects have exhibited relatively diminished vmPFC activation during presentation of incongruent stimuli in the Stroop color-word interference task (Potenza et al. 2003a), during anticipation of gains and losses in the monetary incentive delay (MID) task (Balodis et al. 2012a; Choi et al. 2012), during a simulated gambling task (Reuter et al. 2005), and (in comorbid PG and SUDs) during performance of the Iowa Gambling Task (Tanabe et al. 2007). However, seemingly contradictory findings have also been reported. During high-risk gambling decisions in the Iowa Gambling Task (IGT), fMRI findings demonstrated that PG individuals exhibited relatively greater frontal lobe and basal ganglia activation, particularly in the vmPFC, caudate, and amygdala (Power et al. 2011). Differences in findings across studies may relate to the specific tasks used, populations studied, or other factors. Cue-induction studies have also reported both relatively decreased (Potenza et al. 2003b) and increased (Crockford et al. 2005; Goudriaan et al. 2010) vmPFC activity for problem/PG (versus control) in response to gambling stimuli. Taken together, dysfunction in frontal areas appears to contribute to PG, although the precise nature of the dysfunction is unclear.

Dysfunction in the striatum may also contribute to PG. Decreased ventral striatal activation to reward anticipation in the MID task (Balodis et al. 2012a) and during simulated gambling (Reuter et al. 2005) has been reported among PG. In gambling cue-exposure tasks, PG exhibited decreased activation in the ventral (Potenza 2008) and dorsal (de Greck et al. 2010) striatum compared to controls. These findings are consistent with reward anticipation studies among individuals with substance addictions (Hommer et al. 2011; Wrase et al. 2007). In both PG and alcohol dependence, ventral striatal activation during reward anticipation was inversely correlated with impulsivity measures (Balodis et al. 2012a; Beck et al. 2009). Moreover, both ventral striatal and vmPFC activation were inversely correlated with severity of gambling symptomatology in PG subjects such that greater severity of PG was associated with lower ventral striatal and vmPFC activity during simulated gambling (Reuter et al. 2005).

Aside from frontal and striatal circuits, other brain regions have also been implicated. PG (versus controls) displayed significantly greater activity in the right parahippocampal gyrus and left occipital cortex, including the fusiform gyrus, to video presentation of gambling cues (Crockford et al. 2005). Among PG, subjective intensities of gambling urges following viewing of gambling videos correlated positively with activation in brain regions implicated in the retrieval and processing of emotion including the bilateral temporal poles, medial temporal gyrus, and medial occipital gyrus and inversely with activation in the left dorsal medial frontal cortex, an area involved in performance monitoring; control participants did not show gambling-urge-related correlations at the same threshold (Balodis et al. 2012b). Relatively diminished insula activation in PG during reward processing has also been noted (Balodis et al. 2012a).

Neuroanatomical alterations may also exist in PG. Diffusion tensor imaging (DTI) findings suggest reduced fractional anisotropy (FA) values in regions

including the corpus callosum in PG compared to control subjects (Joutsa et al. 2011; Yip et al. 2013). In addition, multiple regression analyses suggest that this reduction is significantly predicted by PG status as well as age and past alcohol abuse/dependence (Yip et al. 2013). To our knowledge, only two voxel-based morphometry (VBM) studies have been conducted among individuals with PG. Both studies report no volumetric differences in gray and white matter between PG and control subjects (Joutsa et al. 2011; van Holst et al. 2012).

90.2.1.2 Neurochemistry

Dopaminergic findings in PG present a complicated picture. Using positron emission tomography (PET) with the tracer [^{11}C]raclopride, a recent study reported that not only did PG perform worse on the IGT than controls, among PG, dopamine release in the ventral striatum was positively associated with excitement levels (Linnet et al. 2011). Increased dopamine levels may serve a "double deficit" function by reinforcing PG behavior through increasing excitement levels while simultaneously reducing inhibition of risky decisions. D2/D3 receptor availability has also been shown to negatively correlate with mood-related impulsivity ("urgency") within the striatum (Clark et al. 2012) and positively correlate with problem-gambling severity within the dorsal striatum (Boileau et al. 2013) among PG. However, unlike findings in substance addiction literature (Volkow et al. 2001), no significant difference in D2/D3 receptor availability at resting state was observed between PG and control subjects (Boileau et al. 2013; Clark et al. 2012; Linnet et al. 2011). However, a between-group difference in ventral striatum dopamine D2-like receptor availability and dopamine release has been reported in individuals with Parkinson's disease (Steeves et al. 2009). While there were no differences in the magnitude of dopamine release between PG and controls during a slot machine gambling task, among PG, dopamine release correlated positively with problem-gambling severity (Joutsa et al. 2012). Dopamine agonists have been associated with impulse control disorders in Parkinson's disease (Leeman et al. 2012). Further, oral administration of a D2-like receptor antagonist, haloperidol, increased gambling motivations among PG subjects, while no such effect was observed among controls (Zack and Poulos 2007), although individual differences appear to be important (Tremblay et al. 2011). Individual differences may explain with the lack of efficacy of D2-like antagonist drugs (e.g., olanzapine) in the treatment of PG (Fong et al. 2008; Grant and Potenza 2004; McElroy et al. 2008). Taken together, these data suggest a role for dopamine in PG, but one that may include within-group individual differences.

Pharmacological studies also implicate serotonin in PG. Selective serotonin reuptake inhibitors (SSRIs) have had mixed results for PG and substance addictions (Potenza et al. 2009). For example, some randomized control trials have found fluvoxamine and paroxetine to be superior to placebo in treatment of PG (Hollander et al. 2000; Kim et al. 2002), while others have reported negative findings (Blanco et al. 2002; Grant et al. 2003). Heterogeneity in treatment response may result from individual differences, with some data suggesting that individuals with co-occurring anxiety disorders may respond well to SSRIs (Bullock and Potenza 2012).

Other neurotransmitter systems may also contribute to PG. Dysregulated hypothalamic-pituitary-adrenal (HPA) axis and increased noradrenergic levels have been observed in PG (Meyer et al. 2004). Opioid antagonists (e.g., naltrexone and nalmefene) have demonstrated superiority over placebo in multiple randomized clinical trials (Bullock and Potenza 2012; Grant et al. 2010b; Kim et al. 2001). Following a 6-month open-label naltrexone treatment, the majority of PG patients did not relapse during a 6-month medication-free follow-up (Dannon et al. 2007). Thus, opioid antagonist treatment may have lasting effects, although controlled trials with longer-term follow-up are needed to examine this possibility. Lithium and the glutamatergic nutraceutical n-acetyl cysteine have also shown promise in small controlled trials (Bullock and Potenza 2012). Memantine, an N-methyl D-aspartate (NMDA)-type glutamate receptor antagonist, reduced both the number of hours spent gambling per week and money spent gambling in PG after 10 weeks of medication; in addition, PG subjects reported improved cognitive flexibility posttreatment suggesting that glutamate may contribute to impulsive and compulsive behaviors (Grant et al. 2010a).

90.2.1.3 Genetics/Family History

Data from the Vietnam Era Twin Registry estimate the heritability of PG to be 50–60 % (Lobo and Kennedy 2009; Shah et al. 2005). This estimate is similar to those from substance addictions (Kreek et al. 2005). Twin studies suggest that genetic factors may contribute more than environmental factors to the overall variance of risk for developing of PG (Blanco et al. 2012; Slutske et al. 2010).

Genetic polymorphisms related to dopamine transmission (e.g., *DRD2* and Taq1A1) (Comings et al. 1996; Lobo et al. 2010) and serotonin transmission (e.g., *5HTTLPR* and *MAO-A*) (de Castro et al. 1999; Ibanez et al. 2000) have been associated with PG, albeit not in a consistent fashion. These genes may have addictive effects (Comings et al. 2001). However, genetic studies are best considered preliminary given the small sample sizes and absence of stratification by demographics. Replication of candidate gene studies using alternate designs is needed. Towards this end, a recent genome-wide association study was performed but did not identify single-nucleotide polymorphisms (SNPs) reaching genome-wide significance (Lind et al. 2012).

90.2.1.4 Conclusion

PG has been the most frequently studied behavioral addiction and is the most likely to be reclassified from an Impulse Control Disorder (ICD) to the proposed *DSM-5* category, "Addiction and Related Disorders" (American Psychiatric Association 2012). Although the neurobiology of PG is incompletely understood, recent neuroimaging, neurocognitive, neurochemical, and genetic work indicate similarities with SUDs (Leeman and Potenza 2012).

90.2.2 Internet Addiction Disorder

The Internet is integrated firmly into modern society and has radically changed the way we conduct our daily lives. Its popularity, particularly among youth, has raised

concern over its potential harms. While moderate Internet use may enhance one's quality of life by widening social circles and enhancing psychological well-being (Chen et al. 2002; Willoughby 2008), diminished control over Internet use may impact negatively on daily function, family relationships, physical and mental health, and may lead to incarceration and legal troubles (Anderson 2000; Ko et al. 2012; Sanders et al. 2000; Willoughby 2008). While no formal diagnostic criteria for "Internet addiction disorder" (IAD) or problematic Internet use currently exist in the DSM, the condition may involve excessive or poorly controlled urges and a maladaptive obsession with the Internet (Ko et al. 2012). Definitions of IAD are often based on *DSM-IV-TR* criteria for pathological gambling (Dowling and Quirk 2009; Ko et al. 2009b; Young 1999) with some, such as Young's Internet Addiction Scale, having demonstrated sufficient reliability (Bernardi and Pallanti 2009; Widyanto and McMurran 2004). In terms of comorbidity, IAD may frequently co-occur with not only SUDs (Bai et al. 2001; Lam et al. 2009; Yen et al. 2009) but also various psychiatric conditions including impulse control, mood, and personality disorders (Bernardi and Pallanti 2009; Dowling and Brown 2010; Dowling and Quirk 2009; Mazhari 2012).

90.2.2.1 Neural Systems

Electrophysiological studies indicate diminished efficiency of response inhibition in IAD. Recordings of the P3 amplitude, an event-related potential (ERP) associated with response evaluation and inhibitory processing, were found to be higher and have longer peak latency among IAD (versus controls) during a Go/No Go task (Dong et al. 2010). These findings suggest IAD individuals may need to engage more cognitive resources to inhibit behavior and are less efficient in information processing. Another study by the same research group found that for incongruent conditions during the Stroop task, IAD (versus controls) showed reduced medial frontal negativity (MRN), suggesting impaired cognitive control (Dong et al. 2011b). These findings resemble those from SUDs (Garavan and Stout 2005; McGue et al. 2001).

A recent fMRI study reported that IAD (versus control) demonstrated greater activation in the anterior and posterior cingulate cortices for incongruent conditions during the Stroop task (Dong et al. 2012). Moreover, greater anterior cingulate cortex (ACC) activation was associated with slower incongruent reaction time and more severe scores on Young's Internet Addiction Scale across all participants (Dong et al. 2012). In a guessing task with monetary gain and losses, increased activation of the orbitofrontal cortex (OFC) to gain trials and decreased ACC in loss trials was observed in IAD compared to controls suggesting sensitization to reward and desensitization to loss (Dong et al. 2011a). Resting-state abnormalities in IAD subjects have also been detected with increased regional homogeneity observed in the right frontal region, left superior frontal gyrus, right cingulate gyrus, bilateral parahippocampus, and other regions (Liu et al. 2010). Increased regional homogeneity may reflect enhancement of synchronization among these regions which may consequently enhance sensitivity to rewards.

Evidence also indicates potential structural differences. Using MRI, lower gray matter density in regions tied to emotion regulation including the ACC, posterior cingulate cortex, insula, and lingual gyrus has been found (Zhou et al. 2011). Moreover, gray matter volumes of the right dorsolateral prefrontal cortex (dlPFC), left ACC, the right supplementary motor area, and white matter FA measures in the posterior limb of the internal capsule have been negatively correlated with the duration of IAD (Yuan et al. 2011).

In the same study, Yuan et al. (2011) also reported increased FA within the region of the left internal capsule accompanied by decreased FA within the right parahippocampal gyrus among IAD adolescents. This finding appears to contrast with results from Lin et al. (2012) who reported widespread reduction of FA in major white matter pathways and abnormal white matter structure in IAD adolescents. Taken together, these data suggest involvement of white matter microstructures in the pathophysiology of IAD, although the precise relationship warrants further research.

90.2.2.2 Neurochemistry

Several small studies have explored dopaminergic functioning in IAD. A recent study using single-photon emission computed tomography (SPECT) scans reported decreased striatal dopamine transporter expression among male IAD subjects compared to age-matched controls (Hou et al. 2012). In addition, the authors reported significantly decreased volume of the bilateral corpus striatum among IAD subjects. Another study using [^{11}C]raclopride (PET) scanning reported that adult males with IAD (versus male controls) had reduced dopamine D2-like receptor availability in subdivisions of the striatum including the bilateral dorsal caudate and left dorsal putamen compared to controls; moreover, receptor availability was negatively correlated with IAD severity (Kim et al. 2011). Interestingly, dopamine receptor availability in the ventral striatum did not differ between the control and IAD groups (Kim et al. 2011), contrasting results from SUDs (Dalley et al. 2007; Heinz et al. 2004). Further studies are needed regarding the role of dopamine in IAD.

90.2.2.3 Genetics/Family History

Few studies have investigated genetics underlying IAD. Homozygosity of the short allelic variant of the *5HTTLPR* (*SS-5HTTLPR*) gene may be more frequent among male IAD adolescents (Lee et al. 2008). IAD subjects expressing *SS-5HTTLPR* showed higher harm avoidance and scored higher on Young's Internet Addiction Scale than IAD individuals who expressed other variants of the gene (Lee et al. 2008). The nicotinic acetylcholine receptor subunit alpha 4 (CHRNA4) gene may also contribute to IAD. The T-variant (CC genotype) of the rs1044396 polymorphism on the CHRNA4 gene occurred more frequently among IAD (versus control) subjects; further analyses revealed that this finding was driven by females, suggesting sex-specific genetic effects (Montag et al. 2012).

90.2.2.4 Conclusion

IAD is a behavioral addiction that may be increasingly prevalent concurrent with increased Internet availability, accessibility, and popularity. Although the neurobiology of IAD remains under-researched, recent years have shown promising progress. It is important to note that most studies have targeted adolescent males and have been performed in Asia; therefore, results may not be generalizable to other populations. IAD was proposed for inclusion in Sect. III, a part of the *DSM-5* in which conditions that require further research are located. 'Internet Gaming Disorder' has been included in Sect. III and has been flagged as a possible candidate for future inclusions in the addictions category. However, criteria for this condition are currently limited to Internet gaming and does not include Internet use for other purposes including for online gambling, or social media.

90.2.3 Problematic Video-Game Playing

Similar to IAD, problematic video-game playing (PVG) or "video-game addiction" is not currently described in the *DSM* (although Internet Gaming Disorder has been included in Sect. III), and assessment tools are often based on the *DSM-IV-TR* definitions for PG (e.g., Tejeiro et al. 2002). Some have argued that PVG is a subtype of IAD, and both should be considered under the umbrella term pathological technology use (Sim et al. 2012). However, it is important to consider the two conditions individually as each may be associated with different clinical and health-related correlates (Yau et al. 2012). PVG may be both similar to and distinct from other behavioral addictions such as PG and IAD in terms of availability and use of visual and auditory rewards – and such differences may contribute to PVG's unique features (Griffiths 2002; Sussman et al. 2011). However, research on PVG often does not differentiate between online and off-line games, making it difficult to separate PVG from IAD findings.

90.2.3.1 Neural Systems

Electrophysiological data indicate reduced frontal-central error-related negativity (ERN) amplitudes among PVG (versus controls) in response to incorrect trials relative to correct trials in the Go/No Go task, suggesting compromised error processing among PVG subjects (Littel et al. 2012). In addition, ERN amplitude was negatively correlated with weekly gaming hours (Littel et al. 2012). This finding parallels those from SUDs (Franken et al. 2007; Sokhadze et al. 2008) and suggests that individuals engaged in either behavior may be desensitized to negative consequences.

In one of the largest imaging studies on PVG to date, Kühn et al. (2011) conducted MRI scans on 154 14-year olds and found both functional and structural differences between frequent ($\geq$9 h/week) and infrequent ($<$9 h/week) video-game players. In the MID task, frequent players showed greater activation of the ventral striatum during loss feedback compared with no loss. Moreover, higher left striatal gray matter volume was observed among frequent compared to infrequent players, and this volumetric difference was found to negatively correlate with deliberation

time on the Cambridge Gambling Task (CGT). Striatal differences have also been noted in cue-induction studies. Post-cue changes indicative of increased activity have been found in the right NAc and right caudate nucleus among male adults playing >30 h/week on the "World of Warcraft" game compared to "non-heavy" gamers playing <2 h/week (Ko et al. 2009a).

In addition to striatal findings, Ko et al. (2009) also reported greater activation in the right OFC, bilateral ACC, medial frontal cortex, and right dlPFC in heavy (versus non-heavy) players following cue presentation. Activation of these areas was positively correlated with self-reported gaming urge and recall of gaming experience provoked by "World of Warcraft" pictures (Ko et al. 2009a). Similar findings have been reported in subsequent studies examining individuals with current PVG (Han et al. 2010b; Sun et al. 2012) and those in remission from online PVG (Ko et al. 2011). Healthy male adults who played a novel video game for 60 min per day for 10 days showed stronger activation of the left inferior frontal gyrus, left parahippocampal gyrus, bilateral parietal lobes, thalamus, and right cerebellum in response to video-game stimuli compared to neutral-control stimuli (Han et al. 2011). Activation of the right medial frontal lobe and right parahippocampal gyrus also positively correlated with gaming urge (Han et al. 2011).

90.2.3.2 Neurochemistry

In an early neurobiological study of video-game playing using [^{11}C]raclopride (PET) scanning, increased release of dopamine to D2-like receptors in the ventral striatum was observed following 50 min of video-game playing in healthy adult males (Koepp et al. 1998). A more recent study using SPECT similarly suggested increased dopamine release in the caudate during a motorbike racing computer game, compared to baseline measures among healthy adult males (Weinstein 2010). While video-game playing may be capable of inducing dopamine release that is comparable to the effects of psychoactive substances (Farde et al. 1992; Volkow et al. 1994), the role of dopamine dysfunction in PVG is unclear, and to date, no study has directly investigated a relationship.

Following a 6-week trial of bupropion (a drug with influences on dopaminergic and other neurotransmitter systems), individuals with online PVG (>30 h StarCraft/week) demonstrated decreased craving for video-game play, reduced total game play time, and less cue-induced brain activity in the dlPFC compared to pretreatment (Han et al. 2010a).

90.2.3.3 Genetics/Family History

Genetic studies for PVG are very limited, and to our knowledge, only one study has been conducted. Han et al. (2007) reported that the presence of the Taq1A1 allele of *DRD2* and the low activity Val158Met variant of COMT genes were more prevalent among online PVG adolescent males than controls.

90.2.3.4 Conclusion

Despite public attention, PVG remains understudied, and findings are often difficult to compare between studies given the use of different measures across studies.

However, preliminary studies suggest neurobiological similarities with substance addictions, particularly with respect to ventral striatal structure and function.

90.2.4 Hypersexual Disorder

Although "hypersexual disorder" or "sexual addiction" was considered for inclusion in the *DSM-5*, it was ultimately not accepted. It may be defined as recurrent or repetitive compulsive sexual behavior. It is primary conceptualized as a nonparaphilic sexual desire disorder with impulsivity and/or compulsivity components (Fong 2006; Kafta 2010). Some individuals who suffer from hypersexual disorder may display clinical features that resemble addictive disorders including craving prior to behavioral engagement, impaired control over behavioral engagement, and behavioral engagement despite adverse consequences (Kor et al. 2013), while other individuals may present symptoms resembling ICD or obsessive-compulsive disorders (OCD) (Gold and Heffner 1998).

90.2.4.1 Neural Systems

To our knowledge, only one neuroimaging study in hypersexual disorder exists. Using DTI, Miner et al. (2009) found that although mean diffusivity in the inferior frontal region was negatively correlated with impulsivity, FA and mean diffusivity measures of this area did not differ between hypersexual disorder patients and controls. These data suggest possible differences from other behavioral addictions in which associations with inferior frontal white matter disorganization have been reported (i.e., low FA and high mean diffusivity), albeit not always in inferior frontal regions (Grant et al. 2006; Joutsa et al. 2012; Yip et al. 2013; Yuan et al. 2011). Further research is needed to investigate neuroanatomical differences associated with hypersexual disorder.

Evidence from animal research suggests that the medial prefrontal cortex (mPFC) contributes to sexual behaviors. mPFC lesions in rats block the acquisition of sex-aversion condition and impair the suppression of seeking of sexual rewards in the face of aversive consequences (Davis et al. 2010). Whether activity of the mPFC and other frontal areas plays a role in hypersexual disorder remains to be studied.

90.2.4.2 Neurochemistry

Our current understanding of the neurochemistry of hypersexual disorder is predominantly derived from pharmacological studies. In a double-blind, placebo control study of hypersexual disorder in homosexual and bisexual men, the selective serotonin reuptake inhibitor (SSRI) citalopram was found to reduce sexual desire without lessening sexual satisfaction (Wainberg et al. 2006). Another SSRI, fluoxetine, was found effective in reducing symptoms in men with either paraphilia or paraphilia-related disorders (Kafka and Hennen 2000). In addition, better results were obtained when methylphenidate was used in conjunction with fluoxetine, suggesting an additive effect and implicating possible involvement of dopamine and norepinephrine (Kafka and Hennen 2000).

Naltrexone, an opioid receptor antagonist, appears effective in treating hypersexual disorder. Administration of high doses (100–200 mg/day) has been reported to successfully reduce hypersexual disorder symptoms, sexual urges, sexual fantasies, and masturbation in two case report studies (Grant and Kim 2001; Raymond et al. 2002). These features, however, recurred following naltrexone discontinuation (Grant and Kim 2001).

Other investigators have suggested that medications (such as SSRIs and lithium) do not specifically manage sexually addictive behaviors but rather treat comorbid psychiatric disorders which in turn help patients become more accessible to their hypersexual disorder issues (Sealy 1995). Controlled trials and systematic studies are needed to fully examine the efficacies and tolerabilities of medications for hypersexual disorder.

90.2.4.3 Genetics/Family History

Limited findings suggest individuals suffering from hypersexual disorder were more likely to have parents with a similar condition and were more likely to have a first-degree relative with SUDs (Schneider and Schneider 1996). Carnes (1998) reported that 87 % of hypersexual disorder patients come from a family with addiction problems.

90.2.4.4 Conclusion

Hypersexual disorder is a serious clinical condition that can have detrimental effects on daily life. Neurobiological research in hypersexual disorder, particularly with respect to neuroanatomical and neurocircuitry data, is currently very limited.

90.2.5 Food Addiction

Food addiction has been discussed in the popular media and has received some research attention. Addictive processes have been suggested to underlie obesity (Volkow and O'Brien 2007). Emerging neurobiological research suggests both substance use and eating behaviors engage similar neurocircuitry and has consequently led to the conceptualization of "foods as drugs" (Davis and Carter 2009). However, the concept of food addiction remains debated with some investigators arguing that existing research has yielded conflicting results (Ziauddeen et al. 2012a, b) and others arguing that this construct may be particularly relevant to certain subgroups of obese individuals, such as those with binge eating disorder (BED) (Avena et al. 2012; Gearhardt et al. 2011a). Although not labeled as such, several core features of BED share similarities with those for substance dependence including strong food cravings and diminished control over eating (Gearhardt et al. 2011a). Over a quarter of clinicians report often or always using addiction-based therapies for BED (von Ranson and Robinson 2006), further suggesting clinical and phenomenological similarities. It is important to note that for some individuals, overeating is a relatively passive event that takes the form of liberal snacking, eating large portions, and physical inactivity (Avena et al. 2011; Marcus and Wildes 2009), and the extent to which these behaviors constitute an addiction may be debated. Individuals with food addiction may be more impulsive, display

greater emotional reactivity and food cravings than obese individuals without food addiction (Davis et al. 2011), and thus have clinically relevant features associated with food addiction.

90.2.5.1 Neural Systems

Imaging studies in obese (versus lean) subjects have documented significantly increased activation of the vmPFC and dlPFC upon exposure to food-related stimuli (Gautier et al. 2000; Miller et al. 2007). Other prefrontal areas (such as the OFC and cingulate gyrus) have been implicated in feeding motivations (Rolls 2004). Moreover, obese individuals (versus controls) showed greater activation in regions associated with cue-related craving for substance addictions including the ACC, striatum, insula, and dlPFC in response to pictures of high-calorie food versus low-calorie food (Rothemund et al. 2007; Stice et al. 2009; Stoeckel et al. 2008). Healthy adults placed under a nutritionally adequate but monotonous diet, compared to those on an unrestricted diet, showed greater activation of the hippocampus, insula, and caudate in response to cues of foods they favored (Pelchat et al. 2004). Obese versus lean individuals have also shown enhanced corticolimbic-striatal activation to favorite-food cues and stress cues in a guided imagery fMRI task (Jastreboff et al. 2013). In the same study, measures of insulin resistance correlated positively with regional brain activations to favorite-food, stress, and neutral-relaxing cues in obese but not lean individuals, and regional brain activations (particularly in the thalamus) mediated the relationships between insulin resistance and favorite-food-cue-induced craving in obese but not lean individuals. These data suggest that obese individuals may be hyperresponsive to food cues (particularly those of high-caloric value) and that metabolic measures may relate to these brain activations differently in obese and lean individuals.

While cue-induction studies suggest increased activation in regions involved in the reward system among obese people, ingestion of food has been associated with reduced activation of the brain reward system. Stice et al. (2008) found that obese (versus lean) adolescent girls showed diminished caudate nucleus activation in response to anticipated intake and actual consumption of palatable food intake. The authors suggest that this may potentially reflect decreased dopamine receptor availability. Downregulation of the dopaminergic mesolimbic system may motivate overeating to temporarily compensate for an under-stimulated reward system and may ultimately lead to food addiction.

Obesity is a heterogeneous construct and emerging evidence suggests that certain subgroups, such as those with BED, may exhibit food addiction features more so than others. Individuals with BED compared to BMI-matched non-BED obese and lean individuals showed relatively diminished activity in the vmPFC, inferior frontal gyrus, and insula during the Stroop task (Balodis et al. 2013). The same research group found that during a MID task, BED obese individuals showed relatively diminished ventral striatal activity during anticipatory phases relative to non-BED obese individuals, whereas non-BED obese individuals showed heightened ventral striatal and vmPFC responses compared to lean

individuals (Balodis et al. 2013). Taken together, these results suggest that neural differences exist between obesity subgroups.

To our knowledge, only one neuroimaging study has directly assessed food addiction. Gearhardt et al. (2011b) found that activation in the ACC, medial orbitofrontal cortex, and amygdala in response to anticipated receipt of food was positively correlated with food addiction scores among lean and obese young females. Furthermore, females with high food addiction scores, compared to those with low scores, showed decreased activation in the OFC during food intake. No significant correlation was observed between food addiction score and BMI, suggesting that food addiction and related neural functioning may occur among individuals with a range of body weights.

90.2.5.2 Neurochemistry

Dopamine release has been related to food and food cues (Di Chiara and Imperato 1988). Administration of dopamine antagonists can abolish the responding for food in rats (Wise and Rompre 1989). Development of addiction-like reward deficits and onset of compulsive-like food seeking was accelerated by lentivirus-mediated knockdown of striatal D2-like receptor in rats with extended access to palatable, high-fat food (Johnson and Kenny 2010). Studies using [^{11}C]raclopride (PET) scanning have demonstrated that D2-like receptor availability is reduced in obese individuals (Wang et al. 2009) and mice (Geiger et al. 2008; Huang et al. 2006). Moreover, among obese individuals, D2-like receptor availability correlated negatively with body mass index (BMI) scores (Wang et al. 2001).

Data from animal models suggest ingestion of foods of different palatability, and energy density produces different effects in the dopaminergic system. Rats classified as prone to binge eating consumed significantly more highly palatable and energy-dense (high fat, high sugar) food and tolerated higher levels of foot-shock for such foods than binge eating-resistant rats (Oswald et al. 2011). Regular consumption of energy-dense food may have lasting consequences on the brain. Using a diet-induced model of obesity, rats fed a high-sugar diet compared to those on an unrestricted diet showed decreased dopamine release in the NAc following 36 h of food deprivation (Avena et al. 2008). Similarly, Alsiö et al. (2010) found that rats fed a high-fat (versus unrestricted) diet showed decreased expression of D1 and D2 receptors in the VTA, NAc, and PFC following an 18-day withdrawal. Furthermore, obesity-prone rats showed increased craving and anxiety compared to obesity-resistant rats during the second withdrawal week following discontinuation of the energy-dense diet (Pickering et al. 2009). Future studies are needed to examine whether these dietary findings extend to human subjects.

The serotonin and norepinephrine reuptake inhibitors sibutramine and SSRI fluoxetine have shown some efficacy in treating eating disorders and are approved by the Food and Drug Administration for treatment of obesity and bulimia nervosa, respectively, although the former has been recalled in the United States for cardiovascular safety concerns (McElroy et al. 2012). SSRIs in general have been shown to be effective in targeting binge eating, psychiatric, and weight symptoms (Reas and Grilo 2008), although the effectiveness and duration of these medications

remain under debate. Open-label studies report initial SSRI (citalopram and fluoxetine) administration reduced binge eating and weight loss in BED patients; at a 6-month follow-up, these beneficial effects were maintained with continuation of SSRI treatment (Leombruni et al. 2006, 2008). In a randomized, double-blind, 12-week study of escitalopram for the treatment of individuals with co-occurring BED and obesity, individuals receiving high-dose escitalopram treatment had significantly greater reductions in weight, BMI, frequency of binge episodes, and global severity of illness scores than those receiving placebo treatment (Guerdjikova et al. 2008). Fluoxetine treatment for BED significantly increased the odds of binge abstinence immediately posttreatment; however, these effects may not be long-lasting as no significant improvement in BED symptoms was observed during the 29-month follow-up despite improvements in depressive symptoms (Devlin et al. 2007).

Opioids are implicated in eating behavior (Kelley et al. 2002), although the precise nature of their influences are unclear. High doses of the opiate antagonist, naloxone, increased sugar consumption and opiate-like withdrawal symptoms including elevated plus-maze anxiety, teeth chattering, and head shakes in sugar-binging rats following a period of abstinence (Avena et al. 2008, 2009; Colantuoni et al. 2002). These findings may, however, be unique to sugar binging. A recent study by Bocarsly et al. (2011) reported that rats on high-fat diets did not show signs of opiate-like withdrawal when exposed to naloxone. Taken together, these findings suggest that the brain opioid system may be differently affected by the overeating of different nutrients.

90.2.5.3 Genetics/Family History

Obesity is tenfold more likely in people with an obese first-degree relative (Segal and Allison 2002). When pregnant rats maintained a highly palatable and energy-dense (high fat, high sugar) diet, their offspring showed an increased preference for sugar and fat in comparison to those with mothers on a control diet (Vucetic et al. 2010). Additionally, dopamine and opioid receptor expression was increased in reward-related brain regions including the NAc, PFC, and hypothalamus (Vucetic et al. 2010). In humans, obese individuals with BED, in contrast to non-BED obese controls, had lower frequencies of the Taq1A1 allele of the *DRD2* gene and higher frequencies of the G118 allele of the mu-opioid receptor gene (*OPRM1*) (Davis et al. 2009). Taken together, genetic data suggest dopamine and opioid receptor genotypes may be involved in obesity and different patterns of eating. Genetic polymorphism of the *5HTTLPR* has also been implicated. S allele carriers showed higher BMI scores than homozygous LL carriers and were more frequent among overweight adolescents (Sookoian et al. 2007).

90.2.5.4 Conclusion

Unlike some behavioral addictions, eating behaviors have been tested extensively using animal models, and a considerable amount of neurobiological research has been generated. Data suggest that animal results may be transferable to human

populations, although further research is needed. Certain subgroups of people with obesity (e.g., those with BED) and certain diets (e.g., highly palatable, energy dense) may share more neurobiological similarities with SUDs. Such findings have important implications, and the extent to which a food addiction model applies to individuals with obesity and its subgroups merits further consideration.

90.2.6 Compulsive Shopping Disorder

Classically referred to as "oniomania," compulsive shopping disorder (CSD) has had a long-standing history (in comparison to more recent phenomena such as IAD and PVG) and was clinically described a century ago by German psychiatrist Emil Kraepelin (1915). Interest in CSD has rekindled in recent years with work conducted by consumer behaviorists (see review: Black 2007).

90.2.6.1 Neural Systems

A recent fMRI study found stronger NAc activity among compulsive shoppers (versus controls) during the initial product presentation phase of a multiphase purchasing task (Raab et al. 2011). During a subsequent price presentation phase, compulsive shoppers showed reduced activation of the insula and ACC. ACC activity was also higher among compulsive shoppers during the concluding decision phase. To our knowledge, this is currently the only neuroimaging study on compulsive shopping.

90.2.6.2 Neurochemistry

Beneficial results of citalopram, an SSRI, have been reported in a small 12-week open-label trial, and in a 6-month follow-up, CSD patients continuing citalopram were less likely to relapse than those who discontinued the medication (Koran et al. 2002). A subsequent study found those assigned placebo were more likely to relapse compared to those randomized to continue taking citalopram in a 9-week double-blind, placebo-controlled administration following a 7-week open-label trial (Koran et al. 2003). Further research is needed to understand the effects of citalopram discontinuation.

Findings from other SSRIs have been negative. Another study by Koran et al. (2007) found no difference between escitalopram and placebo conditions. Double-blind comparisons of fluvoxamine and placebo similarly found no difference in compulsive shopping symptom reduction (Black et al. 2000; Ninan et al. 2000). As such, further research is needed prior to the clinical utilization of SSRIs for compulsive shopping.

90.2.6.3 Genetics/Family History

There is some evidence that suggests compulsive shopping runs in families. Of 18 individuals with CSD, three had one or more first-degree relative with CSD, and 11 had relatives with an SUD (McElroy et al. 1994). Negative findings have been reported for *5HTTLPR* polymorphisms (Devor et al. 1999).

90.2.6.4 Conclusion

Our current knowledge of the neurobiology and genetics of CSD is limited, but preliminary research suggested altered neurofunctional responses to shopping stimuli. Further research is needed to determine the role of various neurotransmitters, the efficacy of different medications, and the underlying biology of the disorder.

90.3 Conclusion

Research in behavioral addictions is challenging due to the heterogeneity of the behaviors, with certain subgroups arguably fitting better in an addiction framework than others (Grant et al. 2010c). Further complications stem from the arguably normative nature of these behaviors which has caused disagreements among researchers as to what constitutes an addiction (Avena et al. 2012; Block 2008; Yau et al. 2012). Uniformly agreed-upon diagnostic criteria and assessment tools will not only facilitate comparisons across studies but may help to ensure that cutoff points are appropriately generated. Additional research in the domains of neuroimaging, neurochemistry, genetics, and treatment is needed to increase knowledge of behavioral addictions to the level of that for substance addictions. In particular, future studies investigating often underrepresented female populations (especially for IAD and PVG) and studies conducted longitudinally would provide valuable information and more comprehensive understandings.

Keeping these limitations in mind, existing research suggests parallels between behavioral addictions and SUDs. Data are most extensive for PG, and there is sufficient evidence to warrant considering it as a non-substance or behavioral addiction. Although many gaps in knowledge remain, research in IAD, PVG, hypersexual disorder, food addiction, and CSD has accelerated in recent years, with early work yielding promising results. Other behaviors not discussed in this review such as kleptomania, trichotillomania, skin-picking, and intermittent explosive disorder may also merit consideration as behavioral addictions, although few neurobiological studies have investigated these behaviors. In the current state of knowledge, it seems premature to classify all impulse control disorders in the proposed addiction category in the upcoming *DSM-5*.

Neuroscientific approaches to addiction have traditionally been based on the premise that addiction is a process that results from brain changes associated with chronic intake of physical substances. Although the neurobiologies of behavioral addictions remain relatively poorly understood, recent research suggests that prolonged and pathological engagement in addictive behaviors may lead to neuroadaptations and structural changes in ways similar to psychotropic drugs and/or that similar biological features may lead to the development of behavioral and substance addictions. Given the considerable co-occurrences of behavioral and substance addictions, an improved understanding of their relationships has important implications for not only furthering our understanding of the neurobiology of both sets of disorders but also improving prevention and treatment strategies.

Abstract

Conceptualizing, diagnosing, and treating behavioral or process addictions (addictions to nondrug activities, such as gambling, sex, Internet use and gaming, eating, shopping, work, and exercise) have proven to be conceptually complex. As a means of addressing this complexity, we adopt a syndrome model of addiction, which views the disorder of addiction as a syndrome with multiple opportunistic expressions and multiple, interacting biological, psychological, and experiential elements. In this chapter we refine our focus to how the psychological factors of impairment of control, craving, motives and

expectancies, and personality influence the addiction syndrome of excessive behaviors. We draw upon relevant research on these psychological factors as they relate to excessive behaviors, integrate these findings, and propose implications for treating excessive behaviors. A transdiagnostic treatment approach is suggested that recognizes the dynamic interaction between personality characteristics, emotional and cognitive states, interpersonal problems, and excessive behaviors but also uses a tailored case conceptualization to identify the optimal specific treatment focus and approach as relevant to specific individuals and types of behavioral problems.

91.1 Introduction

The notion of behavioral or process addictions, or addictions to nondrug activities, such as gambling, sex, Internet use and gaming, eating, shopping, work, and exercise, is conceptually complex. There is a lack of consensus with regard to labels, criteria, and conceptualization (Mudry et al. 2011). Researchers and practitioners view behavioral addictions from a variety of perspectives: as an impulse control disorder, a compulsive-impulsive spectrum disorder, a disorder of impaired control, a pathological disorder, or an addiction/dependence (Blaszczynski and Nower 2002; Cantinotti et al. 2009; Grant and Potenza 2005).

An addiction disorder can be broadly conceptualized as requiring the following criteria: (a) craving and compulsion, (b) loss of control, and (c) continuing the behavior despite experiencing adverse consequences (Zuckerman 2012). Addiction is not just a label or diagnosis but a dynamic process; those afflicted by addiction have been seen to go through phases of exacerbation and abstention, with episodes of controlled activity (Shaffer 2012). This addiction process is more about a relationship process than about the object, substance, or behavior. Shaffer argues:

> the most common conceptual error committed by clinicians, researchers, and public policymakers is to think that addiction resides as a latent property of an object (i.e., a drug or game of chance) . . . When a particular pattern of behaviour can reliably and robustly change emotional experience in a desirable way, the potential for addiction emerges. The relationship of the addicted person with the object of that person's excessive behaviour – not just the attributes of the object – is what defines addiction. (p. xxxii)

91.2 A Syndrome Model of Addiction

New lines of research have reconsidered addiction as a complex pattern of activity, using a syndrome model of addiction, which we adopt in our conceptualization of behavioral addiction. A syndrome model of addiction (Shaffer et al. 2004) views the disorder of addiction as a syndrome with multiple opportunistic expressions and multiple, interacting biological, psychological, and experiential elements. The addiction syndrome has unique and shared components: unique components manifest as a specific expression of the addiction syndrome as reflected by particular objects

(e.g., cigarettes, slot machines), whereas shared components manifest as common sequelae among various expressions of the addiction syndrome (e.g., depression, deception) (Shaffer et al. 2004). Addiction also has shared neurobiological and psychosocial antecedents and shared experiences (e.g., manifestations and sequelae). Research has shown that various addictions have shared manifestations, parallel natural histories, object nonspecificity (not linked to a particular substance or behavior), concurrent manifestations, and treatment nonspecificity (Shaffer 2012).

According to the syndrome model of addiction, antecedents of the addiction syndrome include individual vulnerability levels, object or behavioral exposure, and interaction. Throughout their lives, people encounter and accumulate specific interactions of neurobiological and psychosocial elements that can influence their behavior. While some elements increase the likelihood of addiction, others have protective mechanisms. Similarly, individuals are exposed to, and have access to, different behaviors and objects, over their life, increasing an individual's likelihood towards excessively engaging in one behavior over another.

When at-risk individuals interact with a particular behavior, they may experience neurobiological consequences that are both common to all types of addiction (e.g., activation of reward circuitry) and also unique to specific behaviors (e.g., psychoactivity) (Shaffer et al. 2004). After repeated engagement in a particular behavior, the neurobiological and/or social consequences of these interactions produce a desirable (or sought-after) subjective shift that is reliable and robust, creating a premorbid stage of the addiction syndrome. Here, people teeter on a delicate balance that can shift them towards an addiction process.

The addiction syndrome can be recursive, its sequelae generating a new vulnerability profile (e.g., provoking reward-system malfunction in a previously normal system). The addiction syndrome itself places individuals with the syndrome at increased risk for continuing addictive behavior and for developing new addictive behaviors. This chain of events is evident in the addiction syndrome, via parallel natural histories of different manifestations of addiction, including relapse patterns, addiction hopping, treatment nonspecificity, and addiction comorbidity.

Some psychosocial antecedents that appear to be relevant are the psychological factors of the individual who is engaging in behaviors excessively. In the remainder of this chapter, we examine the psychological factors that may influence the development and perpetuation of the addiction syndrome. Specifically, we review how the psychological factors of impairment of control, craving, motives and expectancies, and personality influence the addiction syndrome of excessive behaviors.

91.2.1 Impairment of Control and Craving

According to the DSM-IV, the essential feature of impulse control disorders such as pathological gambling is the failure to resist an impulse, drive, or temptation to perform an act that is harmful to an individual (American Psychiatric Association 2000). This description contains features that are similar to the central attributes of our common conceptions of addiction – some degree of impairment of control over

the addictive behavior as well as continuing involvement despite the emergence of negative consequences (Goodman 1990). The concepts of impulse dyscontrol and impairment of control are comprised of both behavioral and psychological aspects. In terms of behavior, the individual engages in the behavior despite a decision to abstain or limit involvement. The addicted drinker drinks much more than intended in an evening and drinks more days than he planned in the week, the addicted gambler returns to the casino despite vowing to stay away, and the compulsive shopper seeks credit at yet another online store breaking a commitment to family members not to go online again. Impairment of control is reflected behaviorally in failure of self-control.

The psychological aspect of impairment of control is typified by an impulse, temptation, urge, or craving that precedes the behavior and intensifies when the individual stops or cuts back their involvement. The addicted smoker experiences a craving for a cigarette shortly after getting up in the morning. The addicted video gamer feels a strong urge to get back to the computer throughout a family celebratory dinner.

Impairment of control and craving are long-recognized concepts in the alcohol and substance dependence field, with an extensive literature available. Although the concepts are ultimately clinically useful, both have been criticized for their unclear, and perhaps flawed, conceptual underpinnings. Impairment of control, for example, has been described as a tautology – it is seen as both evidence of addiction and as resulting from addiction (Eiser 1990). It is used both to describe addiction and to explain addiction (Table 91.1).

The concept of craving is also conceptually fuzzy. Rosenberg (2009) points out that definitions of alcohol and other drug craving may include multiple "response domains" including emotional experiences (e.g., desire, irritability, anxiety), cognitive effects (e.g., intrusive thoughts), physiological experiences (e.g., heart rate, respiration, salivation), and overt behaviors (e.g., seeking alcohol). These domains may, or may not, covary within the individual. Moreover, craving is sometimes viewed as an enduring background state (indicating overall severity of addiction) and sometimes as transient and episodic (influenced by a variety of situational factors). Most definitions describe craving as a subjective experience, although some also describe craving as potentially occurring outside of conscious awareness (Sayette et al. 2000).

Notwithstanding these conceptual issues, a variety of reliable and valid measures of impairment of control and craving have been developed (Marsh et al. 2002; Rosenberg 2009). Advancements in the ability to measure craving, in fact, influenced the proposal by the DSM-5 working committee to add craving to the list of diagnostic criteria for substance addiction (O'Brien 2011). Recent research has also shown that craving is a consistent indicator of alcohol problems cross-culturally, which supports its addition to the DSM criteria set. Cherpitel and colleagues (2010) reported that craving was a mid severity indicator in emergency room samples in four diverse drinking cultures (Poland, Mexico, Argentina, United States). Research on the craving and impairment of control concepts with other behavioral addictions is less advanced.

Table 91.1 Psychological underpinnings

Behavior	Summary points
Impairment of control (IoC)	
Problem gambling (PG)	IoC has been described as a core feature of PG distinguishing between heavy and problematic involvement
	DSM-IV criteria included repeated unsuccessful efforts to control, cut back, or stop gambling
	IoC has been associated with attentional bias to gambling cues, chasing gambling losses, and avoidance style of coping
	Negative affect and alcohol increased IoC within gambling sessions
Sexual behavior (SB)	IoC has been described as a diagnostic feature of excessive SB, although there is little empirical research
	The "dual control" model proposed that "out of control" SB, including masturbation and sexual relationships, results from sexual arousal occurring during periods of negative mood and low inhibition of response
Internet and gaming	IoC is proposed as a core feature to distinguish frequent from problematic involvement
	Studies have identified correlates of impaired control over gaming, including impulsivity, low self-esteem, lower academic performance, and insecure attachment
	No gaming or Internet-specific IoC assessment tool has been described, although a number of related "addiction" scales include individual loss of control items
Shopping	Concepts such as "failure of self-control," "low levels of effortful control," and "failure of self-regulation" appear to capture a phenomenon similar to IoC
Eating	The term "dietary restraint" is frequently used in eating disorders and low restraint suggests lack of control
	IoC in eating has been described as a natural adaptation to food deprivation and low weight
Craving	
Problem gambling (PG)	A number of studies illustrate importance of craving, in particular its predictive validity of relapse and recovery after treatment and persistence after gambling losses
	Imaging studies have used gambling cues to assess the neurocircuitries associated with cravings, generally common with substance addictions
	Self-reported craving may be greater for gambling in pathological gamblers than drinking among alcoholics
	Craving severity has been shown to decrease with use of naltrexone in treatment efficacy studies
	Well-validated self-report scales of craving have been developed
Sexual behavior (SB)	Craving is infrequently investigated, although sexual urges are considered part of the phenomenology of compulsive SB
	A small literature of treatment of sexual addictions include an open-label trial of naltrexone that reduced cravings

(*continued*)

Table 91.1 (continued)

Behavior	Summary points
Internet and gaming	Similar to gambling-related craving, craving has been correlated with both positive and negative affect when individuals were engaged in the activity but only negative affect when prevented from playing
	The neurocircuitry associated with gaming craving is similar to gambling and substance abuse
	An open-label trial of bupropion has reported a decrease in craving
Eating	In behavioral and imaging studies, craving is elicited by exposure to food cues, and degree of reactivity is predictive of binge eating in women
	While the neurocircuitry seems similar to substance abuse craving, whether craving for food is qualitatively similar to craving in other addictions is controversial, as is the conceptualization of compulsive overeating as an addiction
Expectancies	
Problem gambling (PG)	Those with PG are more likely to endorse both positive (enjoyment/arousal, self-enhancement, money) and negative expectancies (over-involvement, emotional impact) relative to non-gamblers, social gamblers, and at-risk gamblers. Both expectancies with respect to gambling outcomes – especially affective types of expectancies – are associated with gambling frequency and gambling-related problems
Sexual behavior (SB)	Whereas one study demonstrated strong associations between expectancies and sexual practices, other studies found weak or no associations. This may be due to the notion that the potential costs and benefits of sexual behavior vary considerably depending on particular individuals and circumstances
Internet and gaming	In one study both positive and negative Internet use expectancies were positively correlated with an addiction measure
	In a second study, the Internet gaming addiction group held greater levels of implicit positive expectancies
Eating	Relatively more rigorous research has been applied to eating disorders. Positive expectancies for eating have differentiated bulimia nervosa from anorexia nervosa patients, normal controls, and psychiatric controls
	Longitudinally, thinness/restricting and eating expectancies predicted the subsequent onset of binge eating and purging behavior among adolescent girls
	Compared to a psychoeducational intervention, a thinness expectancy manipulation intervention produced greater declines in thinness expectancies, body dissatisfaction, and overall eating-disordered attitudes
Motives	
Problem gambling (PG)	At least two gambling motives questionnaires have been developed: a five-factor model (socialization, amusement, avoidance, excitement, and monetary motives) and a three-factor model (enhancement, coping, and social motives). Both have been used to demonstrate associations between gambling motives and gambling frequency and severity
	Researchers have demonstrated that relative to social and enhancement gamblers, coping gamblers scored higher on a variety of different gambling activities and problems and even scored higher on drinking frequency, problems, and coping motives – suggesting consistency of motives across addictive behaviors

(*continued*)

Table 91.1 (continued)

Behavior	Summary points
Sexual behavior (SB)	A four-factor model has been proposed, where sex is used to enhance physical or emotional pleasure (enhancement motives), cope with threats to self-esteem or to minimize negative emotions (coping motives), bond with a socially significant other (intimacy motives), and avoid disapproval by a socially significant other (peer/partner approval motives)
	Intimacy and enhancement motives were strongly associated with positive feelings about sex, more frequent intercourse, and higher levels of satisfaction. Coping and peer/partner approval motives were associated with negative responses to sex, low levels of sexual satisfaction, decreased frequency of sex, and thoughts to lead to riskier, more maladaptive SB
Internet and gaming	One study found that males were more likely than females to score higher on a measure of online gaming addiction and to be endorsed in playing online games to pursue feelings of achievement and make social contacts
	A second study reported that the motives of substitution (a ritualized orientation to fill time, relax, and escape), information seeking, and social interaction were related to Internet use dependency
	Another study highlighted motives related to being lonely and using the Internet to relieve psychosocial problems
Eating	A four-factor model has been applied to eating disorders including coping, social, compliance, and pleasure motives. Each motive was found to be associated with a unique pattern of eating behavior: coping and compliance motives were positively associated with restrictive eating, bingeing, and purging; pleasure motives were positively associated with binge eating, were negatively associated with restrictive eating, and were unrelated to purging; and social motives were negatively associated with restrictive eating and purging but positively associated with bingeing
	Eating-disordered groups have been found to endorse drinking coping motives, suggesting consilience of motives across addictive disorders
Shopping	One consumer marketing study identified seven shopping motives (three functional motives – safety, bargain hunting, convenience – and four hedonic motives: entertainment, freedom, appreciation of modernity, self-identity). Another consumer marketing study identified six hedonic shopping motives (adventure, gratification, role, value, social, idea). The gratification motive resembles the construct of coping motives (shopping for stress relief and mood alteration)
	Other researchers have posited a cognitive-behavioral model of compulsive buying, whereby they allude to more clinically based research suggesting that the primary motivation for compulsive buying is mood alteration
Exercise	Two literatures on excessive exercise have been proposed: one that examines exercise motives in the context of eating-disordered individuals and one that examines exercise motives among nonclinical samples
	Using an exercise motivation questionnaire, researchers found five factors (telic/planning, telic/serious, paratelic, mastery, sympathy), more highly endorsed among regular exercisers versus non-regular exercisers
	Several studies investigated excessive exercise motives among eating-disordered populations with four factors: weight/appearance, fitness/health, mood regulation, and socializing. Eating-disordered patients were more likely to endorse excessively exercising for body weight and shape

(*continued*)

Table 91.1 (continued)

Behavior	Summary points
	reasons as compared to healthy women; and among adult female excessive exercisers receiving inpatient treatment for eating disorders, reduced eating disorder was correlated with a reduction in perceived importance of exercise to regulate negative affect but not with importance of exercise for weight/appearance (these associations were not found in non-excessive exercisers)
Work	One research group has applied self-determination theory to excessive work to derive two primary motives: controlled motivation (working for external and internal rewards and avoiding punishments) versus autonomous motivation (working for personal importance of an activity and interest). Autonomous motivation was positively associated with excessive work, whereas controlled motivation was positively associated with compulsive work
Personality	
Problem gambling (PG)	Across the models researchers have found high levels of impulsivity to be most commonly associated with PG
	Researchers have demonstrated the relevance of low conscientiousness, low openness to experience, low agreeableness, high levels of neuroticism, elevated levels of novelty seeking, both risk-taking and harm avoidance, and lower levels of self-directedness and cooperativeness
	There may be different subtypes of gamblers based on personality characteristics
Sexual behavior (SB)	There is a paucity of research
	Examining the related personality characteristics, one clinical case study utilized Carnes' "Master of the Universe" conceptualization to explain the narcissistic nature of the sexualized addictive personality
	Neuroticism (experiencing and difficulty regulating negative affect) was found to be a predictor of hypersexual behavior
Internet and gaming	Researchers have demonstrated a range of traits as potentially relevant: low self-directedness, lower reward dependence, high novelty seeking, high sensation seeking, high harm avoidance, high neuroticism, high state and trait anxiety, high aggression, low agreeableness, low extraversion, low self-control, low conscientiousness, and narcissistic personality traits
Eating	Few studies examined personality traits related to eating, and those available have focused on binge eating and obesity
	Overweight and obese individuals with binge-eating symptoms scored higher on impulsivity
	Obese persons were more likely to score high in novelty seeking and low in self-directedness
	Women who either binge eat or abuse alcohol exhibited a high degree of impulsivity and endorsed socially deviant attitudes ("externalizers"). Women with both addictive behaviors were not impulsive or socially deviant, but manifested a high degree of emotional instability ("neuroticism"), and might be considered "internalizers"
Shopping	Compulsive buying has been associated with impulsivity, novelty seeking, narcissism, and materialism

(*continued*)

Table 91.1 (continued)

Behavior	Summary points
	"Buying addiction" has been associated with emotional distress (anxiety, depression, and obsessive-compulsiveness), the presence of specific personal qualities (low conscientiousness, low self-esteem, external locus of control, and sensation seeking), and the tendency to escape from or avoid stress produced in daily life
	Impulsive buying is related to extraversion (positive affectivity, sensation seeking); compulsive buying is related to neuroticism (emotional instability, negative affect). Both have been related to lack of self-regulation or effortful control
Work	Associations have been found between workaholism and narcissism, conscientiousness, extraversion, openness to experience, agreeableness, and neuroticism
	Different personality dimensions seem to be related to different aspects of the work construct (work involvement, work drive, and work enjoyment). Work involvement was positively associated with conscientiousness, agreeableness, extraversion, and openness to experience. Work enjoyment has been positively associated with agreeableness, conscientiousness, extraversion, and openness to experience and negatively associated with neuroticism. While conscientiousness and neuroticism were positively related to work drive, agreeableness was negatively associated with work drive, and openness to experience had contradictory associations with work drive
	Somewhat contradictory personality characteristics lend support for subtypes of "workaholics." "Enthusiastic workaholics" are highly involved with work, driven by internal pressure to work, and find great pleasure in doing so. "Non-enthusiastic workaholics" are also highly involved and driven to work-related activities but seem not to derive enjoyment from it
Exercise	Excessive exercise has been associated with high harm avoidance, high persistence, high extraversion, high neuroticism, low self-directness, less mature character, and low agreeableness
	Individuals with high neuroticism could be using exercise as a coping strategy for their stress or be using exercise to address excessive worry or concern over their appearance/health. Upbeat, energetic (extraverted) individuals may be drawn to exercise, and individuals who are low in agreeableness tend to be egocentric and competitive
Multiple areas	Few researchers have examined personality traits common to or differentiating between multiple addictive behaviors
	In comparing bulimia nervosa and PG, researchers have found high novelty seeking to be specifically associated with a diagnosis of problem gambling and low self-directedness to be associated with both bulimia nervosa and PG. Women with both bulimia nervosa and PG displayed higher harm avoidance and cooperativeness than control women, whereas men with problem gambling reported higher reward dependence and persistence than control men, highlighting potential differences between sexes
	Two studies examined compulsive buying and eating disorders. Reward sensitivity and cognitive anxiety have been positively related to excessive eating and compulsive buying. Impulsivity was positively related to compulsive buying, whereas somatic anxiety and social desirability were negatively related

(*continued*)

Table 91.1 (continued)

Behavior	Summary points
	Compulsive buying could be more impulsivity driven, whereas eating disorder symptoms (especially drive for thinness) might be more anxiety related
	In a study examining personality factors related to substance use, gambling, and computer gaming, high impulsivity was the only personality characteristic associated with all addictive behaviors

91.2.1.1 Impairment of Control

In terms of behavioral addictions, the impaired control concept from the substance addiction area has been mostly adopted in the gambling addiction realm. Blaszczynski and Nower (2002), for example, described impaired control as a necessary and core feature of gambling disorders that distinguishes heavy gambling involvement from problematic involvement. The concept is also captured in one of the DSM-IV diagnostic criteria for pathological gambling: repeated unsuccessful efforts to control, cut back, or stop gambling (American Psychiatric Association 2000). At the same time, concerns about the conceptualization of impairment of control in the gambling field, as in the substance abuse field, have been raised with the recommendation that the concept needs to be more clearly operationalized (Cantinotti et al. 2009).

Much of the early descriptive work on impairment of control was conducted by Dickerson and colleagues in Australia, examining electronic gambling machines and other forms of gambling (Dickerson and O'Connor 2006). This research demonstrated that impairment of control seems similar across different types of gambling (O'Connor and Dickerson 2003) and was associated with attentional bias to gambling cues (Boyer and Dickerson 2003), chasing gambling losses (O'Connor and Dickerson 2003), and avoidance style coping with problems (Shepherd and Dickerson 2001). Both negative affect, such as depression and frustration (Dickerson 1993), and alcohol (Baron and Dickerson 1999) increased impairment of control within gambling sessions. Dickerson and colleagues also developed the only gambling-specific measure of impaired control (Corless and Dickerson 2006; O'Connor and Dickerson 2003).

In the sexual behavior area, scholars who use an addiction conceptualization describe impairment of control as a diagnostic feature (e.g., Goodman 2001; Mick and Hollander 2006; Orford 1978), although little empirical research has been reported (Garcia and Thibaut 2010). A "dual control" model proposes that sexual arousal depends upon a balance between arousal and inhibition of sexual response. The model proposes that "out of control" sexual behavior, including masturbation and sexual relationships, results from sexual arousal occurring during periods of negative mood and low inhibition of response (Bancroft 2008). An assessment tool based upon this model has been developed with the hope of promoting empirical investigation (Bancroft et al. 2009).

Impairment of control is also proposed as an essential feature of gaming and Internet addiction to distinguish frequent from problematic involvement

(Charlton and Danforth 2007; Griffiths 2000; Meerkerk et al. 2010; Wood and Griffiths 2007). A qualitative study of online gamers in treatment found that participants described losing control as an important marker of the development of their problem (Beranuy et al. 2013). A number of studies have identified correlates of impaired control over gaming, including impulsivity (Meerkerk et al. 2010) and low self-esteem (Armstrong et al. 2000). Impaired control defined as "refusal self-efficacy" (i.e., lack of confidence in one's ability to refuse involvement) was linked to impulsivity, lower academic performance, insecure attachment, and male gender in Taiwanese college students (Lin et al. 2011). No gaming or Internet-specific impairment of control assessment tool has been described, although a number of Internet and gaming "addiction" scales include individual loss of control items (e.g., Yen et al. 2009; Young 1998).

Although the impairment of control construct is not used in the compulsive shopping and buying literature, concepts such as "failure of self-control" (Baumeister 2002), "low levels of effortful control" (Claes et al. 2010), and "failure of self-regulation" (Peters and Bodkin 2007) appear to capture a similar phenomenon. Similarly, the term "dietary restraint" is frequently used in the eating disorder literature and low restraint suggests lack of control. Impaired control in eating has been described as a natural adaptation to food deprivation and low weight. The difference of this concept from drugs and alcohol is that the desire to eat is biologically adaptive and successful recovery requires a reduction of dietary restraint (Wardle 2011).

91.2.1.2 Craving

The craving construct has also been utilized in conjunction with a number of behavioral addictions. In the area of gambling, a recent review of research on assessment of craving uncovered a number of studies that illustrate the importance of craving as an element of gambling disorders (Ashrafioun and Rosenberg 2012), in particular its predictive validity of relapse and recovery after treatment (Cantinotti et al. 2007; Hodgins and el-Guebaly 2004; Ladouceur et al. 2007; Smith et al. 2010) and persistence after gambling losses (Young and Wohl 2009). A number of imaging studies have used gambling cues to assess the neurocircuitries associated with cravings in gambling disorders (e.g., Crockford et al. 2005; Goudriaan et al. 2010; van Holst et al. 2010), and results generally show commonalities with substance abuse addictions (Mudry et al. 2011). Two studies directly compared self-reports of craving from alcoholics and pathological gamblers and found that the intensity of craving was greater for gambling (de Castro et al. 2007; Tavares et al. 2005). Craving has been shown to be associated with psychosocial stress (Elman et al. 2010) and gambling advertising (Binde 2009), but, unexpectedly, not with attentional bias to gambling cues (Brevers et al. 2011). Craving severity has also been shown to decrease with use of naltrexone in treatment efficacy studies (e.g., Kim et al. 2001; Walther et al. 2012).

In their review, Ashrafioun and Rosenberg (2012) identified a number of well-validated self-report scales of craving in gambling, as well as indirect measures

such as physiological reactivity that had been used in substance abuse craving research. Beyond the gambling area, specific measures of craving have not been developed for other behavioral addictions, although some research exists.

The literature on craving in Internet and video gaming is smaller than gambling but seems to be developing along similar lines. A qualitative study of online gaming addicts receiving treatment found that craving is an indicator of problem development (Beranuy et al. 2013). A recent study of 160 gamers involved in massive multiplayer online role-playing games concluded that gaming shows the same emotional pattern as gambling-related craving. Craving correlated with both positive and negative affect when individuals were engaged in the activity but only negative affect when prevented from playing (Stoeber et al. 2011). From a neurobiological perspective, imaging studies have suggested that the neurocircuitry associated with gaming craving is similar to gambling and substance abuse (Han et al. 2010b; Ko et al. 2009, 2011). An open-label trial has demonstrated a decrease in craving associated with administration of bupropion, an antidepressant used for smoking and other addictions (Han et al. 2010a).

The concept of craving has been infrequently investigated in the area of sexual behavior although sexual urges are considered part of the phenomenology of compulsive sexual behavior (e.g., Coleman 1992; Goodman 2001). Fong (2006) reviewed a small literature of treatment of sexual addictions, including an open-label trial of naltrexone that reduced cravings (Ryback 2004). In the eating literature, the effect of food cues has been investigated in a number of behavioral and imaging studies. For example, it has been shown that craving is elicited by exposure to food cues, and degree of reactivity is predictive of binge eating in women, although perhaps not men (Sobik et al. 2005). Similarly, in imaging studies in other behavioral addictions, the neurocircuitry involved seems similar to substance abuse craving (Pelchat et al. 2004). However, whether craving for food is qualitatively similar to craving in other addictions is controversial, as is the conceptualization of compulsive overeating as an addiction more broadly (Davis and Carter 2009; Liu et al. 2010; Wardle 2011; Wilson 1991, 2010).

91.2.2 Expectancies and Motives

Expectancies and motives are two closely linked, albeit distinct social-cognitive constructs. They were first heavily researched in the alcohol literature as determinants of alcohol use and problematic drinking and have since been applied to other substances and addictive behaviors. Whereas expectancies refer to an individual's belief regarding the effects or outcome of a particular substance or addictive behavior, motives refer to an individual's reasons for using a particular substance or engaging in a particular addictive behavior (Cooper 1994; Goldman et al. 2006).

Cox and Klinger (1988) first articulated the relationship between expectancies and motives in their motivation model for alcohol use. According to their model, drinking behavior is embedded in historical (e.g., genetic disposition), personality (e.g., extraversion, sensation seeking), sociocultural (e.g., drinking styles),

environmental (e.g., alcohol availability), and situational (e.g., reinforcement from recent drinking) factors, as well as alcohol expectancies and drinking motives (Kuntsche et al. 2007). Motives are thought to be more proximal than expectancies and are regarded as the gateway through which more distal influences, such as expectancies, are mediated (Cooper et al. 1995; Kuntsche et al. 2007). In the alcohol literature, environmental influences (both familial and individual-specific) have been found to shape expectancies, while heritable influences have been suggested to predispose motives (Agrawal et al. 2008). As might be expected, the relationship between expectancies and motives has received less empirical attention in the area of behavioral addictions.

91.2.2.1 Expectancies

There is a rich literature providing empirical evidence for the explanatory role of alcohol expectancies in the variation of drinking patterns, whereby among both adolescents and adults, alcohol expectancies have been found to have moderate to strong associations with drinking (Goldman et al. 2006). Typically, positive expectancies (e.g., beliefs that positive feelings will be enhanced and negative feelings will be reduced) have been found to be related to initiation and early consumption of alcohol use, whereas negative expectancies (e.g., beliefs that negative consequences will occur) have been found to be related to reduction and cessation of alcohol use (Jones et al. 2001).

While research into the etiology and maintenance of behavioral addictions is relatively new compared to substance-related addictions, the concept of expectancy has been applied to gambling (e.g., Gillespie et al. 2007; Shead et al. 2008; Walters and Contri 1998; Wickwire et al. 2010), sexual behavior (e.g., Gilbert et al. 1986; Katz et al. 2000; Lavery et al. 1993), Internet and gaming addiction (e.g., Lin et al. 2008; Yen et al. 2011), and eating disorders (e.g., Annus et al. 2008; Hohlstein et al. 1998; Smith et al. 2007). To our knowledge, not a single study has investigated expectancies in the context of shopping, exercise, or work, which clearly points to the need for future research in these areas.

In the area of gambling, Gillespie and colleagues (2007) have developed a Gambling Expectancy Questionnaire (GEQ) that taps five distinct outcome expectancy constructs: three related to positive expectancies (enjoyment/arousal, self-enhancement, and money) and two related to negative expectancies (over-involvement and emotional impact). Using the GEQ, the authors found that probable pathological gamblers were more likely to endorse both positive and negative expectancies relative to non-gamblers, social gamblers, and at-risk gamblers. Similar findings have been reported demonstrating that positive and negative expectancies with respect to gambling outcomes – especially affective types of expectancies – are associated with gambling frequency and gambling-related problems (e.g., Shead et al. 2008; Walters and Contri 1998; Wickwire et al. 2010).

The small expectancy literature in the area of sexual behavior has been equivocal. Whereas one study demonstrated strong associations between expectancies and sexual practices (Gilbert et al. 1986), other studies have found weak or no associations (Katz et al. 2000; Lavery et al. 1993). Katz and colleagues speculate

that one reason for the weak or no associations observed might be due to the notion that the potential costs and benefits of sexual behavior vary considerably depending on particular individuals and circumstances (e.g., the potential consequences associated with having unprotected sex with a monogamous partner differ from those associated with having unprotected sex with a stranger).

Two studies based in Taiwan have examined the expectancy construct with respect to Internet and gaming addiction. In the first study, both positive and negative Internet use expectancies were significantly and positively correlated with an Internet addiction measure among college students (Lin et al. 2008). In the second study, young adults with Internet gaming addiction reacted faster in an implicit association task to congruent pairing of Internet gaming screenshots and liked words compared to control participants, thereby suggesting that the Internet gaming addiction group held greater levels of implicit positive expectancies for Internet gaming (termed by the authors as positive motivational implicit responses) (Yen et al. 2011).

Compared to other behavioral addictions, relatively more rigorous research with respect to expectancies has been applied to eating disorders. For example, positive expectancies for eating have been found to differentiate bulimia nervosa patients from anorexia nervosa patients, normal controls, and psychiatric controls (Hohlstein et al. 1998). Longitudinally, thinness/restricting and eating expectancies have been found to predict the subsequent onset of binge eating and purging behavior among adolescent girls (Smith et al. 2007). Moreover, compared to a psychoeducational intervention, a thinness expectancy manipulation intervention has been found to produce greater declines in thinness expectancies, body dissatisfaction, and overall eating-disordered attitudes, thereby providing further support for the role of expectancies in the etiology of eating-disordered behaviors (Annus et al. 2008).

91.2.2.2 Motives

Motives have been described as more proximal and diagnostic than expectancies (Cooper 1994). Following Cox and Klinger's (1988) motivational model, Cooper (1994) first proposed a framework of motives, whereby motives are characterized by valence (positive vs. negative) and source (internally generated vs. externally generated). The result of this framework produced a four-factor model of drinking motives: drinking to obtain social rewards (social motives), drinking to enhance positive affect (enhancement motives), drinking to cope with negative affect (coping motives), and drinking to avoid social rejection (conformity motives). Originally, Cooper and colleagues demonstrated differential associations between drinking motives and alcohol use behavior; for example, social and enhancement motives were found to be related to heavy drinking and to drinking in situations where heavy drinking is tolerated (such as at parties), whereas coping motives were found to be related to drinking in isolation (such as at bars) (Cooper 1994; Cooper et al. 1995). As with expectancies, a wealth of empirical research has since demonstrated that drinking motives are associated with and can predict alcohol use behavior, whereby in general, social motives appear to be associated with

moderate alcohol use, enhancement motives with heavy drinking, and coping motives with alcohol-related problems (Kuntsche et al. 2005; Schelleman-Offermans et al. 2011).

With respect to behavioral addictions, motives have been investigated in the context of gambling (e.g., Lee et al. 2007; Stewart and Zack 2008; Stewart et al. 2008), sexual behavior (e.g., Cooper et al. 1998, 2011), Internet and gaming addiction (e.g., Junghyun et al. 2009; Ko et al. 2005; Sun et al. 2008), eating disorders (e.g., Jackson et al. 2003; Luce et al. 2007), shopping (e.g., Arnold and Reynolds 2003; Farrag et al. 2010; Kellet and Bolton 2009), exercise (e.g., Bratland-Sanda et al. 2010; Cash et al. 1994; Keele 2009; Mond and Calogero 2009), and work (e.g., Van den Broeck et al. 2011).

Derived from Cooper's (1994) alcohol motives model, at least two gambling motives questionnaires have been developed: one is a five-factor model (socialization, amusement, avoidance, excitement, and monetary motives) (Lee et al. 2007) and the other is a three-factor model (enhancement, coping, and social motives) (Stewart and Zack 2008). Both questionnaires have been used to demonstrate associations between gambling motives and gambling frequency and severity. Moreover, Stewart and colleagues (2008) used their gambling motives questionnaire to demonstrate that relative to social and enhancement gamblers, coping gamblers scored higher on a variety of different gambling activities and gambling problems and even scored higher on drinking frequency, drinking problems, and drinking coping motives, thereby supporting an empirical approach to subtyping gamblers based on motives and suggesting consistency of motives across addictive behaviors.

Shortly after Cooper (1994) developed her alcohol motives model, the framework was applied to the area of sexual behavior in the form of a four-factor model: having sex to enhance physical or emotional pleasure (enhancement motives), having sex to cope with threats to self-esteem or to minimize negative emotions (coping motives), having sex to bond with a socially significant other (intimacy motives), and having sex to avoid disapproval by a socially significant other (peer/partner approval motives) (Cooper et al. 1998). This model has been used to demonstrate that both intimacy and enhancement motives were strongly associated with positive feelings about sex, more frequent intercourse, and higher levels of satisfaction. Coping and peer/partner approval motives were associated with negative responses to sex, low levels of sexual satisfaction, and decreased frequency of sex and are thought to lead to riskier and more maladaptive sexual behavior (Cooper et al. 2011).

Although not explicitly derived from Cooper's (1994) alcohol motives model, the concept of motives has been investigated in the area of Internet and gaming addiction. For example, one study found that among Taiwanese adolescents, males were more likely than females to score higher on a measure of online gaming addiction and were more likely to endorse playing online games for reasons to pursue feelings of achievement and make social contacts (Ko et al. 2005). Another study reported that among American adults, the motives of substitution (a ritualized orientation to fill time, relax, and escape), information seeking, and social

interaction were related to a measure of Internet use dependency (Sun et al. 2008). Consistent with the construct of coping motives, yet another study reported that among American undergraduate students, motives related to being lonely and using the Internet to relieve psychosocial problems were associated with measures of compulsive Internet use and negative outcomes (Junghyun et al. 2009).

Cooper's (1994) alcohol motives model has been specifically applied to eating disorders, whereby a four-factor model yielding the following motives has been developed and validated: coping, social, compliance, and pleasure motives (Jackson et al. 2003). Each motive was found to be associated with a unique pattern of eating behavior, such that coping and compliance motives were positively associated with restrictive eating, bingeing, and purging; pleasure motives were positively associated with binge eating, were negatively associated with restrictive eating, and were unrelated to purging; and social motives were negatively associated with restrictive eating and purging but were positively associated with bingeing. As in the gambling motives literature, the relationship between eating disorders and drinking motives has also been investigated, whereby eating-disordered groups have been found to endorse drinking coping motives (Luce et al. 2007), suggesting consilience of motives across addictive disorders.

While Cooper's (1994) alcohol motives model has not yet been explicitly applied to the area of shopping, motives for shopping have been investigated in a rather piecemeal fashion in two related but distinct literatures: clinical research that examines shopping addiction versus consumer marketing research. For example, one consumer marketing study using an Egyptian sample identified seven main shopping motives (three functional motives, safety, bargain hunting, and convenience; and four hedonic motives, entertainment, freedom, appreciation of modernity, and self-identity) (Farrag et al. 2010), whereas another consumer marketing study identified six hedonic shopping motives (adventure, gratification, role, value, social, idea) (Arnold and Reynolds 2003). While these two studies did not attempt to link motives with shopping-related problems or addiction, it is noteworthy that the gratification motive in Arnold and Reynolds' (2003) study resembles the construct of coping motives, as it describes shopping for reasons of stress relief and to alleviate negative mood. Indeed, Kellet and Bolton (2009) have posited a cognitive-behavioral model of compulsive buying, whereby they allude to more clinically based research suggesting that the primary motivation for compulsive buying is mood alteration.

As with the shopping motives literature, a perusal of the exercise motives literature also reveals a schism between two literatures: one that examines exercise motives in the context of eating-disordered individuals and one that examines exercise motives among nonclinical samples. For example, Keele (2009) developed an exercise motivation questionnaire with Mexican American adults in the general population and discovered five factors (telic/planning, telic/serious, paratelic, mastery, sympathy), all of which were more highly endorsed among regular exercisers versus non-regular exercisers. In contrast, several studies have investigated excessive exercise motives among eating-disordered populations and have employed a modified Reasons for Exercise Inventory (Cash et al. 1994) with four factors that are reminiscent of Cooper's (1994) model: weight/appearance, fitness/health, mood

regulation, and socializing. For example, Mond and Calogero (2009) found that eating-disordered patients were more likely to endorse excessively exercising for body weight and shape reasons as compared to healthy women; and Bratland-Sanda et al. (2010) found that among adult female excessive exercisers receiving inpatient treatment for eating disorders, reduced eating disorder psychopathology was correlated with a reduction in perceived importance of exercise to regulate negative affect, but not with importance of exercise for weight/appearance (these associations were not found in non-excessive exercisers).

Finally, to our knowledge, only one research group has investigated motives in the context of excessive or compulsive work (see Van den Broeck et al. 2011). This line of research has applied self-determination theory (Deci and Ryan 2000) to derive two primary motives: controlled motivation (working for external and internal rewards and avoiding punishments) versus autonomous motivation (working for personal importance of an activity and interest). In one of their studies, the researchers found that autonomous motivation was positively associated with excessive work, whereas controlled motivation was positively associated with compulsive work (Van den Broeck et al. 2011).

91.2.3 Personality

The notion of an "addictive personality" suggests that a particular personality profile may yield a greater propensity for an individual to develop an addiction. While early researchers have not found definitive evidence of an "addictive personality," scholars continue to attend to and measure the influence of personality traits on addictive behaviors. Personality is conceptualized and measured differently by researchers, and several attempts have been made to identify sets of traits that may encompass the full variety of human emotion, cognition, and behavior. The various models list factors necessary to explain individual variation, all of which may be accurate, though incongruent with one another, emphasizing aspects of personality. Personality trait theories have been popular among addiction researchers to explain and understand addictive behaviors.

Two common models used in addiction research are Cloninger's psychobiological personality model and the Five-Factor Model of Personality, also known as the "Big Five." Cloninger's psychobiological personality model (Cloninger 1987) and measure (the Temperament and Character Inventory, TCI) consists of four temperament dimensions (novelty seeking, harm avoidance, reward dependence, and persistence) and three acquired character dimensions (self-directedness, cooperativeness, and self-transcendence) (Cloninger et al. 1994). The Five-Factor Model of Personality identifies the following five factors as composing personality: extraversion, agreeableness, conscientiousness, emotional stability (vs. neuroticism), and openness to experience (Goldberg 1990). In general, there is a lack of robustness in findings relating to addictive behaviors and personality variables, as researchers often use different measures, variables, and small samples and yield findings that are sometimes inconsistent and even contradictory.

Research examining personality factors across behaviors remains sparse; however, research examining personality factors involved in specific behaviors is more common. Not surprisingly, gambling has had the longest history of study and has paved the way for such research. Across the various personality trait models, researchers have found high levels of impulsivity to be most common in those who gamble excessively (Benson et al. 2012; Chiu and Storm 2010; Forbush et al. 2008; Grall-Bronnec et al. 2012; Hwang et al. 2012; MacLaren et al. 2011; Myrseth et al. 2009; Reid et al. 2011; Tavares and Gentil 2007). Using the TCI, researchers have demonstrated that gamblers have elevated levels of novelty seeking and harm avoidance (Forbush et al. 2008; Nordin and Nylander 2007) and lower levels of self-directedness (Forbush et al. 2008; Janiri et al. 2007; Nordin and Nylander 2007) and cooperativeness (Forbush et al. 2008; Janiri et al. 2007). Using the five-factor model, researchers have demonstrated the relevance of low conscientiousness (Hwang et al. 2012; MacLaren et al. 2011), openness to experience (Hwang et al. 2012; Myrseth et al. 2009), and agreeableness (MacLaren et al. 2011) and high levels of neuroticism (MacLaren et al. 2011; Myrseth et al. 2009; Reid et al. 2011) or negative emotionality (King et al. 2010).

In a large-scale population-based American longitudinal study, Slutske and colleagues (2005) found problem gambling at age 21 years to be associated with higher levels of negative emotionality and with lower levels of constraint measured at age 18 years compared with control subjects. Problem gambling was also associated with risk-taking and impulsivity. These young adults were characterized by negative emotions such as nervousness or worry, anger, or aggressiveness; feeling mistreated or victimized; and unconstrained behaviors of risk-taking, impulsivity, and rebelliousness.

It may be the case that there are different subtypes of gamblers based on personality characteristics, which provides support for heterogeneity of problem gamblers. Alvarez-Moya and colleagues (2010) found four clusters of problem gamblers in Spain. Type I (disorganized and emotionally unstable) gamblers had schizotypic traits, high impulsiveness, substance and alcohol abuse, and early age of onset, as well as psychopathological disturbances (most severe gambling behavior). Type II (schizoid) gamblers showed high harm avoidance, social aloofness, and alcohol abuse. Type III (reward-sensitive) gamblers showed high sensation seeking and impulsiveness but no psychopathological impairments. Type IV (high functioning) showed a globally adaptive personality profile, low level of substance and alcohol abuse or smoking, and no psychopathological disturbances. Two of the types showed no impulsiveness or sensation seeking and one of them even exhibited good general functioning.

Similarly, in Canada, Vachon and Bagby (2009) found three clusters of gamblers: a simple subtype (with an absence of comorbidities); a "hedonic" subtype who were characterized by a strong attraction to excitement and pleasure (excitement seeking, positive emotions), as well as a tendency to be excitable and careless; and a "demoralized" subtype who were characterized by extreme negative affect (high neuroticism), impulsivity, low self-discipline, distrust, and poor motivation. This empirically based typology of gamblers is consistent with, and provides support for, Blaszczynski and Nower's (2002) "pathways model" of problem gambling.

There is a paucity of research examining the personality characteristics of individuals engaging in excessive sexual behavior. One clinical case study (Nixon and Theriault 2012) utilized Patrick Carnes' (1991) "Master of the Universe" conceptualization to explain the narcissistic nature of the sexualized addictive personality. In a larger American study, Reid and colleagues (2008) found neuroticism to be a strong predictor of hypersexual behavior; individuals who manifested symptoms of hypersexual behavior were more likely to experience negative affect (including alexithymia, depression, and vulnerability to stress) and deficits in regulating this affect.

Next to gambling, excessive engagement in online gaming or time on the Internet has been studied most. Although there is generally a lack of robustness in findings relating personality variables to Internet usage, researchers have demonstrated that certain personality traits may potentially play a role in excessive Internet use and gaming. Low self-directedness appears to be a predictor of problematic Internet use (Montag et al. 2011, 2010) and has been found to be a better predictor than neuroticism (Montag et al. 2010). Those engaging in excessive Internet use tend to score lower on reward dependence and higher on novelty seeking and harm avoidance than control subjects (Ko et al. 2006, 2010). Using the five-factor model, excessive Internet use has been positively correlated with high neuroticism (Charlton and Danforth 2010; Mehroof and Griffiths 2010; Peters and Malesky 2008; Tsai et al. 2009) and negatively correlated with agreeableness, extraversion, and conscientiousness (Peters and Malesky 2008).

Researchers have begun examining online gaming separate from and potentially different from excessive Internet use (no studies to date have compared the two in the domain of personality). Mehroof and Griffiths (2010) found five traits with significant associations with online gaming addiction among university students in the UK: neuroticism, sensation seeking, trait anxiety, state anxiety, and aggression. The strongest predictors were state anxiety and sensation seeking. Self-control had the least impact on online gaming addiction. While the findings regarding neuroticism, trait and state anxiety, and sensation seeking appear to fit in line with excessive Internet use, examining aggression is new to the literature. In South Korea, researchers have also found aggression and narcissistic personality traits to be positively correlated with online gaming addiction, with self-control negatively correlated (Kim et al. 2008).

Few studies have examined personality traits related eating or food addiction, and those available have focused on binge eating and obesity. Barry et al. (2009) found that overweight and obese individuals with binge-eating symptoms had high scores on a personality measure of impulsivity. Using the TCI, Sullivan and colleagues (2007) found that obese persons were more likely than normal weight individuals to have high novelty seeking scores and lower self-directedness scores. Comparing binge eating and alcohol abuse, Benjamin and Wulfert (2005) found women who either binge eat or abuse alcohol exhibited a high degree of impulsivity and endorsed socially deviant attitudes ("externalizers"). Women with both addictive behaviors were not particularly impulsive or socially deviant, but manifested a high degree of emotional instability ("neuroticism"), and might be considered "internalizers."

Just as Internet and online gaming have similarities and differences to gambling, so too does compulsive shopping or buying. Impulsivity (Black et al. 2012; Lejoyeux et al. 1997) and novelty seeking (Black et al. 2012) may be important in compulsive buying similar to other behaviors, as well as narcissism and materialism (Rose 2007). In a large Spanish study examining "buying addiction," Rodriguez-Villarino and colleagues (2006) found evidence for a connection between addictive buying and symptoms of emotional distress (anxiety, depression, and obsessive-compulsiveness), the presence of specific personal qualities (low conscientiousness, low self-esteem, external locus of control, and sensation seeking), and the tendency to escape from or avoid stress produced in daily life.

The tendency to use shopping as a means to escape stress or negative feelings may be a component of compulsive buying or a characteristic of a particular type of compulsive buying. In a small clinical sample in Germany, researchers found two distinct personality clusters (Mueller et al. 2010). The first cluster showed average scores on all the Big Five personality traits, whereas the participants in cluster II scored significantly higher on neuroticism and lower on the other four personality traits (negative scores on extraversion, openness, agreeableness, and conscientiousness). Subjects in cluster II showed higher severity of compulsive buying and a lower degree of control over compulsive buying symptoms and were more anxious, interpersonally sensitive, and impulsive.

Claes and Mueller (2011) found evidence to distinguish between impulsive and compulsive buying, based on personality traits of a nonclinical student sample. They argued that impulsive buying is related to extraversion (positive affectivity, sensation seeking), whereas compulsive buying is related to neuroticism (emotional instability, negative affect), with both impulsive buying and compulsive buying related to lack of conscientiousness (lack of self-regulation or effortful control).

Excessive engagement in work or "workaholism" is usually composed of three factors (work involvement, work drive, and work enjoyment) (Spence and Robbins 1992). Associations have been found between components of workaholism and narcissism (Andreassen et al. 2012; Clark et al. 2010), conscientiousness (Andreassen et al. 2010; Aziz and Tronzo 2011), extraversion (Andreassen et al. 2010; Burke et al. 2006), openness to experience (Andreassen et al. 2010; Aziz and Tronzo 2011; Burke et al. 2006), agreeableness (Andreassen et al. 2010; Aziz and Tronzo 2011), and neuroticism (Andreassen et al. 2010; Burke et al. 2006).

Different personality dimensions seem to be related to different aspects of the work construct. For example, conscientiousness (Aziz and Tronzo 2011), agreeableness (Aziz and Tronzo 2011; Andreassen et al. 2010), extraversion (Andreassen et al. 2010; Burke et al. 2006), and openness to experience (Andreassen et al. 2010) have been found to be positively associated with work involvement. Work enjoyment has been positively associated with agreeableness (Aziz and Tronzo 2011), conscientiousness (Aziz and Tronzo 2011), extraversion (Andreassen et al. 2010; Burke et al. 2006), and openness to experience (Andreassen et al. 2010; Aziz and Tronzo 2011) and negatively associated with neuroticism (Andreassen et al. 2010; Aziz and Tronzo 2011). While conscientiousness (Andreassen et al. 2010; Burke et al. 2006;

Aziz and Tronzo 2011) and neuroticism (Andreassen et al. 2010; Burke et al. 2006) were positively related to work drive, agreeableness was negatively associated with work drive (Andreassen et al. 2010), and openness to experience had contradictory associations with work drive (Burke et al. 2006; Aziz and Tronzo 2011).

The somewhat contradictory personality characteristics associated with the different facets of work addiction lend support to the notion subtypes of "workaholics." In this model, "enthusiastic workaholics" are highly involved with work, driven by internal pressure to work, and find great pleasure in doing so. Whereas "non-enthusiastic workaholics" are also highly involved in work-related activities and driven to work but seem not to derive enjoyment from doing so (Alvarez-Moya et al. 2007).

In the small domain of excessive exercise, researchers have found higher levels of harm avoidance and persistence and lower self-directness and less mature character among those who exercise excessively (Grandi et al. 2011). Among American university students, Hausenblas and Giacobbi (2004) found extraversion, neuroticism, and low agreeableness to predict exercise dependence symptoms. They reasoned that individuals with high neuroticism could be using exercise as a coping strategy for their stress or using exercise to address excessive worry or concern over their appearance/health. They also suggest that upbeat, energetic (extraverted) individuals may be drawn to exercise, and individuals who are low in agreeableness tend to be egocentric, skeptical of others' intentions, and competitive, with excessive exercising satisfying a competitive nature.

Few researchers have examined personality traits common to or differentiating between multiple addictive behaviors. In a Spanish study, researchers compared binge-eating disorders and pathological gambling with controls (Claes et al. 2012). They found that both eating-disordered individuals and pathological gamblers showed significantly higher scores on harm avoidance and lower self-directedness compared with control subjects. In addition, compared to control subjects, gamblers were characterized more by novelty seeking and persistence. Also in Spain, Alvarez-Moya and colleagues (2007) examined the personality risk factors in bulimia nervosa and pathological gambling and found high novelty seeking to be specifically associated with a diagnosis of problem gambling and low self-directedness to be associated with both bulimia nervosa and gambling. In addition, women with both bulimia nervosa and pathological gambling displayed higher harm avoidance and cooperativeness than control women, whereas men with problem gambling reported higher reward dependence and persistence than control men, highlighting potential differences between sexes.

Two studies examined compulsive buying and eating disorders. Davenport et al. (2012) found reward sensitivity and cognitive anxiety to be positively related to excessive eating and compulsive buying. Impulsivity was positively related to compulsive buying, whereas somatic anxiety and social desirability were negatively related. Claes and colleagues (2011) found compulsive buying among Belgian and German individuals to be positively related to BAS reactivity (fun seeking, reward responsiveness, impulsivity) and low effortful control,

whereas eating disorder symptoms were found to be related to high BIS reactivity (especially drive for thinness) and low effortful control. They concluded that compulsive buying is more impulsivity driven, whereas eating disorder symptoms (especially drive for thinness) are more anxiety related.

Finally, Walther et al. (2012) conducted a large German study examining personality factors related to substance use, gambling, and computer gaming. High impulsivity was the only personality characteristic associated with all addictive behaviors. Depression and extraversion were specific to substance users. Four personality characteristics were specifically associated with problematic computer gaming: irritability/aggression, social anxiety, attention deficit hyperactivity disorder (ADHD), and low self-esteem. Problematic computer gamers and gamblers did not match in any personality characteristics apart from high impulsivity. The authors argued that problematic gamblers seem to be more similar to substance users than problematic computer gamers.

91.2.4 Summary and Integration

A syndrome model of addiction (Shaffer et al. 2004) espouses multiple interacting biological, psychological, and experiential elements acting to initiate and sustain the syndrome. The psychological factors (i.e., impairment of control, craving, motives and expectancies, and personality) that we have discussed in this chapter comprise the shared components of the syndrome model. These psychological factors influence the expression of and fuel the maintenance of the addiction.

For example, experience of cravings and urges involve emotional experiences (e.g., desire, irritability, anxiety), cognitive effects (e.g., intrusive thoughts), physiological experiences (e.g., heart rate, respiration, salivation), and overt behaviors (e.g., seeking alcohol) (Rosenberg 2009). These response domains may be influenced by particular personality characteristics, and particular personality characteristics may influence how an individual responds to urges and cravings. Similarly, propensities towards particular motives may be associated with particular personality profiles. One's motive for engaging in behavior and expectancy of the outcome will determine whether or not the individual decides to engage in the behavior. He or she may engage in online gaming from a social motive, because of a tendency towards introversion and wanting to connect with others. Similarly, an individual may engage in behavior to cope (coping motive) with negative affect, which may be associated with a tendency towards neuroticism.

Neuroticism and impulsivity seem to be particularly relevant in addictive behaviors. The tendency to excessively engage in behavior as a form of escapism appears to be important and is in line with the notion that control over an impulse is often sacrificed in times of emotional distress (Tice et al. 2001). When individuals feel unpleasant emotions, they generally seek symptom relief, a desire perceived to be urgent, which undermines impulse control. This pattern and coping motive has been found in excessive behaviors such as problem gambling (Reid et al. 2011).

The excessive use of behaviors as a form of escapism or as a means to modulate affect might be indicative of a particular subtype of addictive behavior (Alvarez-Moya et al. 2010; Mueller et al. 2010; Vachon and Bagby 2009). Different personality characteristics may provide different motives for engaging in the same behavior. For example, an individual high on neuroticism may engage in gambling as a means to regulate emotional distress, whereas another individual (high in extroversion, sensation seeking, and novelty seeking) may gamble for thrill-seeking purposes (Vachon and Bagby 2009).

In addition to motives or precursors to engaging in a particular behavior, an individual's personality traits may lead to an individual's preference of one type of excessive behavior over another. For example, individuals high on extraversion may be more likely to engage in excessive work (Andreassen et al. 2010; Burke et al. 2006) or exercise (Hausenblas and Giacobbi 2004), whereas individuals low in extraversion may be more likely to excessively engage in online gaming (Charlton and Danforth 2010; Peters and Malesky 2008).

A syndrome model of addiction can be used to explain inconsistencies across behaviors. For example, personality characteristics (i.e., agreeableness and conscientiousness) not typical of some behavioral addictions (i.e., gambling) have been found to be associated with others, for example, facets of work addiction (Andreassen et al. 2010; Aziz and Tronzo 2011). Acknowledging the importance of motives and expectancies may help explain the personality profiles of individuals who engage in work excessively. Van den Broeck and colleagues (2011) divided controlled motivation for work engagement (working for external and internal rewards and avoiding punishments) from autonomous motivation (working for personal importance of an activity and interest). This division seems to fit with Andreassen and colleagues' notion of the "enthusiastic workaholic," who is highly involved with work, driven by internal pressure to work, and finds great pleasure in doing so, and the "non-enthusiastic workaholic," who does not to derive enjoyment from work (Andreassen et al. 2007).

What remains unknown is whether work addiction is qualitatively different (based on common personality characteristics) from other behavioral addictions or whether these excessive behaviors compose a heterogeneous group. Further research is required to examine the psychological components across behavioral addictions, particularly non-gambling behaviors. Examination of these constructs across and between the behaviors would clarify the homogeneity or heterogeneity of the group. Longitudinal research on personality is also required, allowing for measurement of enduring, "trait-like" personality risk factors for addictive behavior (Slutske et al. 2005).

91.2.5 Implications for Treatment

Personality traits often interact with other psychological factors and situational variables to produce emotional and cognitive states, which then result in certain types of

behavior. Particular personality characteristics may lead to interpersonal problems encouraging engagement in particular behaviors, and engagement of behaviors excessively may affect interpersonal difficulties. The implication of this dynamic interaction between personality characteristics, emotional and cognitive states, interpersonal problems, and excessive behaviors suggests that a model of treatment that targets or addresses all of these domains might be particularly effective.

The syndrome model of addiction highlights both shared and unique components of the syndrome and correspondingly, the treatment. The shared components aspect of the syndrome model suggests that behavioral addictions ought to be treated in the same way as substance addictions. There has been movement towards a transdiagnostic approach to treatment across mood and anxiety disorders (e.g., Ellard et al. 2010); perhaps a similar approach may be warranted for behavioral addictions. Ellard and colleagues established support for a dimensional conceptualization of psychopathology, targeting core affective factors of mood and anxiety disorders rather than diagnosis-specific symptoms. This transdiagnostic model aims to "address the dynamic and interacting nature of these disorders, or the true holistic experience" of the individuals (2010, p. 99). Furthermore, since behavioral and substance addictions have a shared sequelae, such as depression or anxiety, the syndrome model suggests that a concurrent disorder treatment approach is ideal that not only targets the "substance" or "behavior" but the sequelae as well.

Additionally, the unique components aspect suggests that there are particular idiosyncrasies that are specific to the addictions, which calls for differential or tailored treatment for each addictive behavior, depending on the psychological characteristics of the particular client. A "one size fits all" approach may not be appropriate. For example, clients excessively engaging in work may differ from those who engage in gambling. Thus, addressing agreeableness via communication skills training might not be an issue for workaholism (for those who score high on agreeableness), whereas it might be beneficial for gambling where it is negatively correlated.

The importance and dynamic nature of psychological factors in addictive behaviors suggests that treatment ought to target one or more of these psychological factors, depending on what the tailored case formulations suggest are most saliently sustaining the addiction or are most amenable to treatment. For example, cognitive-behavior therapy or motivational interviewing may be useful for targeting emotional and cognitive states, motives and expectancies, beliefs regarding impairment of control and craving, beliefs about the stability of personality, deception/denial, and counterconditioning to new activities. Interpersonal therapy and systems and family therapy might be beneficial for social and interpersonal aspects of the addiction. Pharmacological treatment may be beneficial in alleviating cravings and withdrawal, and relapse prevention and twelve-step programs may address the longitudinal nature of addiction. Finally, brief therapy or self-help treatments may be incorporated for a stepwise-care approach, recognizing the dimensional and dynamic nature of addiction severity. Just as the syndrome model of addiction is multifactorial, treatment ought to be multifactorial as well, suggesting that multi- and interdisciplinary teams might be a particularly suited and effective model of care. Future treatment research is warranted at many levels of analysis:

from dismantling studies that evaluate particular techniques within treatments, practice-based or process studies to examine the treatment program, and studies that evaluate an entire multi- or interdisciplinary program that can provide pharmacotherapy, psychosocial therapy, family therapy, and long-term care.

Clinical Management of Gambling Disorder

92

Enrique Echeburúa

Contents

Abstract

This chapter deals with the new developments in the treatment of disordered gambling, as well as with the challenges for further research. Abstinence versus moderated gambling as therapeutic goals is an issue that raises many concerns and that needs to be addressed. Current psychological treatment for disordered gambling involves a number of different options, including inpatient treatments, individual and group cognitive-behavioral options, Gamblers Anonymous, and pharmacotherapy, as well as an intervention in relapse prevention. Most of the treatment is delivered on an outpatient basis. Cognitive-behavioral therapy and motivational enhancement therapy may have a success rate ranging from 50 % to 80 % of treated patients in a long-term follow-up. Psychopharmacological therapy may have incremental benefit when patients have comorbid depression or high impulsivity. A relevant issue relates to treatment intensity and the emergence of a plethora of so-called brief interventions. Responsible gambling may be a therapeutic option for young gamblers or people without a severe

dependence. Further information is required about treatment for online gambling addictions and for dealing with specific populations (e.g., women and young people). Unanswered questions for relapse prevention and future research in this field are commented upon.

92.1 Introduction

Gambling disorder (GD) is a relatively common and often disabling psychiatric condition characterized by intrusive urges to engage in deleterious gambling behavior in terms of time invested and money wagered, which results in significantly negative effects on gamblers daily lives and on quality of life.

Pathological gamblers often suffer from comorbid disorders, such as a mood disorder, bipolar disorder, generalized anxiety disorder, posttraumatic stress disorder, and substance addictions or personality disorders, such as borderline and antisocial personality disorder (Lorains et al. 2011).

In the DSM-IV pathological gambling was classified as part of "Impulse-Control Disorders Not Elsewhere Classified," which also included disorders like kleptomania, pyromania, and trichotillomania. In the new edition (DSM-5), pathological gambling, now renamed "gambling disorder," joins substance-related addictions in a group called "Addiction and Related Disorders." This reclassification of GD alongside other addictive behaviors is more appropriate. Classifying gambling disorder separately from other addictions drives an artificial wedge between substance addictions and behavioral addictions, even though there are many commonalities between them and they are treated using similar methods. GD is the only behavioral addiction in this category because it is the only disorder with enough existing data to progress with classification as an addiction (el-Guebaly et al. 2012). Further research is needed to consider other behavioral addictions, such as Internet addiction.

Another change is that, where in the DSM-IV there were ten behaviors listed reflecting different aspects of pathological gambling, in the DSM-5 there are only nine. Whether or not a gambler has committed an illegal act (like theft or fraud) to finance gambling is no longer considered a sign of GD. This behavior was, in fact, the least frequently found symptom on the DSM-IV. Illegal acts symptom is most helpful only for identifying those with the highest levels of gambling problem severity. In addition, DSM-5 reduces the number of criteria required for a diagnosis of GD from five to four.

DSM-5 criteria for gambling disorder focus on preoccupation with gambling, need to gamble increasing amounts of money, and repeated unsuccessful efforts to control gambling. From a clinical perspective, two elements are the most representative of GD: continuous or obsessional chasing of losses and family, job, and social disruption by gambling.

The prevalence of GD varies considerably across different studies. Anyway about 0.8–1.5 % of the adult population can be classified as probable pathological gamblers, while the prevalence of problem gambling is 2.5 %. In particular, substance abusers and patients seeking treatment for medical and psychological

disorders (e.g., anxiety and mood disorders) tend to have high rates of gambling problems. However, since the occurrence of PG varies from country to country and the measures for calculating the prevalence are not always the same, current estimates of the prevalence of GD must be treated with a degree of caution (Kessler et al. 2008).

Men are more likely to be gamblers than women and also more likely to develop gambling-related problems than them. However, there is evidence that gambling problems have increased among women in recent years. In addition, GD is associated with poorer measures of mental health in women compared to men. Women are more likely than men to gamble in order to relieve feelings of depression and anxiety and to escape dysphoria. Whereas men frequently begin gambling early in life, report slow emergence of problems, and seek help well after developing problems; women start gambling later in life, then rapidly develop dependence, and seek help more quickly (Echeburúa et al. 2011a).

92.2 Main Interventions for Gambling Disorder

92.2.1 Psychological Treatment

The interventions for GD that have been developed and reported in the literature are quite similar to methods of treating other addictions and include approaches that are psychoanalytic, behavioral, cognitive, pharmacological, addiction based and multimodal, and self-help. Often these approaches are combined to varying degrees in most treatment programs or counseling settings. Although gambling treatment dates several decades, few empirically supported treatments for GD have been developed.

92.2.1.1 Treatment Goals for Gambling Disorder

Abstinence versus moderated gambling is an issue that raises many concerns and that needs to be addressed. Like in the case of chemical addictions, the gold standard for disordered gamblers recovery is total abstinence. Abstinence is closely associated with recovery of pathological gamblers (Echeburúa et al. 2000).

However, complete abstinence from gambling may not be necessary for successful treatment in problem gamblers who have behavioral problems and negative consequences of gambling, but they are not still dependent on gambling. In these cases evidence supports strategies aimed at reducing harmful negative consequences incurred through involvement in risky behaviors. Controlled gambling can be defined as gambling in the absence of the subjective sense of impaired control and adverse financial consequences, based on self-rating and confirmation from a partner or significant other. Strict abstinence goals may discourage problem gamblers from seeking treatment.

Irrespective of the need of going on with clinical trials comparing therapeutic modalities with varying treatment goals, both goals are necessary for different kinds of patients. While abstinence-focused treatments are the best option for strictly

pathological gamblers, moderated gambling in a harm reduction approach may be interesting for problem gamblers or for a primary prevention approach. Therefore these goals are complementary strategies.

92.2.1.2 Effective Treatments for Gambling Disorder

Current treatment for GD involves a number of different options, including inpatient treatments, intensive outpatient, individual and group cognitive-behavioral options (CBT), and pharmacotherapy. Most of the treatment is delivered on an outpatient basis. Inpatient care is generally limited to patients with severe acute crises, treatment failures, and severe comorbid disorders, particularly depression and attempted suicide.

Behavioral Therapies

Behavioral approach considers gambling behavior as having three components: antecedents (financial pressure, gambling cues, positive or negative emotions, interpersonal factors, urges to gamble), overt or covert behavior itself (money spent in gambling, coping strategies to deal with anxiety or depression, thinking about gambling or about how to attain money), and consequences, both positive (autonomic arousal, opportunities to socialize, escape from personal problems, monetary gain) and negative (anxiety and depression, low self-esteem, work and relationship conflict, financial loss). Anyway gambling-based arousal is the central factor in the reinforcement process. Approach to gambling in regular gamblers is triggered by a wide range of environmental features: driving the car, leaving work, the sight of money in the wallet, and so on. Gambling is also highly reinforcing because of the variable pattern of reinforcement and the tension relief (Hodgins and Holub 2007).

Behavioral therapy considers pathological gambling a learned behavior and relies on techniques such as stimulus control, systematic exposure, and skill development (e.g., relaxation techniques and improving stress management and social skills) to reverse the learned behavior and the association between arousal and conditioned elicitors. Reduction in gambling is expected if patients can successfully develop and use alternative coping responses to deal with urges to gamble. Behavioral counseling, in which the gambler is given verbal reinforcement for desired outcome behaviors, and in vivo exposure, in which the gambler is exposed to gambling behaviors but is not allowed to gamble, are also mentioned in the literature (Hodgins and Holub 2007).

Stimulus control involves limiting access to money, not visiting venues that offer gambling and not spending time with people associated with heavy gambling. As treatment advances, the control of stimuli is gradually faded, except avoiding gambling friends and to signing up for the self-exclusion program. Recovering gamblers are also encouraged to take themselves off mailing lists from the casino, to meet with a financial planner, to cancel all credit cards, and to turn over control of money to another person. Self-exclusion from gaming venues can be an adjunct to treatment. Actually participants tend to comply with the commitment of abstinence and have more positive outcomes when they are also involved in complementary treatment or self-help groups (Nelson et al. 2010).

Table 92.1 Program of in vivo exposure in gambling disorder

Exposure	Characteristics
1st week of exposure	The co-therapist (a relative or a close friend) is together with the patient when he is practicing exposure to a slot machine
	The patient takes money only for his daily needs
2nd week of exposure	The co-therapist goes with the patient to the gambling site, but stays outside waiting for him when the patient is practicing exposure exercises
	The patient takes money only for his daily needs
3rd week of exposure	The co-therapist stays at home when the patient goes to the gambling site to practice exposure exercises. If the patient is in a jam, he can phone the co-therapist
	The patient takes money only for his daily needs
4th week of exposure	The co-therapist no longer takes part in the exposure task
	The patient takes money only for his daily needs

Exposure with response prevention is focused on making patients experience the desire to gamble and teach them how to resist it in a gradually more self-controlled way. The aim of systematic exposure to cues and situations of risk is to make the cues lose their power to induce urges and gambling behavior. If responses are prevented or controlled, the stimulus-response relationship will weaken. In addition patients are taught alternative strategies to cope with their increased anxiety. Exposure tasks take place 6 days a week for a minimal time of 15–20 min. Patients cannot drink alcohol or other drugs during the exposure tasks. Only stimuli relevant to the individual should be included if generalization is to occur in the natural environment. The characteristics of the application of this technique are shown in Table 92.1. This type of therapy is designed to deal with cravings and urges for gambling by increasing confidence in the ability to impose self-control over gambling.

McConaghy et al. (1991) randomly allocated 120 participants to aversion treatment, imaginal desensitization, imaginal relaxation, or in vivo exposure. Patients assigned to imaginal desensitization reported better outcomes at 1 month and up to 9 years later. In a further investigation of this sample, the abstainers and controlled gamblers showed a significant reduction in arousal levels, anxiety, and depression during the follow-up period compared with those who could not control their gambling (Blaszczynski et al. 1991).

Another behavioral controlled investigation with a wait list control group was done by Echeburúa et al. (1996). They compared the effectiveness of cognitive and behavioral techniques in a Spanish sample of 64 men and women who met DSM-III-R criteria for pathological gambling. Participants were randomly assigned to one of four treatments: individual stimulus control and in vivo exposure with response prevention, group cognitive restructuring, a combination of the first two, and a waiting-list control group. At 12-month follow-up, the most favorable outcome was associated with the first two groups, which reported therapeutic success rate (abstinence or one or two gambling episodes in which the amount

gambled did not exceed the amount gambled in the week prior to treatment) of 69 % and 37 %, respectively. The behavioral therapy was found to be more effective than the group cognitive restructuring in terms of reducing gambling frequency.

Grant et al. (2009) compared a six-session CBT program, combining imaginal cue-exposure plus the negative mood induction (focused on the negative consequences of gambling while the urge is active) with GA. The 64 % of participants assigned to behavioral program maintained abstinent at 1-month follow-up as opposed to only 17 % of patients assigned to GA.

In sum, according to the meta-analysis of Pallesen et al. (2005), interventions involving developing relaxation skills, exposure to gambling cues, and direct behavioral action are effective in improving gambling urges, time and money spent, and abstinence. In addition, behavioral change is related to cognitive change after treatment.

Cognitive-Behavioral Therapies

Excessive gambling can be driven by distorted and maladaptive cognitions, such as illusion of control, superstitious thinking, or misperception of probability. Two major beliefs (gambling outcomes can be correctly predicted and controlled) appear to describe the problem gamblers' irrational cognition. Disordered gamblers believe they have the ability to control random or chance events by relying on superstitious behavior or methods. This illusion of control is stronger as gamblers become more familiar with a game. Thus they can believe that a big win is imminent and persists despite mounting losses, with an unrealistic hope that they will recover their losses if they persevere with the gambling (the gambler's fallacy) (Ladouceur and Walker 1998).

Cognitive therapy aims to help patients challenge and overcome irrational thoughts that are believed to initiate and maintain the undesirable behavior. Patients are taught to be aware of the link among thoughts, behavior, and emotion. Many patients do not understand the concepts of probability and randomness, believing that they can exert some control over whether they win or lose. Treatment typically involves teaching patients strategies to correct their erroneous thinking by providing corrective information through education, logical discussion, or behavioral experimentation. Thus the therapist will ask the gamblers to describe what they are saying to themselves when gambling. If the erroneous perceptions and understanding of randomness in the gambler can be corrected, then the motivation to gamble should decrease dramatically. Cognitive therapy also aids gamblers in coping with urges to gamble, managing negative emotions and training in problem solving techniques (Ladouceur and Walker 1998).

The more recent randomized clinical trials have focused on combined cognitive and behavioral approaches (cognitive correction, problem solving training, and social skills training). In two different trials Ladouceur et al. (2001, 2003) compared a 12-month follow-up individual and a 24-month follow-up group CBT (ten weekly sessions), respectively, with a wait-list control group. In the second trial a relapse prevention component was also included. People receiving treatment met fewer DSM criteria for pathological gambling, and treatment gains were

maintained over the follow-up period. However, dropout rates were high (47 % in the first trial and 26 % in the second one).

An individual eight-session manualized form of CBT has also been compared (either delivered by a professional counselor or completed alone by the patient in a self-help workbook) with a group referred to GA. Although participants in all groups reduced gambling, CBT in both conditions was better than GA in terms of days gambled and number of gambling criteria met. In the GA group attendance at meetings was positively associated with abstinence from gambling (Petry et al. 2006).

In the Jiménez-Murcia et al. study (2012), exposure and response prevention do not improve the results of a group CBT for male gamblers due to its increasing effect on the dropout rates. However, in other studies with different results, exposure and response prevention are used together with stimulus control in a behavioral management program and in an individual format (e.g., Echeburúa et al. 1996, 2000, 2011b).

In sum, both individual and group CBT appear effective for reducing gambling. Individual CBT may be enhanced if patients receive compliance-improving interventions, such as a reinforcement of self-efficacy, reminder phone calls, assessment feedback, and a weekly decisional balance exercise to complete. Group CBT may be enhanced if individuals have interactive written exercises. In this way that mapping may serve to individualize the group treatment, leading to greater effect (Melville et al. 2004).

However, the cognitive therapy studies have not yet determined the optimal number of sessions needed to reduce gambling symptoms and maintain improvement (Grant and Odlaug 2012).

Motivational Enhancement Therapy

Another approach adopted to help problem gamblers focuses on the use of short-term brief motivational enhancement therapy and telephone counseling, mailed self-help workbooks, and online resources. Brief treatment is defined as that using less professional resources or time (four or fewer sessions and sometimes one single session) than usual face-to-face interventions (typically, six to twelve sessions of therapist contact). This therapeutic modality may be an important innovation to helping people with gambling problems who fail or refuse to seek treatment in traditional therapeutic settings and may enhance patients' sense of control over their own recovery (Hodgins and Holub 2007).

Motivational interviewing (MI) focuses on patient's intrinsic motivation for change and on patient's strengths to enhance self-efficacy. Motivational interviewing strategies act in some way to resolve ambivalence and promote greater commitment to change.

This approach has proven to be effective, at least with those with less severe gambling problems (Hodgins et al. 2001). In the latter study, at a 24-month follow-up, 77 % of the entire sample was rated as improved, but gamblers receiving the workbook and a telephone motivational support reported less frequent gambling and lower severity scores than workbook-only group. In other studies of the same

group (Diskin and Hodgins 2009; Hodgins et al. 2009), patients who received the motivational interviewing plus workbook gambled less and spent less money than workbook-only group.

A combined motivational interviewing and CBT program applied in group or individual format, or even adapted to a web-based format (Carlbring and Smit 2008), can improve GD behaviors, as well as gambling correlates. Moreover the addition of motivational interviewing to CBT can reduce treatment attrition and improve outcomes (Wulfert et al. 2006).

However, these motivational approaches, which are more attractive to gamblers and may result in an increase of treatment seekers, cannot be so effective with severe pathological gamblers or patients with comorbid pathology. More research is needed to determine the efficacy of these programs when compared to more established CBT.

Gamblers Anonymous

Modeled after the traditions and spiritual principles of Alcoholic Anonymous, Gamblers Anonymous (GA) is the primary self-help group and uses an abstinence-based treatment program. DG is conceptualized as an illness which can be arrested but never cured, so people affected by this problem have a permanent predisposition for losing control over their gambling.

The therapeutic rationale for GA is that the 12 steps to recovery will lead gamblers to attain abstinence. The group format is intended to provide a sense of common purpose and understanding, emotional and spiritual support, and hope. Anonymity allows for members to feel safe in sharing openly with other members (Hodgins and Holub 2007).

The efficacy of GA has not been demonstrated in controlled studies. Relapse rates tend to be quite high. Stewart and Brown (1988) found that total abstinence was reported by only 7.5 % of members surveyed 1 year after their first attendance and by 7.3 % at 2 years. Attrition rate is also high. People attending GA have better gambling outcomes than those who do not, even though they are engaged in professional treatment concurrently (Petry et al. 2006).

The therapeutic effectiveness of Gamblers Anonymous has also been explored with respect to participation by the gambler's partner. There is a trend for higher abstinence rates for gamblers whose partners are present at meetings compared with gamblers whose partners do not attend.

There is a particular need for studies of the role of GA in recovery and treatment outcomes. A recent study found that there were not any differences on key gambling variables (e.g., frequency, abstinence rates, money wagered) at 12 months between a program of CBT and 12-step therapy (Toneatto and Dragonetti 2008). If there is a high dropout rate from Gamblers Anonymous, as the literature suggests, then it is important to investigate its causes and strategies for reducing it.

In sum, GA may be increasing in popularity, but whether participating in meetings makes a significant and lasting impact is still not well known.

92.2.1.3 Relapse Prevention

A challenge in the treatment of pathological gambling is preventing relapse. Many personal and environmental factors interact to influence the risk of relapse for any individual trying to recover from an addiction. Relapse prevention is focused on training patients to identify high-risk situations for relapse, such as social pressure, negative emotional states (e.g., anxiety, depression, and anger), and interpersonal conflicts, and providing them adequate strategies for coping with problematic situations. Pathological gamblers are deficient in the number of coping skills they have available and in their ability to flexibly choose the skill most appropriate to the stressful, or potentially relapse-triggering, situations they face. Relapse prevention techniques increase the likelihood of engaging in adaptive coping behaviors.

Successful recovery also involves the development of new skills (e.g., cognitive reframing) and lifestyle patterns that promote positive patterns of behavior. The integration of these behaviors into day-to-day activities is the essence of relapse prevention.

The problem solving approach is oriented to increasing the gambler's abilities to cope with urges or cravings and to deal with anxiety, depression, or personal crises for which the gambling is an escape. For example, substance abusers with a gambling problem utilize significantly more avoidance and impulsive coping styles.

Echeburúa et al. (2000) evaluated the efficacy of providing relapse prevention strategies as a follow-up to behavioral treatment focused on total abstinence from gambling. Sixty-nine pathological gamblers received behavioral treatment (stimulus control and exposure with response prevention), followed by random assignment into one of the three conditions: individual relapse prevention, group relapse prevention, or no treatment control group. The results related to the 12-month follow-up relapse showed a success rate higher in both individual (83 %) and group (78 %) relapse prevention than in the control group (52 %). There were no differences between both experimental modalities. These results raise the need of relapse prevention programs in the treatment of pathological gambling. This study reported a dropout rate of 14.5 %. On the other hand, most relapses were observed in the first 3 months after treatment. The main triggers of relapse were inadequate money management, negative emotional states, alcohol abuse, craving, and social pressure (Echeburúa et al. 2001).

92.2.2 Pharmacotherapy

Pharmacotherapy is a relatively new approach to the treatment of GD and may be effective for reducing gambling urges and behavior. A variety of medications have been examined with varying results. Actually there are no approved medications for the treatment of pathological gambling (Grant et al. 2012).

Neurobiological studies suggest the involvement of serotonin, norepinephrine, and dopamine in GD because these transmitters are strongly associated with reward pathways. The norepinephrine system has been associated with arousal and novelty seeking, dopamine with reward and motivation, and serotonin with impulsivity and compulsivity (Hollander et al. 2005).

The medications target one or more of these neurotransmitter systems. The current pharmacological strategies for treating GD suggest the use of serotonin reuptake inhibitors (SSRI), mood stabilizers, atypical antipsychotics, and opioid antagonists.

SSRI antidepressants can reduce urges to gamble or prevent from compulsive behaviors. The rationale for this medication is the phenomenological association between GD and compulsivity. These medications are also helpful if anxiety disorders are associated to GD (Potenza 2012).

Opioid antagonists (naltrexone) can block feelings of euphoria related to gambling behavior and result in reductions of gambling urges and thoughts and in improvement in psychosocial functioning. The rationale for this medication is the similar neurological pathways for GD and substance addictions and the commonalities between clinical symptoms of both disorders. This class of medication, dosed at 50 mg/day, should be considered a first-line treatment for GD (Grant et al. 2012). Naltrexone may be particularly helpful for those with strong gambling urges at treatment onset and/or a family history of alcoholism (Potenza 2012).

In turn, mood stabilizers, such as lithium or topiramate, can reduce the use of gambling to regulate negative mood (most of all, if bipolar tendencies are present), but some recent controlled trials have failed to show any significant treatment effect for topiramate on the primary or secondary outcome measures.

Another avenue of approach is the use of medication to treat comorbid conditions. In practice, this is probably the most frequently cited reason for putting gamblers on medication. Comorbid disorders for which medications are commonly prescribed include depression, bipolar disorder, and attention-deficit hyperactivity disorder.

In sum, certain medications may be beneficial in treating this disorder. Pharmacotherapy research needs to be expanded to determine if this approach has an important role in the treatment of pathological gamblers and plays an adjunctive role to psychological treatments. We still do not know if medications provide therapeutic effect by ameliorating the pathological gambler's cravings, ruminations, or negative feelings. Heterogeneity of GD treatment samples may also complicate identification of effective treatments. In addition, some studies have reported high placebo response rates (Potenza 2012) and high rates of study dropout (30–50 %) (Petry 2005).

92.2.3 Issues in Treatment

Only a small proportion of the individuals who are suffering from GD (about 6 %) seek formal treatment. The satisfactions provided by their addiction, a desire to

handle the problem by themselves, and shame have been identified as contributing factors to resistance to treatment. Motivation becomes adequate when people identify gambling as a destructive agent in their life. Natural recovery from problem gambling can occur in about 35 %, but most disordered gamblers report a chronic course, with symptom severity fluctuating over time (Grant and Odlaug 2012).

Therapists have been confronted with the problem of treatment compliance. For pathological gamblers, compliance is an issue because they are often ambivalent about giving up their gambling or altering long-standing patterns of coping, no matter how ineffective. Some people do not seek treatment, some drop out after one or two sessions, and some can decide to terminate treatment after a few weeks thinking that their problem has been solved. It is a challenge to identify the characteristics and the reasons of individuals who refuse treatment, drop out, or simply do not show up for the first session. There are no obvious solutions to these matters, but motivational enhancement therapy, behavior contracts, and flexible treatment goals might improve treatment compliance.

Despite the growing trend toward harm reduction strategies and controlled behavior approaches for addiction problems, most gambling treatment programs, like those that treat substance abuse, favor abstinence. Some programs, however, particularly those dealing with problem gamblers in their early stages, aim at reducing and controlling rather than stopping gambling. Anyway clinical trials comparing treatments with varying treatment goals are necessary (Ladouceur et al. 2009).

A relevant issue relates to treatment intensity and the emergence of a plethora of so-called brief interventions. A distinction should be drawn between minimal intervention or advice in a primary care setting and brief intervention within a specialist context (one to three sessions). It is difficult to know if there are remarkable differences between brief and extended interventions for pathological gamblers. For instance, there are important differences between treatment-seeking populations as distinct from those that are selected as a result of opportunistic screenings. Anyway it is relevant to investigate the active ingredients of brief interventions which seem to be, at least, relatively successful (Grant and Odlaug 2012).

Interventions should be tailored to the needs of the patients. Substantial progress has been made in understanding the treatment of this disorder, but there is not yet research basis for matching patients to treatments according to different characteristics (e.g., subtypes of gamblers, different type of gambling, or gender of gamblers). That is, individuals with gambling problems cannot be treated as a homogeneous group, but refinement in matching treatment strategies with gambler typologies must await completion of controlled treatment studies.

Advances in family therapy for treating substance abuse problems have been adapted for gambling disorders, such as a self-help workbook of the Community Reinforcement and Family Therapy (CRAFT) model (focused on the training of family members to use behavioral principles to reinforce non-gambling behaviors) (Hodgins et al. 2007) or a coping skills training program for those with a pathological-gambling partner (Rychtarik and McGillicuddy 2006). Further research is warranted to improve the design and targeting of these approaches.

92.2.4 Internet Gambling

Internet gambling can be defined as any type of wagering that takes place by using the Internet. Common forms of online gambling are online poker, online casino, sports betting, and online bingo; though, there are some other ways to gamble using the Internet that hold strong potential for additional growth, e.g., gambling by mobile devices and gambling on the Internet games (Laplante and Braverman 2010).

Men are more likely to gamble using the Internet than women. Emotional states, maladaptive cognitions, and life events can serve as triggers for Internet abuse. The pervasiveness of Internet gambling sites on the web makes it an especially risky form of gambling. One of the most attractive features of Internet gambling is its convenience (e.g., playing comfortably at home and at a convenient time is reported to be the most important reason for playing online poker). The anonymity of Internet gambling presents an opportunity for the development of gambling-related problems. For example, because of anonymity, people may gamble under the influence of alcohol or drugs, be underage, or even gamble from the school or workplace. Solitary gambling, like Internet gambling, where people can gamble at their own pace with no outsiders interrupting or any other distractions, is also a risky factor. Computers and the Internet create isolation and a sense of fantasy. In summary, a cursory consideration of numerous risk areas logically suggests that the Internet might increase the speed of the negative effects of gambling or exacerbate gambling-related problems (Griffiths and Barnes 2008).

Minors might gain access to a credit card and gamble with other people's money. This raises concerns that children and adolescents' participation basically is unrestricted. In addition to being illegal, such an occurrence would be problematic because early exposure to gambling is linked with the development and persistence of gambling-related problems (Derevensky and Gupta 2007).

Appropriate treatment for online gambling addiction is still being researched. Treatments that are effective for gambling addiction work well for online gambling addiction. It is important to consider the individual needs when devising a treatment plan to tackle an online gambling addiction. Every person is different and could be addicted for different reasons.

Stimulus control involves for the Internet gambling addicts to engage in opposite activities, use of timers to end online sessions, set time limits, prioritize tasks, and record Internet usage to abstain from Internet abuse.

Group therapy is commonly suggested as a treatment option as well. If patients are attending support groups such as GA, they can use that group to help cope with their online gambling addiction.

Online gambling addiction, gambling addiction, and Internet addiction, which are all closely related, can create problems outside of the individual. They can cause damage to one's finances, marriage, and even their entire family. In these cases, financial counseling, marriage counseling, and family therapy are all beneficial treatment options.

In conclusion, a combination of individual, family, and group therapy may be the best option, although individualization should be emphasized. Medication (e.g., SSRIs) may be needed to treat associated anxiety or depression. Anyway our understanding of Internet gambling is still quite limited. There is no evidence-based research for treatment options regarding this topic.

92.3 Concluding Remarks

Behavioral and cognitive-behavioral therapy appear to be the most successful treatment approaches in different formats (individual, group, and self directed), regardless of the type of gambling behavior practiced (Gooding and Tarrier 2009). However, it continues to be controversial which form of CBT is best and for whom and what is the optimal duration of therapy. Many behavioral interventions often include cognitive components, so it may be difficult to isolate the most potent agent of change. However, the presence of irrational beliefs and attitudes about gambling in pathological gamblers do not always justify to confront them with a cognitive approach. Interestingly, a behavioral approach, which is focused on short-term cessation of gambling behaviors, can also result in a decrease of erroneous beliefs of patients, without treating them specifically (Echeburúa et al. 2000).

Both individual and group CBT appear to be effective in the treatment of GD and its correlates. Group therapy is not only just cost-effective; it also enables gamblers to learn from and support each other. Individual therapy may be more suitable for those who can afford therapy and those who prefer discussing life events on a one-to-one basis (Oei et al. 2010).

Pharmacotherapy appears to have a role in the treatment of coexisting depression, rather than as a primary treatment for GD. However, research on the pharmacological treatment appears promising, particularly in the case of opioid antagonists. There is growing recognition that multiple treatment components should be considered given the patient's specific configuration of problems. Thus, patients with dysphoria should be evaluated for antidepressant medication; family therapy may be indicated in the presence of extreme family estrangement; and substance abuse counseling may be necessary for those whose addictive behavior also includes alcohol or other drug abuse. Inpatient programs for severe pathological gamblers, with comorbid disorders or attempted suicide (or suicidal ideation), continue to be in use, but more rigorous research on effectiveness is warranted because to date there are no randomized trials (Grant and Odlaug 2012).

Very few studies have examined the combination of drug and behavioral treatments. Similarly, despite their high rates, there have been very few studies on the treatment of GD in conjunction with comorbid disorders, such as depression and personality or drug- or alcohol-use disorders. Irrespective of the effectiveness of CBT for pathological gamblers with or without other mental disorders, treatment must be adapted to these different circumstances. Thus gamblers who have

comorbid schizophrenia may require more sessions of therapy (i.e., 20 sessions), and a treatment focused more on behavioral than on cognitive components (Echeburúa et al. 2011b).

As problem gambling significantly affects patients relationships with their families, interventions for gambling problems have also been directed at affected families. Family interventions are at an early stage of development and evaluation. It will be important to determine their efficacy and cost-effectiveness compared to treatment provided to the gambler alone (Hodgins and Holub 2007).

Virtual counseling (Internet or computerized therapy) is another treatment option. Presently there are only a few gambling specialty treatment programs, and one way to expand treatment services is to provide telephone and Internet counseling. Some pathological gamblers may be reluctant to enter individual or group therapy due to stigma, lack of resource availability, or denial. Numerous chat rooms have emerged for GA 12-step fellowship and are available anonymously 24 h a day.

Gambling studies should focus particularly on treatments that have manual-guided treatments. Poor specification of the therapeutic methods used hinders the replication of successful programs. Not only do therapist's manuals guide interventions but they also facilitate the clarification of the specific contribution of particular treatment components.

The National Problem Gambling Clinic 93

Henrietta Bowden-Jones and Neil Smith

Contents

Abstract

The National **Problem Gambling** Clinic is the first and only **National Health Service** clinic (provider of free state medical treatment) designated to the treatment of **pathological gamblers** from all over the UK.

The current prevalence of problem gambling in Great Britain is 0.9 % according to the latest British Gambling Prevalence Survey (NatCen 2010). This showed a 50 % increase since the previous survey of 2007 reported a prevalence of 0.6 %.

Currently therefore, there are deemed to be at least half a million **pathological gamblers** in the country with as many more scoring on screening for at-risk behaviors in relation to gambling (Natcen 2010).

Our clinic was set up by Dr. Henrietta Bowden-Jones as a direct result of the public concerns at a time when the British government was planning to allow the construction of several more casinos and when advertising gambling products had become legal.

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment: International Perspectives*, DOI 10.1007/978-88-470-5322-9_74,

The idea behind the project was to provide patients with a gold standard, evidence-based time-limited service providing specialist treatment delivered by psychologists and psychiatrists.

We have now had over 3,000 referrals and own the largest problem gambling database in Europe, and the amount of information collected has allowed us to reach in-depth understanding of the clinical subtypes presenting.

93.1 Introduction

The National Problem Gambling Clinic is the first and only National Health Service clinic (provider of free state medical treatment) designated to the treatment of pathological gamblers from all over the UK.

The current prevalence of problem gambling in Great Britain is 0.9 % according to the latest British Gambling Prevalence Survey (NatCen 2010). This showed a 50 % increase since the previous survey of 2007 reported a prevalence of 0.6 %.

Currently therefore, there are deemed to be at least half a million pathological gamblers in the country with as many more scoring on screening for at-risk behaviors in relation to gambling (Natcen 2010).

93.2 The Clinic Activities

Our clinic was set up by Dr. Henrietta Bowden-Jones as a direct result of the public concerns at a time when the British government was planning to allow the construction of several more casinos and when advertising gambling products had become legal.

The idea behind the project was to provide patients with a gold standard, evidence-based time-limited service providing specialist treatment delivered by psychologists and psychiatrists.

We have now had over 3,000 referrals and own the largest problem gambling database in Europe, and the amount of information collected has allowed us to reach in-depth understanding of the clinical subtypes presenting.

The types of gambling that patients are involved in are also recorded.

The most frequent activities are sports betting and electronic roulette machines, called fixed odds betting terminals in the UK. Internet gambling is increasing and about a third of our patients are now doing this regularly, sometimes to the exclusion of land-based gambling following a migration of habit.

Personal and psychiatric histories are also collected in an attempt to link activity and experience to outcomes; this is particularly relevant when we look at early adverse events in childhood and their predisposing negative impact on future illness.

Our patients tend to be male and aged between 30 and 40 years old, and most will be in either full-time or part-time employment.

Many, 84 %, have committed illegal acts to fund their gambling at some point in their lives.

Twenty percent have lost their jobs due to gambling, and 50 % have lost significant relationships such as their marriage due to gambling.

Many of the patients we see are depressed or anxious at the time of assessment and about a third have lifelong comorbid presentations, at times with severe and enduring mental illnesses such as schizophrenia.

Our approach is to treat everyone apart from the acutely psychotic patients, but even then, we advise on the best antipsychotic and agree to delay treatment temporarily so we do not turn people away as our strength is in understanding the complexities of dual diagnosis presentations.

The yearly funding for the treatment of what are now over 700 referrals a year comes in several ways, but the main bulk of the money, about £330,000, is received from the Responsible Gambling Trust, a government charity set up to distribute voluntary donations from the gambling industry to avoid a compulsory levy based on earnings.

Other funds come from government working parties attended by the Director of the clinic, court reports written by forensic psychiatrists trained at the clinic in pathological gambling expertise, industry training days, some Employee Assistance work, and lecturing fees. Further funds come via the successful research grant applications that may free up the clinical time of some researchers to contribute in clinical time for the access to problem gamblers in research projects of which there are many.

Although cognitive behavioral therapy is deemed to be a highly effective way of treating problem gamblers, we do offer other interventions such as a Money Management assistance service which in the UK is funded by the banking world to assist people with mental health issues. This service provides a session of psychoeducation around managing finances but also individual help with setting up repayment plans.

Another integral part of the clinic is the assistance we offer to relatives and carers of problem gamblers. Often, it will be an elderly mother who has read about us in the newspapers and has referred her son for treatment. At other times, spouses of gamblers are brought into clinic once the patient begins therapy. The support we offer to carers is also manualized and linked to psychological outcomes to determine the usefulness of the intervention, but we are more relaxed about our data collection as we really do want to help the individuals feel more supported in their suffering.

93.2.1 Treatment

Pathological gamblers who attend our clinic are offered a 90-min face-to-face assessment with a clinician. This assessment covers current and previous gambling history including first gambling experiences and emotional links to the gambling, for example, some patients only spent time with their father in childhood when they

were gambling. This has important implications for the right treatment approach as we do offer some more psychodynamic treatment for some patients who need a more interpretative approach. A history of medical and psychiatric difficulties is also taken along with any history of parental gambling problems. A brief personal life history is also obtained. Clients also complete a comprehensive battery of questionnaires including gambling and mental health screens. All assessments are discussed in a weekly multidisciplinary team (MDT) meeting where decisions are made regarding treatment packages offered.

The basic treatment offered by the clinic is an eight-session cognitive behavioral therapy treatment developed from work conducted by Nancy Petry (2005; Petry et al. 2006). The treatment is manualized in the sense that there are a set number of sessions and each session topic is guided by a specific handout. Within this protocol, therapists are expected to deliver the treatment flexibly in order to best meet the client's individual needs. Homework is an essential component of this treatment, with each session topic having comprehensive handouts including homework tasks. Clients are informed that homework is essential to change. Topics covered include stimulus control, rewards, coping with cravings, increasing pleasant activities, trigger management, understanding lapses, coping with gambling thoughts, and managing lapses. The treatment includes a strong psychoeducational component where clients are socialized to an addiction model of problem gambling, drawing on research from scanning studies to highlight commonalities with drug and alcohol addiction. This serves to "normalize" the problem and reduce confusion and the degree of personal guilt and judgment that clients often present with.

The service is guided by the "pathways model" of problem gambling (Blaszczynski and Nower 2002). This seminal paper suggested that three levels of severity of difficulties can be observed in problem gamblers. These levels relate to different etiological factors for problem gambling and increasing levels of associated and comorbid difficulties, with each level requiring more intensive treatment. In the MDT, a decision is made as to whether the individual assessed is of a "lower," "moderate," or "higher" severity, based on criteria derived from the pathways model and from internal audits of client characteristics.

Patients who present at the "lower" end of the severity spectrum are offered a brief intervention. This comprises the provision of an 85-page self-help workbook, with four individual sessions with a therapist. The workbook contains all handouts from the eight-session CBT treatment, with guided self-help exercises included.

Clients assessed as being of "moderate" severity are invited to attend the eight-session manualized treatment delivered in a group format. These sessions are of 90 min length and up to 20 individuals are invited to each group. Sessions involve group feedback of progress and homework and delivery of session topic content and finish with reflections on the session and homework for the coming week. Groups are strongly encouraged by the service; gathering with other individuals has the effect of normalizing a problem that often presents in highly isolated individuals.

Clients assessed as being of "higher" severity will receive the eight-session group CBT program plus additional individual CBT sessions with a therapist.

Each of these types of additional intervention is designed to prevent relapse and provide a solution for the problem of the "revolving door" in addiction services where clients with more severe difficulties often represent multiple times. These sessions may be offered for three reasons: additional support for gambling problems, provision of support for related comorbidity, and cognitive formulation work. Additional support for gambling is offered if individuals have not achieved control over their gambling by the end of the eight-session program or the clinicians are concerned that abstinence may only be temporary. The provision of support for related comorbid difficulties focuses on obvious comorbid, and often premorbid, psychological difficulties such as anxiety or depression that may hinder ongoing recovery. In the case of more severe comorbid difficulties, care planning for referral onto specialist mental health services will take place. The cognitive formulation is an intervention that provides an understanding for the client as to why gambling has become problematic for them. It may also help with other difficulties in the client's life that hinder recovery. The cognitive formulation follows methods pioneered by Aaron Beck of establishing how childhood experiences may contribute to negative core beliefs and the development of subsequent dysfunctional rules and strategies in adult life. In clients with gambling problems, it is very common to observe adverse upbringings leading to the development of core beliefs of "failure" or "defectiveness." These can leave an individual vulnerable to addiction if exposed to gambling. Understanding these core beliefs and challenging them are often an essential part of treatment.

The core eight-session manualized CBT treatment may be delivered by individual therapists instead of in a group format under one of the following three conditions: language difficulties, risk issues to self or others, and low intellectual functioning. Individuals who are anxious about group working are encouraged to try out groups prior to opting for an individual CBT treatment.

We also offer a brief Motivational Enhancement Intervention for individuals who may be unsure as to whether they have a gambling problem. This comprises a four-session treatment with a therapist using motivational enhancement principles to guide discussions about the gambling behavior. If, as often happens, during these sessions the individual decides they do have a problem and wish to change, then the therapist delivers the manualized CBT treatment.

As not all individuals can be grouped together in the main CBT program due to different levels of cognitive functioning, special group programs for the following distinct populations have been established: a women's group for emotionally vulnerable women who present with significantly low mood and anxiety and a reticence to attend the predominantly male groups, a homeless persons group held either at the clinic or in a homeless hostel and funded by the homeless national services, and a mental health group. All follow a modified version of the core CBT program.

Following the completion of treatment, each individual has a discussion with their therapist as to whether they feel they have received a sufficient intervention to help them combat gambling difficulties. With the group program, this is delivered by telephone following the end of the eight group sessions.

If individuals are happy with the treatment they received, they are invited to attend the Aftercare Group. This is held once a month and patients who complete treatment can attend for as long as they wish. The Aftercare Group is an open-forum group; facilitators start by setting an agenda of topics that the attendees wish to discuss. These topics may involve positive or negative experiences of recovery. The conversations are then steered by the facilitators to cover the topics in the manualized treatment. The group serves as a reminder for individuals of techniques and strategies learned in the CBT sessions they attended. Members are invited to support each other within this group, but preferably by suggesting techniques from the manualized intervention.

93.2.2 Education and Prevention

Because the clinic is the only one, it has a significant role in British society that goes far beyond its remit to treat problem gamblers.

Here is a list of activities we believe a National Clinic needs to attend to as well as deliver high-quality treatment:

- Any time a newspaper article or other media program is planned, the clinic will be asked to contribute to it in light of its expertise and perspective.
- The aim for us is to remain as politically neutral as possible while still enforcing what we believe are fundamental societal needs to protect gamblers, such as adequate self-exclusion policies, the protection of children and young people from the proliferation of gambling products, the need for more stringent laws around advertising gambling activities, and ensuring enough attention is paid to the quality of treatment services at a national level when they fall outside the remit of the NHS.
- Peer-reviewing journals.
- Training the next generations of psychiatrists and psychologists.
- Maintaining links both nationally and internationally in the field writing articles on case studies and disseminating knowledge about problem gambling to professional groups (Bowden-Jones and Clark 2011).
- Lecturing to medical students and other mental health professionals on the topic of problem gambling.
- Teaching the general public about the issues via open lectures and invited talks.
- Facilitating the work of the neurobiological research group currently neuroimaging the gamblers.

All of the above need to be addressed and constantly updated if we are to continue leading the way in the UK.

Our hope is that in the future, the State will recognize the need to fund problem gambling treatment throughout the UK and include pathological gambling in the illnesses it recognizes. The need for smaller clinics set up to be linked up to our central "hub" is a cost-effective one that we will be working on for years to come.

Abstract

This paper investigates the concept of Internet addiction disorder (IAD). The phenomenon of excessive Internet use is increasingly becoming a public health issue. Increasing research evidence indicates common clinical, neurobiological, and neuroimaging findings between IAD and addictive disorders. Different clinical descriptions and research findings suggest however the existence of various types of Internet addictions (i.e., gaming, cyberpornography, etc.). The Internet could be then rather the facilitating vector of an addiction to a given behavior linked to specific stimuli and operant conditioning mechanisms.

As an attempt to increase understanding and knowledge related to IAD, a number of screening tools were studied. Various forms of excessive Internet use or IAD seem also associated with a number of coping strategies as well as personality characteristics and possible comorbid psychiatric disorders.

In spite of a number of clinical treatment programs dedicated to IAD, there are still limited publications on the efficacy of such treatments. The few existing ones mostly relate to interventions inspired by cognitive-behavioral therapy.

The determinants, the evolution of the possible IAD-related disorders, as well as the validation of adequate treatments are yet to be clearly established. Longitudinal studies using large and representative samples are required.

94.1 Introduction

Internet addiction disorder (IAD) is increasingly becoming an issue, especially in adolescents, the most studied subpopulation. Various deaths in cybercafés (Choi 2007) and videogame-related murders (Koh 2007) have been reported. Moreover, a significant number of adolescents are reportedly in need of treatment (on average ten million Chinese and 2.1 % of 6–19-year-old South Koreans) (Ahn 2007). This has led some countries (i.e., China and South Korea) to consider IAD as a serious public health issue (Block 2008). The European Union also funded a multisite prevalence study into adolescent problematic Internet use (PIU). The findings showed a prevalence rate of 4.4 %, with some variation between countries (Durkee et al. 2012).

IAD is an emerging concept that has not yet been refined. It refers indiscriminately to excessive Internet use and problematic Communication and Information New Technologies (CINT) use (e.g., cell phones). This concept is starting to generate debate within the scientific community. There is some reluctance to "pathologize" human behaviors. There is also a need to avoid qualifying every passionate or extensive engagement in pleasurable activities as a disorder (e.g., gambling, chatting, watching pornography, gaming). If a new medical concept (e.g., IAD) arises, the question is how to scientifically define the cutoff between nonproblematic, problematic, or pathological use.

The disorder was first described in 1998 by Kimberly Young (1996) as including numerous symptoms that are similar to the criteria for addictive disorders. These include (a) tolerance (i.e., the need to spend increasing amounts of time using the

Internet and withdrawal symptoms such as irritability and tension), (b) preoccupation, (c) inability to cut back, and (d) negative consequences for private, social, and professional life. Three separate categories have been identified: excessive video gaming, obsessive and compulsive sexual behaviors, and overuse of social networks (Block 2008).

Increasing research evidence indicates common clinical, neurobiological, and neuroimaging findings between IAD and substance use disorders (SUD). This body of evidence suggests that the addictive spectrum hypothesis is the most appropriate conceptualization of IAD. These findings have led to the consideration of IAD for inclusion in the forthcoming Diagnostic and Statistical Manual of Mental Disorders (DSM-V) (Block 2008). It was however not included in the DSM-V. More studies on IAD and on Internet gaming disorder (see chapter VI for more details) and other forms of Internet addictive use were still needed before possible inclusion of IAD in the addictive and related disorder category.

Different clinical descriptions and research findings suggest the existence of various types of Internet addictions. From a cognitive-behavioral perspective, Davis (2001) proposed two categories of problematic Internet use (PIU): "generalized PIU" (GPIU) and "specific PIU" (SPIU). GPIU refers to a multidimensional overuse of the Internet and SPIU refers to overuse in a specific area (e.g., online gaming). From this perspective, the Internet could be the facilitating vector for preexisting addictive disorders (e.g., gambling). Alternatively, it could be the vector for a new addictive behavior (e.g., chatting).[1]

IAD has also been conceptualized as a primary impulse control or obsessive-compulsive disorder (Yellowlees and Marks 2007) or as a comorbid condition (e.g., ADHD, anxiety, depression). This suggests that IAD could be a secondary disorder to some psychiatric conditions.

94.2 Epidemiological Data

One way to assess the stability of IAD as a disorder, and determine its prevalence, is to screen for it in the general population and specific samples. Lack of epidemiological studies and adult samples limits our understanding of the phenomenon. The major obstacle that the scientific community has faced in the last decade is the lack of validated and consensual screening tools. Prevalence rates of IAD are reported to vary from 2.7 % (Dong et al. 2010) to 20.9 % (Kormas et al. 2011) for 10–30-year-old Internet users. Similarly, they range from 3 % to 36.8 % (Zanetta Dauriat et al. 2011) for 10–54-year-old online video games. Furthermore, variation between countries (Durkee et al. 2012; Sun et al. 2012) suggests cultural factors may influence Internet use habits. This increases the complexity of evaluating IAD.[2]

[1]For further details, see "What Is Addictive in the Internet" section.

[2]For epidemiological data from the USA, Asia, and Europe, see Moreno et al. (2011) and Durkee et al. (2012).

The differences in IAD prevalence are due to differences in the samples studied but also to the variety of the assessment tools used. In a 28-month period (January 2010 to April 2012), 37 articles were published and indexed in PubMed, containing 14 different screening tools (Achab et al. 2012). The most frequently used (39 %) is the 20-item IAT (Young 1996). However, using the same tool (e.g., IAT), and focusing on similar student samples, variation in prevalence rates was still found (2.7–20.9 %). Gender characteristics and differences in IAD cutoff scores contribute to these disparities. Furthermore, variations on the focus of interest (i.e., general Internet overuse, video games, Internet-based sexual addiction, etc.) also affect prevalence figures. Finally, selection bias was found, with two thirds of the studies involving nonrepresentative samples of students.

These findings are supported by a recent review on PIU using the Strengthening the Reporting of Observational Studies in epidemiology (STROBE) criteria. Particularly Moreno et al. (2011) found weak internal and external validity of the concept when using epidemiological data from similar populations (i.e., US adolescents and college students).

94.3 Internet Addiction Screening Tools

A number of IAD screening tools are available. Screening tools have been found to strongly correlate with each other and also with self-reported Internet addiction (Achab et al. 2011; Widyanto et al. 2011). The theoretical construct underlying the development of IAD screening tools followed different models. (a) **The addiction model** is the basis for some tools that are adapted from **DSM IV substance dependence criteria**. For these tools, the word *substance* was substituted with *online activity* or *online video gaming* (DSM Adapted Scale for online video gaming (DAS) (Achab et al. 2011). (b) **The impulse control disorder model** is the basis for other tools adapted from **DSM pathological gambling criteria** [the Young Diagnostic Questionnaire (YDQ) and Young Internet Addiction Test (IAT)] (Moreno et al. 2011). Other tools were inspired by the (c) ***cognitive and behavioral PIU model*** (Davis 2001). This defines PIU as a four-dimensional entity consisting of diminished impulse control, loneliness/depression, social comfort, and distraction (Davis' Online Cognition Scale OCS) (Moreno et al. 2011). (d) The **PIU behavioral addiction model** is the basis for the Compulsive Internet Use Scale (CIUS) (Meerkerk et al. 2009). It also informs the Griffith Addiction Components Criteria (i.e., salience, mood modification, tolerance, withdrawal, relapse, and harm) (Moreno et al. 2011).[3,4] Other attempts to define PIU have included the amount of time spent online. However, this is not considered to be a necessary condition for IAD (King et al. 2013).

[3]Beard (2005) identifies the theoretical concepts underlying the IA assessment tools in his review.

[4]For a detailed review of Internet addiction assessment tools, translated versions, and further possible improvements, see King et al. (2013).

In summary, the IAD concept needs additional research. Studies should be methodologically comparable and focus on each area of Internet use (SPIU). They should also consider cultural differences. This is of great importance, given the possible implications of the phenomenon, and increased demand for clinical treatment (Kormas et al. 2011; Alavi et al. 2012; Tonioni et al. 2012).

94.4 IAD Determinants

The Internet provides a new lifestyle for the population by providing immediate and extensive information. It also enables interaction with others and/or software through a wide range of leisure activities. Individuals can interact in an unlimited and "anonymous" way. However, several negative aspects balance these positive ones. Particularly, the Internet can be overused as a maladaptive coping strategy. It may become a "vector of social reward," source of "displacement from offline to online social interactions" or "compensation strategy" for life difficulties (Shen and Williams 2011). Some aspects of psychopathology are associated with problematic Internet use such as personality traits and environment characteristics (Shen and Williams 2011).

Risk factors contributing to the development of PIU have recently been investigated (Tsitsika et al. 2011). Data on European college students suggests that young males who lack emotional and psychological support are more likely to demonstrate PIU (Durkee et al. 2012). Psychoticism was also linked to excessive Internet use in a recent study on Greek adolescents (Fisoun et al. 2012).

In addition to sociodemographic and psychological determinants, neuroimaging studies have been conducted. These demonstrate similarities between IAD and substance abuse disorders, suggesting there may be common neural substrates. Cue-induced craving for online activities, for example, has shown the same functional cerebral images as substance dependence (Ko et al. 2009). Similarly, reduced dopamine levels and glucose metabolism have been found in cerebral regions associated with impulse control and reward processing (Schoenbaum et al. 2003). Enhanced reward sensitivity and reduced loss sensitivity have also been reported (Dong et al. 2011a). These neural findings in IAD subjects give weight to the addictive spectrum theory.

In comparison with controls, people with IAD show impaired executive functions. This includes longer reaction times and a greater number of errors in a color-word Stroop task (Dong et al. 2011b). Poorer cognitive control has been reported (Dong et al. 2010). Delayed strategy learning is possibly more marked than in other addictive behaviors (Sun et al. 2009). However, compared to drug abusers and pathological gamblers, people with IAD demonstrate better response inhibition (Sun et al. 2009). Decision-making in college students has been found to improve in IAD subjects during a repetitive risky condition task (IGT).[5] This is reported to

[5]Iowa Gambling Task (IGT) tests the somatic marker hypothesis postulating that biasing signals, arising from neural emotional circuitry, influence reasoning. (Bechara and Damasio 2002).

be due to better implicit emotional learning skills, when compared to healthy controls (Ko et al. 2010). Further studies should investigate more precisely the cognitive and emotional mechanisms involved in IAD. They should also determine whether impaired cognitive skills are a preexisting condition or a secondary consequence of IAD.

In addition to functional impairments, structural cerebral changes have been reported in adolescents with IAD. These include a lower location for gray matter density (Zhou et al. 2011) and white matter abnormalities in the cerebral areas involved in working memory (Le Bihan et al. 2001).

From a longitudinal perspective, IAD has been alternatively conceptualized as (a) **temporary** (e.g., Internet novelty) (Kraut et al. 1998; Widyanto and McMurran 2004), linked to **stressful life events** (Armstrong et al. 2000) or a **dependent** phenomenon (Shek and Yu 2012), or as (b) a **persistent disorder** with underlying **personality traits** (self-reliance, emotional sensitivity, reactivity, vigilance, nonconformism, low self-disclosure) (Young and Rogers 1998). It may also meet certain needs (i.e., providing a sense of belonging and information for neurotic subjects and communication and relationships for extraverted subjects) (Amiel and Sargent 2004). Recent findings demonstrate the stability of IAD over time (1 year) for Asian adolescents. There were no demographic factors found that could predict the duration of the excessive behaviors. Given these findings, early interventions to treat problem Internet users appear important (Shek and Yu 2012).

Identifying long-term risk factors for IAD is also important in order to guide preventive healthcare and improve Internet governance policies.

94.5 IAD and Related Disorders

Excessive Internet use has been reported to correlate with numerous conditions including impaired social and professional functioning, some personality traits, and psychiatric disorders.

Family dysfunction or problems, poor academic performance, and limited hobbies have been found to be more frequent for teenagers with IAD (Huang and Leung 2009; Tsitsika et al. 2011). In adult samples IAD included a self-perceived negative impact on family, partners, work, emotional state, hobbies, sleep quality, friendships, and health (Achab et al. 2011; Bergmark et al. 2011). However, no longitudinal data currently exists on this. Comorbid psychopathology with PIU has received some scientific interest. Two recent reviews (Ko et al. 2012; Carli et al. 2013) summarize the published findings, the majority of which use Asian samples. In the cited studies, PIU was significantly associated with depression, ADHD, anxiety, obsessive-compulsive symptoms, and hostility/aggression. Surprisingly, PIU was not found to be correlated with social phobia (Carli et al. 2013). The strongest link was found between PIU and depression (Carli et al. 2013) (major depressive disorder, dysthymic disorder, and suicidal ideation). It is possibly linked to Internet-based perceived social support, escapism, achievement, and sense of control (Ko et al. 2012). The clinical results are

consistent with the common biological vulnerability found within depression and IAD (i.e., transporting serotonin polymorphism) (Wrase et al. 2006). The literature review also highlighted more ADHD symptoms in children and adults with IAD. Furthermore, a tendency to become addicted to the Internet was found for adolescents with ADHD. This could be explained by some Internet characteristics (e.g., rapid response, easier and delayed interpersonal relationships, immediate reward, multiple stimulating tasks). Such characteristics may serve to reduce boredom and provide stimulation and a sense of efficiency. However, the contribution of these potential gains is yet to be established. Methylphenidate showed possible efficacy in treating coexisting IAD and ADHD, in favor of possible common biological substrate (Ko et al. 2012). PIU was also associated with the presence of a hostility trait. Internet could be a means of expressing this personality trait or escaping from resulting interpersonal difficulties in the real world (Ko et al. 2012). An association was found between social anxiety symptoms and PIU. This is proposed to be due to online social support and avoidance of face-to-face interactions, provided by the Internet (Ko et al. 2012). One study (Yen et al. 2012) showed that symptoms decreased during online social interactions in comparison with offline interactions. This suggests that progressive exposure to social situations could be a suitable psychotherapeutic approach. Surprisingly in a recent systematic review of publications, no correlation has been found between PIU and social phobia, after controlling for confounding variables[6] (Carli et al. 2013). The cooccurrence of IAD and substance use disorders has been reported in some studies involving adolescents. However, the link remains unclear (problematic behavioral model, common neurocognitive substrates) and needs further research (Ko et al. 2012).

In summary, the causality and the evolution of disorders related to IAD are yet to be clearly established. Longitudinal studies using large and representative samples are required.

94.6 What Is Addictive About the Internet?

To understand what is addictive about the Internet, comparisons with substance addiction are useful. We can take the example of tobacco smoking. When people refer to a tobacco addiction, it is in fact the nicotine in the tobacco that is addictive. Therefore, we need to make some clarifications. When we speak about tobacco, the distinction should be made between:

1. Addictive products (nicotine)
2. First-order vectors: the carrier of the addictive substance (tobacco leafs)
3. Second-order vectors: the mode of consuming tobacco leaf (in cigarettes or pipes)

If we apply this distinction to the Internet, it helps to clarify the concept of Internet addiction. From this perspective, the Internet itself is simply a vector of addictive products. If we refer to our example, the computer or smartphone

[6]For a detailed review, see Carli et al. (2013).

(hardware) are the first-order vectors (the carrier of a product). Hardware has different characteristics which influence how or when a product can be used. This may be constant (smartphone), difficult to access (expensive Internet café in some countries), high-speed connection or not, etc. The software (online games, social networks) are the second-order vector.

If we want to understand what is addictive about the Internet, we have to identify the addictive product on the Internet. This product may be delivered in a more or less efficient manner. Using our example of tobacco consumption, some pertinent questions are as follows: Is it easy and cheap to find tobacco? How should it be consumed? (in a cigarette or chewed?) But these questions are relevant only if tobacco contains nicotine; without nicotine, no addiction process is possible.

To understand what is addictive about the Internet, specific stimuli that are available online need to be studied. Causes of behavioral addictions are now understood to be salient stimuli that trigger the reinforcement process (via the mesolimbic dopaminergic system). This leads to compulsive and automatic behaviors (Walter et al. 2005). Rewards generated by substance abuse are triggered by the neurobiological actions of the substance. This leads to an increase in the extracellular concentration of dopamine in the nucleus accumbens (Volkow and Li 2004). Increases in dopamine can also be achieved by nonpharmacological stimuli such as monetary rewards (Izuma et al. 2008). Similarly, this effect can be created by sexual stimuli, social acceptance, fairness, cooperative social interactions (Tabibnia and Lieberman 2007), social hierarchies, or humor. Internet software (the first-order vector) can contain varying amounts of salient stimuli. The intuitive idea that gaming or social networking software are more addictive than work software is true when looking at the amount of salient stimuli in these programs.

To be addictive, the presence of salient stimuli alone is not enough. The schedule of the rewards in terms of amount and frequency is crucial to the addictiveness of any stimuli. A parallel with gambling is useful here: The addictive properties of slot machine (fast-paced rewards, delivered in a reinforcing manner) are greater than those of a once-weekly lottery game, with low gain probability (Griffiths 1999). One theory that explains the addictive properties of Internet contents is operant conditioning (Skinner 1977). According to this theory, the likelihood of a specific behavior is increased or decreased through positive or negative reinforcement. Different types of operant conditioning exist, but the vast majority, found in Internet addictive components, are *variable-ratio schedules*: These arise when a behavior is reinforced after an unpredictable number of responses. Variable reinforcement schedules create a high steady rate of responding and are efficient for maintaining a behavior. This type of schedule is mostly seen in online role-playing games where repeated actions by an avatar can trigger a variable reward. An example is the repeated action of killing enemies in games. In World of Warcraft, the most popular massive online role-playing game, most of the actions involve defeating monsters. When a monster is defeated, the avatar gains a virtual reward. There are similarities, here, with the reward schedule used in slot machines. The avatar has a small chance of winning a rare item such as a powerful weapon. Winning this weapon can be compared to winning the jackpot in a slot machine, as

the probability of winning modest rewards (1X your bet in slot machines or a "standard weapon") is higher. Social network programs such as Facebook use the same mechanism. The whole structure of Facebook promotes certain behaviors or actions: posting comments, videos, and pictures and obtaining a reward (a number of friends answering to this post or liking this post). The number of comments or likes varies in terms of time and quantity. As mentioned before, the content of these comments is salient stimuli (positive social interactions, social acceptance).

In conclusion, the distinction between vectors and products helps us to be more accurate when defining an Internet addiction. Internet is then probably a vehicle of possible addictive products. The identification of specific stimuli and operant conditioning mechanisms present in the Internet product will predict their addictive risks. It is therefore not surprising that the contents of MMORPGs (first-order vector) are one of the most addictive products on the Internet as these contain numerous salient stimuli. Furthermore, rewards are mainly delivered on a variable-ratio schedule.

94.7 Treatment of Internet Addiction

Today there are many specialized clinic treatment programs which exist mainly in Asian countries. These are also found in Europe and English-speaking countries. The programs are often developed in association with dedicated gambling addiction programs. There are however limited publications on the efficacy of such treatments. The few existing publications (Khazaal et al. 2012) primarily relate to interventions inspired by cognitive-behavioral therapy (for details, see Table 94.1). Pharmacotherapy in Internet addiction has also known few scientific interest (Achab, Bertolini and Karila 2012).

A preliminary meta-analysis (Winkler et al. 2013) highlights the limited number of existing controlled studies. Findings highlighted a number of limitations such as absence of clear definition for the disorder treated and limitations of the instruments used. Moreover, there are omissions in the description of participants and inclusion processes. A further difficulty is linked to the wide diversity of Internet-related disorders. The Internet may amplify another primary addiction (sexual behaviors, purchasing, gambling). It can also be integral to the structural characteristics of a primary addiction (MMORPG-type video games). The vast majority of studies describe interventions for people presenting with a MMORPG addiction.

94.7.1 Nonspecific Approaches

Currently, the studies that have been published are based upon current techniques for addiction treatment. These include self-support concepts adapted from the 12 steps model, rehabilitation programs in residential setting, the motivational approach, cognitive-behavioral techniques to identify triggers and cognitive distortions, and psychoeducation for emotions (King et al. 2011, 2012). It is not often clear

Table 94.1 Psychosocial treatment for Internet addiction: open-label studies and controlled trials

Publication	Assessment	Method	Population	Treatment	Outcome	Effect size
Bai and Fan (2007) China	Chinese addiction scale – revised	Open-label study $N = 48$	College students Age: $m = 19$ 16.7 % women	Multilevel counseling model: CBT, social competence training, self-control strategies, communication skills (in group)	Reduction of Internet addiction symptoms	IA: 1.45
Cao et al. (2007) China	YDQ/Chinese addiction scale revised/screening for childhood related anxiety disorders	Open-label study $N = 57$	2,620 students from four middle schools of Changsha City were surveyed using YDQ Following clinical interview, students who met IA criteria were recruited	CBT	Reduction of emotional symptoms Reduction of addiction symptoms	IA: 1.09 Anxiety: 0.78
Du et al. (2010) China	Beard's Diagnostic Questionnaire	Randomized controlled trial $N = 56$	School students Age: $m = 12$–17 Met diagnostic criteria according to Beard's Diagnostic Questionnaire	Multilevel school-based intervention involving 8 sessions of group-based CBT	Reduction of Internet use and anxiety Improvement in time management Treatment gains observed at 6 months follow-up	Posttreatment IA: Cohen's $d = 1.08$ Follow-up (6 months) IA: Cohen's $d = 1.35$
Kim (2008) Korea	Korean Internet addiction	Controlled trial $N = 25$	University student Volunteers from a sample of 32 Internet addicts who were screened	Group counseling Reality therapy (5 weeks)	Reduction of Internet addiction symptoms Increase in self-esteem	Not reported
Lanjun (2009) China	Internet addiction scale, State-trait anxiety inventory for adults	Open-label study $N = 70$	College students 45.71 % women	Multilevel counseling model: CBT + sport	Reduction of anxiety Reduction of addiction symptoms	IA: 2.98 Anxiety: 0.43

Li and Dai (2009) China	Chinese Internet addiction scale	Controlled trial $N = 76$	Adolescents 10.53 % women	CBT (individual)	Reduction of addiction symptoms	IA: 1.46
					Reduction of anxiety, depression, and compulsions	
Orzack et al. (2006) US	Orzack Time Intensity Scale (OTIS)	Open-label study $N = 32$	Men age: $m = 26$–59	Multilevel counseling model: CBT, readiness to change, motivational interviewing	Better quality of life	Time: 0.27
	Beck Depression Inventory		Involved in Internet-related problematic sexual behavior		Reduction in depressive symptoms; patients with comorbid anxiety/mood disorders responded best to treatment	Depression: .35
Su et al. (2007) China	Young Diagnostic Questionnaire (YDQ)	Controlled trial $N = 65$	University students recruited from a university in Beijing	Self-help (3 types)	For all groups	YDQ: Cohen's $d = 0.72$–0.82
			Voluntary screening with YDQ ($N = 91$) – participants: classified as "dependant" or "at risk" according to YDQ or being online for more than 14 h per week		Reduction of addiction symptoms	
					Reduction in hours spent online	Online activity: Cohen's $d = 0.75$–0.98
Young (2007) US	YDQ Hamilton depression scale	Open-label study	Clients seen through the "Center for Online addiction" screened using the IAT	CBT (12 sessions)	Reduction of clients' thoughts and behaviors related to compulsive Internet use	IA: 0.93 Time: 2.38
			42 % women		Gain observed at 6 months follow-up	
			Age: $m = 38$ for men			
		$N = 114$	$m = 46$ for women			

IA Internet addiction, *CBT* cognitive-behavioral therapy

whether individual or group interventions have been used. When Internet use arises as part of another addiction, the clinical approach focuses on that domain (see chapters VII-3, VII-6, VII-8). There has also been an emergence of Internet-based therapeutic programs (Su et al. 2011). These can be a suitable gateway to care for intensive electronic media users (Zematten et al. 2010).

94.7.2 Treatment of Comorbidities and Pharmacological Approaches

Two pilot studies have investigated methylphenidate and bupropion for people with a MMORPG addiction. At posttest (6–8 weeks), a reduction in the length of gaming sessions in addition to a reduction in cue-induced brain activity was observed (Han et al. 2009, 2010). However, the study on methylphenidate included a population with ADHD and also included a high dropout rate. The study on bupropion excluded subjects with a comorbid axis I diagnosis. In practice, so far, no medication has received accreditation for the treatment of behavioral addictions. In clinical practice, the indication of pharmacotherapy is then based on the presence of possible comorbid disorders such as symptoms anxiety or mood disorders (Ko et al. 2012).

94.7.3 Cognitive-Behavioral Approach for Family Members and Significant Others

To our knowledge, a single randomized study has been published for family approach of Internet addictions (Du et al. 2010). The study focused on young adult online players. A multimodal behavioral intervention for groups was evaluated. The program emphasized communication techniques and management of triggers, alongside parents monitoring their children's emotions. It also included problem-solving techniques and practical advice for parents on limiting home Internet use. In addition, an electronic media awareness program for relevant school professionals was implemented. When compared to the control condition, a significant reduction in Internet use was observed at posttest and maintained at 6 months follow-up. A lasting reduction in anxiety and improved time management were also observed.

Abstract

Internet gaming disorder is one of the main types of Internet-related disorders. Recently, and despite inconsistencies in classification and limited data regarding the etiology of the condition, Internet gaming disorder has been included in Sect. 3 (research appendix) of the DSM-5. The focus of the current chapter was the dysfunctional involvement in a specific type of video game which has some inherent characteristics reinforcing its addictive nature: Massively Multiplayer Online Role-Playing Games (MMORPGs). MMORPGs are indeed one of the most recent and popular types of video games played worldwide, and problematic and uncontrolled involvement in playing MMORPGs is the most frequently reported activity by people seeking help for an Internet-related problem. In this chapter, we first described the specific structural characteristics of MMORPGs

themselves (e.g., permanent world, reinforcement schedule, advancement systems, interface favoring social exchanges) and explained how they can increase their "addictive potential". Then, the main psychological factors (motives to play, impulsivity traits) were reviewed alongside neurobiological features (e.g., changes in neural circuitry involved in controlled regulation of behavior and reward drive) related to the development and maintenance of MMORPG addiction. The few available studies having tested the efficacy of treatments targeting Internet and video game addictions were also briefly considered. Limitations of existing data are emphasized, and avenues for further research proposed (both at the theoretical and clinical levels).

95.1 Introduction

There is growing evidence to support the claims that the use of the Internet can become dysfunctional and cause negative impact in daily living and has given birth to the construct of "Internet addiction." Internet addiction is generally considered as an addictive disorder that shares most features of drug addictions (i.e., salience, craving, tolerance, loss of control, mood modification, withdrawal, relapse). Over the last few years, there have been a number of calls to incorporate Internet addiction as a new diagnostic category in the next edition of the DSM. However, the DSM-5 task force recently decided that there is not enough empirical research to warrant inclusion of "Internet addiction" as a new psychiatric disorder in the DSM-5.

The validity of the Internet addiction construct is challenged by theoretical and empirical concerns. Internet addiction is indeed an umbrella construct that encompasses a variety of different dysfunctional behaviors related to the involvement in online activities that do not necessarily coexist (e.g., video game playing, cybersex, social networking, online gambling, etc.). Nevertheless, the empirical evidence regarding the risk factors that are shared among cyber addictions (i.e., factors implicated in the etiology of all cyber addictions) from those that are specific (i.e., factors implicated in the etiology of a specific cyber addiction, e.g., online gambling) is scarce. Another concern is raised by the elevated comorbidity rates between cyber addictions and other psychiatric disorders, which implies that cyber addictions can be either primary or secondary disorders (e.g., resulting from a depressive disorder) (Gentile et al. 2011).

Recently, and notwithstanding inconsistencies in classification and limited data regarding the course and the etiology of the condition, **Internet Gaming Disorder** has been included as a new clinical entity in Sect. 3 of the DSM-5 (Petry and O'Brien 2013). The goal of this section is to foster research on the conditions included therein. In this context, the current chapter focuses on the dysfunctional involvement in a specific type of video game which has some inherent characteristics reinforcing its addictive nature: Massively Multiplayer Online Role-Playing Games (MMORPGs). Problematic and uncontrolled involvement in playing MMORPGs is indeed the most frequently reported activity by people seeking help for an Internet-related problem (e.g., Thorens et al. 2013).

95.2 Massively Multiplayer Online Role Playing Games (MMORPGs)

95.2.1 Structural Characteristics of MMORPGs

MMORPGs are one of the most recent and popular types of video games played worldwide. An estimation of the total number of MMORPG players around the world is 20 million. MMORPGs are a type of computer role-playing game in which a large number of players interact with one another in a **persistent** virtual world – an environment that exists independently of the players. Consequently, both events and interactions between other players occur while the user is absent from the persistent world. In MMORPGs, players assume the role of a fictional character (often in heroic-fantasy-based worlds such as the one depicted by writer J. R. R. Tolkien in the saga "*Lord of the Rings*") and take control of many of that character's actions. Character creation typically involves various components such as the selection of an avatar (i.e., a visual representation of the character in the virtual world) but also specific skills and attributes that define the character (e.g., gender, race, profession, physical aspects). The concept of **advancement** is a fundamental characteristic of playing MMORPGs, implying that a user's character will acquire new powers, skills, and items (i.e., objects that can be found in the game, such as a special weapon or gold pieces) as rewards for succeeding in certain missions or quests (e.g., defeating an opponent or exploring a special place in the virtual world). Another important feature of playing MMORPGs is **social interaction**. It is indeed possible, when playing, to communicate easily with other players (written chat or audio). Furthermore, players can also regroup themselves in virtual social networks named guilds, which are persistent hierarchical organizations of characters with common objectives and backgrounds. Each guild has its own rules and users who want to be enrolled generally need to present their motivations and proofs that their characters meet the guild's requirement. These abovementioned specificities (permanent world, advancement and reinforcement system, social interactions aspects) have been proposed as **structural characteristics** reinforcing the addictive nature of this specific type of video game (e.g., King et al. 2010). It has, for example, been shown in a longitudinal study by Smyth (2007) that MMORPG players, in comparison to other types of video game players (e.g., arcade, console or solo-computer players), reported significantly more hours spent playing, worse health (e.g., more cigarettes smoked, less physical exercise, worse sleep quality, etc.), and greater interference in real-life socializing and academic work at a 1-month follow-up. This finding was confirmed in a recent cross-sectional study by Kuss et al. (2012) that emphasized MMORPG players (compared to those playing other types of video games) more often displayed signs of dysfunctional use. In the last years, a growing number of studies have focused on problematic involvement in video games and more particularly in the playing of MMORPGs (see Kuss and Griffiths 2012a, for a review). Most of these studies, which have considered dysfunctional use within the framework of "behavioral addictions", tried to identify the **psychological factors** and/or the **neurobiological correlates** involved in its development and maintenance.

95.2.2 Psychological Factors

Two types of psychological factors have been extensively investigated in relationship to MMORPGs overuse: (1) motives to play online and (2) individual differences in self-control.

Recent research on MMORPGs revealed that an individual's motivations for playing have an important role in the onset of online game involvement and in its continuation (Billieux et al. 2013; Yee 2006). A critical step regarding the comprehension of players' motives resulted from the work of Yee (2006) who explored players' motives through an online survey including 3,000 users of *World of Warcraft* (currently the most popular MMORPG worldwide). Yee's study revealed the existence of three broad types of motivations, namely, the achievement motive, the social motive, and the immersion (in a virtual world) motive. Each of these broad motives can actually be divided into subcomponents (e.g., the social factor comprises separate motives such as liking socializing while playing, playing to create new relationships, or seeking to solve problems through teamwork). A growing number of studies tried to identify motives to play online that predict the involvement in dysfunctional online gaming based on Yee's model of players' motives (e.g., Billieux et al. 2011, 2013; Kuss et al. 2012; Yee 2006). On the whole, these studies revealed that specific achievement- and immersion-related motives are strong predictors of problematic online gaming (as reflected by scales measuring symptoms of addiction and impact in daily life). Regarding achievement-related motives, problematic use was consistently associated with "advancement" (i.e., the desire to gain power, progress rapidly, and accumulate in-game symbols of wealth or status) and "mechanics" (i.e., interest in analyzing the underlying rules and system in order to optimize character performance). Regarding immersion-related motives, systematic relations were highlighted with "escapism" (i.e., the need to play to avoid thinking about real-life problems). The "role-play" component of the immersion motive (i.e., the aspiration to create a character with a background story and to interact with other players according to it) was also related to problem gaming, although the size of the highlighted associations was smaller ($r < 0.30$). In contrast, the available studies based on Yee's model consistently emphasized that social-related motives (e.g., playing to meet people or teamwork) are not related to problematic use. These data sustain that dysfunctional engagement in MMORPGs can either result from an uncontrolled drive to look for achievement in the game or be the consequence of a maladaptive strategy used to cope with negative affect (e.g., boredom, anxiety, dysphoria). This assumption has recently received support by a study of Billieux et al. (2013) using *avatar* monitoring techniques (i.e., measuring behaviors made by players in the virtual world by their character). Results of the study indeed highlighted that the escapism motive is unrelated to actual in-game behaviors, as well as to progression in the game (measured through an 8-month avatar monitoring), implying that escapers play to be immersed in a virtual reality more than to reach specific objectives in the game. In other words, it can be postulated that for certain problematic players, the game is used as a kind of dissociative technique to escape real life.

A large body of evidence tied dysfunctional video game use (and more largely Internet-related disorders) to poor self-control (e.g., traits of impulsivity and sensation seeking, lack of inhibitory control, impaired decision-making, reward drive) (see Billieux and Van der Linden 2012, for a review about Internet-related disorders and self-regulation).[1] This focus on self-control and impulsivity lies in the fact that dysfunctional video game involvement is most of the time conceptualized as an addictive behavior and that uncontrolled use is a key symptom of this disorder (King et al. 2013).

Several studies have highlighted that video game addicts have higher levels of self-reported impulsivity. In particular, a study by Gentile and colleagues (2011) found in a 2-year longitudinal study that greater impulsivity acts as a risk factor for the development of problematic use of video games. Impulsivity is however an umbrella construct that encompasses a combination of multiple and separable psychological dimensions. In the last decade, a growing number of researches supported a model that clarifies the multidimensionality of impulsivity by subdividing it into four dimensions, which are related but also specific (the UPPS model of impulsivity; Whiteside and Lynam 2001). These four dimensions are defined as follows: urgency, the tendency to act rashly when experiencing intense emotions (both positive and negative); premeditation, the tendency to take into account the consequences of an act before engaging in that act; perseverance, the capacity to remain focused on a boring and/or difficult task; and sensation seeking, the tendency to enjoy and pursue new and exciting activities. Notably, a growing number of studies have highlighted specific links between these impulsivity facets and various psychiatric disorders (e.g., substance abuse, problem gambling, compulsive buying, suicide ideations and attempts, aggressive behaviors). Recent studies showed that problematic MMORPG involvement (measured with scales assessing addiction symptoms, such as loss of control, as well as with the related impact on various spheres of daily life) is firstly predicted by the urgency facet of impulsivity (when controlling for other impulsivity components), although relationships with low premeditation and perseverance were also emphasized (Billieux et al. 2011, 2014). In contrast, the sensation-seeking facet of impulsivity was inconsistently related to problematic MMORPGs use (and more largely Internet overuse). A potential explanation for the absence of a systematic relationship between sensation seeking and dysfunctional MMORPGs use is that the questionnaires targeting this impulsivity component probably do not assess how people seek stimulation and rewards through online game involvement.

Recent evidence suggests that the various facets of impulsivity are related to specific psychological executive and motivational mechanisms involved in the regulation of behaviors. More precisely, it has been emphasized that three of the dimensions of impulsivity (urgency, lack of premeditation, lack of perseverance)

[1] See Billieux and Van der Linden (2012) and Kuss and Griffiths (2012a) for comprehensive lists of publications having investigated self-regulation-related constructs in Internet and video games addictions.

are related to executive mechanisms underlying self-control abilities (e.g., inhibitory control, decision-making abilities, resistance to cognitive interference), whereas the last dimension (sensation seeking) rather depends on motivational mechanisms related to reward sensitivity and approach tendency. Behavior thus depends on the interaction of controlled (conscious) processes with automatic processes (less conscious). For example, when faced with a critical internal or external stimulus (e.g., a cybercafé, an unexpected pop-up related to an online game, an emotional state), a MMORPG player is susceptible to experience intrusive thoughts and/or craving about the game, which can automatically trigger the approach motivational system involved in reinforcement seeking. In such a situation, the capacity of this player to exert self-control (e.g., voluntary inhibiting the gaming behavior) will depend on the effectiveness of its controlled (or executive) processes. These last years, a few studies highlighted that video game addicts (in comparison to matched control participants) are characterized by impairments in a specific executive mechanism involved in self-control, namely, the ability to suppress prepotent responses (e.g., Littel et al. 2012). Furthermore, it was also demonstrated that individuals having dysfunctional involvement in MMORPGs display poor decision-making ability (e.g., Pawlikowski and Brand 2011). Although these studies shed some first light on the self-control deficits involved in uncontrolled MMORPGs use, further studies are required to confirm and strengthen the findings, as well as to explore other mechanisms involved in self-regulation (e.g., reinforcement learning, resistance to cognitive interference).

Other potential psychological factors involved in the etiology of online game addictions have been considered, although they remain currently less investigated than the factors mentioned above. For example, individual differences in self-esteem (i.e., the extent to which individuals view themselves as likeable and worthy) predict the involvement in online games. Several studies indeed revealed associations between a low level of self-esteem and symptoms of MMORPG addiction (e.g., Billieux et al. 2014), which suggests that excessive playing can serve to approach a more ideal virtual self by avoiding the actual self. Another line of research focused on the potential role of schizotypal personality (and related manifestations such as delusions) in the onset of excessive involvement in Internet-related activities, including MMORPGs (e.g., Mittal et al. 2013). Although preliminary, these studies suggested that schizotypy-related behaviors can promote the development and the perpetuation of over involvement in online games. Further research is thus required to extend our comprehension of the various psychological mechanisms (and their interactions) in the etiology of online game addictions.

95.2.3 Neurobiological Factors

A number of neurobiological factors have been found to be associated with Internet and online gaming addiction. In a recent systematic literature review, Kuss and

Griffiths (2012b) found that in eighteen empirical studies,[2] neuroimaging has been used in order to elucidate Internet and gaming addiction against the background of more traditional substance-related addictions. State-of-the-art neuroimaging techniques have been used in the included studies, namely, electroencephalograms (EEG), positron emission tomography (PET), single-photon emission computed tomography (SPECT), as well as functional and structural magnetic resonance imaging (fMRI and sMRI). With EEG, brain activity in the cerebral cortex is assessed. PET measures the level of positively charged electrons in the brain which provides an indicator for metabolic neuronal activity, whereas SPECT measures neuronal activity following the injection of radioactive tracers. With fMRI, brain blood oxygen levels are quantified in order to demarcate regions of activity. Finally, sMRI images brain structure, using methods such as voxel-based morphometry (VBM) and diffusion-tensor imaging (DTI).

Using these neuroimaging techniques, the systematic literature review revealed that Internet and gaming addiction are in no way inferior to substance-related addictions on three levels. On a biochemical level, frequent engagement in online and gaming activities has been shown to alter neuronal dopamine levels via reductions in dopamine transporter availability. This may lead to molecular dysfunctions in the dopaminergic system. On the level of neural networks, brain alterations appear as a result of excessive engagement with the Internet and online games. The brain adapts to the perpetual reinforcing stimulation and in turn becomes desensitized to natural reinforcers and thus needs more of the former, putting in motion a vicious cycle. The studies show that the function and structure of the orbitofrontal cortex gyrus changed as a consequence of excessive Internet use and gaming. The latter becomes more salient for the users who lose control over their behaviors. They have learned to use the Internet and games compulsively to recreate neuronal homeostasis. Finally, studies combining neuroimaging and behavioral techniques confirmed that people suffering from Internet and gaming addiction develop a number of cognitive deficits, including impairments in executive and attentional controls. However, on the bright side, a number of skills are advanced in this group. Studies indicate that the integration of perceptual information to the brain via the nervous system is facilitated, and hand-eye coordination is improved (Kuss and Griffiths 2012b).

In sum, state-of-the-art neuroimaging research offers compelling evidence for the similarities between Internet and gaming addiction with substance-related addictions. From the cited review, it appears that Internet and gaming addiction can be classed as behavioral addiction as the former fulfills a variety of characteristics that typify addictions. Correspondence between addictions exists on a molecular, neurocircuitry, and behavioral basis, indicating the addiction may best be conceptualized as a syndrome with common etiology, but different manifestation (Shaffer et al. 2004).

[2]For a detailed listing and evaluation of included empirical studies, refer to the original systematic review paper (Kuss and Griffiths 2012b).

95.2.4 Treatment of MMORPG Addiction

Internet addiction in general and addiction to playing MMORPGs are relatively new clinical phenomena. Consequently, research on their treatment is limited. However, a couple of systematic studies with the goal of evaluating treatment effectiveness have been published (King et al. 2011; Liu et al. 2012). Each of these is briefly outlined.

King et al. (2011) made use of the gold standard of clinical trial evaluation, the CONSORT (Consolidated Standards of Reporting Trials) statement (Schulz et al. 2010), in order to evaluate Internet addiction treatment studies (including MMORPG addiction). The CONSORT statement sets out a number of quality indicators for pharmacological and non-pharmacological clinical trials, such as transparence in justifying and reporting study methodology. These include stating eligibility criteria for participants, description of respective treatments, and a power analysis for the utilized sample size (Schulz et al. 2010). Only eight studies[3] met the established criteria, including one randomized controlled trial. The included studies differed significantly in design, definition, and assessment of Internet addiction, treatment, follow-up assessments, randomization and blinding, sampling, and recruitment. As regards treatment, it was particularly varied ranging from cognitive-behavioral therapy (CBT), motivational interviewing (MI), reality training, and individually designed therapy including psychological and or counseling elements. Overall, treatment was provided by trained professionals or via especially developed computer programs, lasting between one session and 19 months in total (King et al. 2011).

For their empirical review, Liu et al. (2012) selected Internet addiction outcome studies based on whether they reported treatment outcomes, included young Internet addiction patients aged 9–23 years, and were carried out in China, resulting in a final sample of 24 studies.[4] In order to evaluate these studies, criteria from the CONSORT statement were adopted including objectivity, sample size, power, outcome, randomization, active comparison, baseline, manualization, treatment adherence rating, collateral report, objective measures, intention to treat (ITT) analysis, and blinding. In terms of the outcome, more than half of the included studies were considered "methodologically strong" in sequence generation and ITT analysis, however weak with regard to the remaining criteria. With regard to treatment approaches, exercise programs, cognitive-behavioral therapy, electroacupuncture, family therapy, group-based treatment, motivational interviewing, and psychotropic medication were used most commonly, with over 50 % of studies using multimodal techniques. On average, the effect size was high (i.e., 1.89), suggesting that Internet addiction therapy is efficacious; however, the quality of the results was found to be low. The highest effect size was found for the most prominent multimodal treatment, CBT combined with psychopharmacotherapy, i.e., 3.93, attesting to its efficaciousness (Liu et al. 2012).

[3]For a detailed description of the included studies, please refer to the original review paper by King et al. (2011).

[4]A detailed description of studies is provided in Liu et al. (2012).

From the reported reviews of treatment studies, it appears that there is no single standardized evidence-based Internet addiction treatment available to date. The treatment studies published to date offer a wide range of therapy approaches, using dissimilar diagnostic criteria and heterogeneous treatment delivery. Taken collectively, more treatment research that fulfills high-quality standards is available in the Chinese-speaking rather than English-speaking world, indicating that the problem of Internet and MMORPG addiction may be more pressing in the former. From the few studies to date, it appears that a combination of CBT with pharmacotherapy yields the most promising results. The first cognitive-behavioral therapy manual for the treatment of computer game and Internet addiction has now been published in Germany (Wölfling et al. 2013). It combines group with individual therapy sessions on an outpatient basis. The manualization of Internet and MMORPG addiction treatment may be taken as first step toward the adoption of established clinical protocols, which will benefit managing risks, implementing research findings promptly, and standardizing treatment that is more cost-effective and efficient in the long run.

95.3 Conclusion

This chapter focused on a specific disorder of the spectrum of cyber addictions, namely, the dysfunctional involvement in MMORPGs. Having explained how some specific structural characteristics of the games themselves (e.g., permanent world, reinforcement schedule, advancement systems, interface favoring social exchanges) increase their "addictive potential," the main psychological factors (motives to play, impulsivity traits) were reviewed alongside neurobiological features (e.g., changes in neural circuitry involved in controlled regulation of behavior and reward drive) related to the development and maintenance of MMORPG addiction. The few available studies having tested the efficacy of treatments targeting Internet and video game addictions were also briefly reviewed.

In concluding, it is also noteworthy to mention some key points that should be taken into account both in clinical practice and empirical research:

- The empirical bases available to support the existence and exact nature of video game addictions (and other cyber addictions) are still scarce in comparison to those existing for substance addiction and some other behavioral addictions (e.g., pathological gambling). Empirical data about treatment efficacy is clearly lacking; however, the demand for treatment is likely to increase (e.g., Thorens et al. 2013).
- Video game addictions (and other cyber addictions) can be either primary or secondary disorders. Among other things, this implies that the prevalence rates reported in the literature are most likely overestimated and/or not representative of a specific disorder (e.g., sexual addiction versus online game addiction) and that the symptoms identified are not necessarily related to the postulated disorder.

- The studies now being carried out are becoming better both methodologically (e.g., development of in-game tracking techniques) and theoretically (e.g., development of psychological models of problematic use) although there is still a heavy reliance on self-selected samples. Further studies should thus focus on the recruitment of more representative samples.
- Recent studies challenged the demographic characteristics regarding individuals involved in playing online video games. First, this activity is no longer just a male adolescent or preadolescent activity, and online games are now also played by adults. The mean age of MMORPG players in many recent studies is often between 25 and 30 years old. In addition, it appears that there is an increasing feminization of gaming with more girls and women becoming gamers.
- The gaming studies field needs to develop better instrumentation to assess the symptomatology and prevalence of MMORPG addiction with sufficient specificity and sensitivity. In addition to diagnostic tools (i.e., scales used to differentiate problematic and non-problematic gamers), it would also be necessary to develop instruments that allow multidimensional scoring (e.g., loss of control, withdrawal, conflict, craving, compromised time control, hedonic aspects, mood regulation). Indeed, available studies often provided limited comprehension of the factors involved in the etiology of MMORPG addiction (e.g., personality traits, motives), as they have too often been conducted without considering its multifaceted nature. For example, a study designed to elucidate the role of self-regulation in dysfunctional online game symptomatology would benefit from using a scale able to measure aspects such as loss of control or pleasure seeking (psychological mechanisms or processes) as separate from aspects such as negative impact upon daily living (outcomes of the problematic behavior).
- Although MMORPGs appear to be more attractive video games when compared to "stand-alone" console-type games (due to structural characteristics such as 24/7 availability mentioned above), other less researched genres of online gaming (such as Real Time Strategy Games and First Person Shooters) may also require similar consideration in the future.

Compulsive Buying Disorder

96

Tatiana Zambrano Filomensky and Hermano Tavares

Contents

Abstract

The increasing availability of credit has made buying a frequent behavior in everyone's life. Compulsive buying disorder (CBD) is characterized by loss of control over buying, accruing debts, and psychosocial distress. Reported by the founding fathers of modern psychiatry, Kraepelin and Bleuler described it as a monomania and named it oniomania. CBD may have a profound impact upon both individuals and society; however, it remains absent from current diagnostic classifications. There are still doubts regarding the psychopathology and nature of CBD; some regard it as a behavioral addiction or a member of two different groups, either the bipolar spectrum or the obsessive-compulsive spectrum of

disorders. Conservative estimates describe a prevalence around 2 % in the general population with an extra 6 % at risk for CBD. An association with female gender is usually described, but it has been recently challenged. The CBD construct is based upon three concepts: emotional activation, urges, and affect regulation. Current and lifetime psychiatric comorbidities are usual among treatment-seeking compulsive buyer, respectively, 50 % and 90 %; the most common are mood, anxiety, and impulse control disorders. Accounts of subtypes of CBD patients describe a thrill- and pleasure-seeking impulsive type and an emotionally stricken compulsive type. SSRIs in general and citalopram in particular have been used to treat CBD, but so far, its efficacy remains undetermined. The modulation of dopamine pathways within the brain reward system has been speculated as a promising pharmacological approach. So far, the best evidence-based treatment approaches come from cognitive-behavioral models.

96.1 Introduction

Since antiquity, the act of buying has been present in society. The emergence of currency modified cultural and moral values, marking a period in which power went from being determined by the family name to being defined by commerce, gaining momentum with the adoption of monetary systems (Vissering 2008). The act of buying continued to distract and enrapture people throughout the subsequent millenniums, driving commerce and influencing governmental structure. The lack of control over this behavior aroused the concern that we could be facing a clinical disorder.

Compulsive buying disorder (CBD) was described at the beginning of the twentieth century by two descriptive psychiatrists, Kraepelin (1915) and Bleuler (1924). Both founded their descriptions on Esquirol's (1838) concept of monomania. Kraepelin (1915), the first to elaborate the syndrome, titled it oniomania – from the Greek *onios* (for sale) and *mania* (insanity), describing it as a pathological impulse. He underscored the predominance of the female sex and believed that oniomania would be a subclinical variation of kleptomania. Bleuler (1924) emphasized the impulsive nature of the disorder and likened it to the insanities of impulse along with pyromania (apparently much more abundant at that period that it appears to be today) and kleptomania (Tavares et al. 2008).

CBD did not arouse the interest of researchers in the following decades, except among the study of consumer behavior (O'Guinn and Faber 1989; Elliott 1994) and psychoanalysts that elaborated case reports (Krueger 1988). During the early 1990s, three independent clinical case series studies involving 90 individuals were published, after which CBD once again returned to be globally discussed (Christenson et al. 1994; Schlosser et al. 1994), with reports originating from countries such as Germany (Scherhorn et al. 1990), Brazil (Bernik et al. 1996), Canada (Valence et al. 1988), France (Lejoyeux et al. 1997),

England (Elliott 1994), and the USA. This renewed interest was probably fostered by the perception of the profound impact that CBD may have upon individuals as well as on society. Indeed, it is estimated that in the USA compulsive consuming generates more than US$4 billion in annual purchasing (Kacen and Lee 2002; Tavares et al. 2008).

Despite being described by researchers and scholars for more than a century, CBD continues to be, inexplicably, undefined and understudied. It is absent from modern classifications in psychiatry, except possibly for the classification in the residual category of Impulse Control Disorders Not Otherwise Specified in the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR) (APA 2000) or the International Classification of Diseases of the World Health Organization, 10th Edition (ICD-10) (Filomensky et al. 2012). A possible explanation for this state of affairs is the existence of diagnostic doubts regarding the psychopathological nature of CBD. Some researchers consider CBD to be an addictive disorder, incorporating it into the classification of drug and alcohol abuse disorders, or behavioral addictions, which include pathological gambling, kleptomania, Internet addiction, and compulsive sexual behavior (Glatt and Cook 1987). Others consider CBD to be an excessive behavior secondary to mood disorders, associated within the frameworks of mania, hypomania, or mixed episodes in bipolar disorder (Lejoyeux et al. 1996), or as a subsidiary symptom of hoarding, on the obsessive-compulsive disorder spectrum (Hollander et al. 1996; Filomensky et al. 2012).

There is also a stream of researchers who criticize the attempts to classify compulsive consumption as a disorder, stating that it implies medicalization of variations within the spectrum of consuming behaviors (Lee and Mysyk 2004). Unfortunately, this view ignores the reality that CBD is a prevalent and severe syndrome and stigmatizes the attempts to recognize, understand, and treat the condition.

96.2 A Biopsychosocial View of Compulsive Buying

96.2.1 Epidemiology

Studies estimating the prevalence of CBD in the general and specific populations report rates of approximately 2–8 %. In spite of the increasing scientific and layman interest in the disorder, there is no evidence to suggest that the prevalence of CBD is increasing. A study by Faber and O'Guinn (1992) selected 292 Americans from the general population in Illinois to respond to the Compulsive Buying Scale (CBS) estimated that almost 6 % of the population would be at risk for CBD. Grant et al. (2005) evaluated 204 psychiatric inpatients and reported a prevalence rate of CBD over the lifetime of 9 %. More recently, a study by Koran et al. (2006) interviewed approximately 2,500 American adults through an anonymous telephone questionnaire. They determined a CBD prevalence rate of about 5 %, and a ratio of men to women of 1:1, which indicates a rather larger participation of men than previously reported. The anonymous nature of this telephone survey may have

helped male compulsive shoppers to be open about their difficulties. Indeed, other reports that pointed to male-to-female ratio around 1:4–1:5 were almost all conducted in clinical settings (Filomensky et al. 2012). Kraepelin and Bleuler had already proposed the predominance of the female gender in CBD, suggesting that the female compulsive buyer was in search of risk and excitement, much like the risk-seeking behavior in pathological gambling predominantly seen among men. For Dittmar and Drury (2000), the prevalence of the female gender in CBD appears as a compensation strategy to combat negative emotions and low self-esteem. They state that the gender difference is genuine and should not be attributed to the underrepresentation of males in clinical samples, basing their conclusion in a study conducted in the general population of the UK, in which 92 % of the respondents classified as compulsive buyers were women. Interestingly, in 2005 Dittmar carried out another survey about consuming behaviors in adolescents. Two-hundred and five teenagers between the ages of 16 and 18 were selected from two schools in England. The results indicated a CBD prevalence ratio similar to the adult survey, but without gender imbalance, suggesting that regarding uncontrolled shopping men are likely to catch up with women in the near future (Dittmar 2005). Nonetheless, gender differences regarding favored purchasing will likely remain, with female compulsive shoppers targeting mainly clothes, handbags, shoes, perfumes, makeup, and jewelry, while men prefer electronics and objects that display elevated social status such as expensive suits, watches, electronic gadgets, and cars (Christenson et al. 1994; McElroy et al. 1994; Black 1996, 2001).

It is believed that CBD begins toward the end of adolescence, around 18 years of age, or at the beginning of adulthood. This is the period in which the adolescent develops more autonomy and emancipation from the nuclear family, when they are likely to acquire credit for the first time (Black 2001). Nevertheless, the perception of buying behavior as a problem occurs later, around 30 years of age, and treatment seeking between 31 and 39 years of age.

Before 18 years of age, uncontrolled buying is generally associated with a more diffuse general pattern of behavioral disinhibition, which can include smoking, alcohol and drug misuse, and premature sex (Roberts and Tanner 2002). Besides, 24-h shopping made possible by online credit card purchasing could be a contributing factor to adolescent onset. Indeed, it has been reported that among computer compulsive users, up to 19 % would fulfill the criteria for CBD (Black 2001). In view of this fact, it is likely that some compulsive shoppers will enter their adult lives already with a substantial debt.

CBD is commonly associated with severe personal impairment, both financial and familial (Black 2001), as well as other psychiatric disorders, including personality disorders (Black 2007; Tavares et al. 2008). Although there are a lack of longitudinal studies for CBD, some studies indicate that the course of the disorder can be chronic or recurrent (Christenson et al. 1994; Schlosser et al. 1994). However, the treatment of CBD can modify the course of the disorder, as shown in a study in which patients who responded to treatment with citalopram maintained states of remission during 1 year (Koran et al. 2003; Aboujaoude et al. 2003).

96.2.2 Diagnosis and Assessment Scales

In 1989, O'Guinn and Faber defined compulsive buying as an addictive behavior characterized by "a response to an uncontrollable drive or desire to obtain, use or experience a feeling, substance, or activity that leads an individual to repetitively engage in a behavior that will ultimately cause harm to the individual and/or others (p. 148)," underscoring the chronic and repetitive nature of CBD. Valence and colleagues (1988) proposed that CBD was a three-pillar construct defined as follows: (1) a strong emotional activation when exposed to a shopping environment and shopping opportunities, (2) tension and buying urges elicited by the exposure to such stimuli, and (3) shopping and buying as means to obtain affect regulation, shortly lived because it is usually followed by post-purchase guilt. Moreover, it is likely that later negative consequences (indebtedness, family and friends reproaches, etc.) enhance the negative affective state, which in turn will lead to stress relief-seeking behavior through further shopping and buying, thus closing a cycle of self-reinforced behaviors. Both group of researchers developed their own scales based on these roughly equivalent approaches to CBD. One study pointed to the complementary nature of these scales, reflecting the interrelated aspects of both models. Although subtle, the difference between shopping (perusing showcases and malls and analyzing objects in display) and actual buying (the exchange of money for the acquisition of a desired object) seems relevant. Indeed, it appears that Valence's approach has a better focus over shopping behavior and its effect over affect regulation, while Faber and O'Guinn's perspective seems to better capture the extremes of uncontrolled buying, associated behaviors, and consequences. Thus, their scale may be better suited for the assessment of clinical samples. In both cases, the models suggest that CBD cannot be characterized solely by impulsive purchasing, which for that purpose has to be combined with attempts at emotional self-regulation by shopping and buying.

In 1994, McElroy and colleagues proposed the following diagnostic criteria for CBD, emphasizing the inability to resist the impulse to buy:

(A) Maladaptive preoccupation with buying or shopping, or maladaptive buying or shopping impulses or behavior, as indicated by at least one of the following:
   1. Frequent preoccupation with buying or impulses to buy that is/are experienced as irresistible, intrusive, and/or senseless.
   2. Frequent buying of more than can be afforded, frequent buying items that are not needed or shopping for longer periods of time than intended.

(B) The buying preoccupations, impulses, or behaviors cause marked distress, are time-consuming, significantly interfere with social or occupational functioning, or result in financial problems (e.g., indebtedness or bankruptcy).

(C) The excessive buying or shopping behavior does not occur exclusively during periods of hypomania or mania.

These criteria are currently the most employed, despite the scarcity of studies endorsing their validity and reliability. The lack of official and specific diagnostic criteria for CBD is an additional factor contributing to the disorder's permanence in a residual diagnostic category in the section for Impulse Control Disorders Not Otherwise Specified (APA 2000).

It is important to differentiate normal from uncontrolled buying. Essentially, the distinction is not based on the quantity of money spent in relation to the income level, but on a subjective feeling of irrepressible urges to buy, the experience of being out of control while buying (e.g., feeling as if one's behavior was led by an external force), the extent of worry, the degree of distress suffered by the individual, and the appearance of adverse and negative consequences. At any moment of their lives, people may experience an occasional shopping binge, particularly in special occasions such as birthdays or holidays. However, isolated episodes of unrestrained buying should not be confused with CBD's impulsive, harmful, and recurrent purchasing.

Several researchers have developed instruments for the investigation and diagnosis of CBD or for severity assessment. The Minnesota Impulsive Disorders Interview (MIDI), developed by Christenson et al. (1994), is a semi-structured interview that evaluates the presence of CBD, kleptomania, trichotillomania, intermittent explosive disorder, compulsive sexual behavior, pathological gambling, and compulsive exercise. Grant et al. (2005) report that based on McElroy's criteria for CBD, the MIDI presented a sensibility of 100 % and specificity of 96 %.

Faber and O'Guinn's (1992) previously mentioned scale, the CBS, is a seven-item self-report one-dimension scale with high internal consistency (Cronbach's alpha = 0.95) that seems to reliably distinguish normal from compulsive buyers, with estimated sensitivity of almost 90 % and specificity of 85 %.

Monahan and colleagues (1996) adapted the Yale-Brown Obsessive-Compulsive Scale (YBOCS – 1989) to measure the severity of CBD. The YBOCS – Shopping Version (YBOCS-SV) evaluates cognitions and behaviors associated with CBD. It has been mostly used to assess the effects of treatment in clinical trials. The mean pretreatment score for CBD patients was 21 (range 18–25), which was grossly larger than the mean score of 4 (range 1–7) for healthy controls. Unlike the other scales that base their approach on the impulse control disorder framework, due to its original source, the YBOCS-SV is able to tap into the compulsive aspects of CBD.

In that sense, the Richmond Compulsive Buying Scale is unique in its attempt to combine both impulsive and compulsive aspects of CBD. The authors also tried to address another conceptual limitation due to a tautological flaw in the definition of psychiatric disorders by which a behavioral syndrome constitutes a disorder because it implies negative consequences and the reason why it causes negative consequences is because it is a disorder. Thus, Richmond's CBS focuses on behavioral aspects of buying rather than shopping and purposefully avoids tapping into negative consequences. It has convergent validity with Faber and O'Guinn's CBS and its six-item simple structure makes it feasible for population surveys (Ridgway et al. 2008).

Other scales have been developed by various groups, but have not seen ample use; for a thorough overview of the available CBD-related scales and their psychometric properties, usage, and references, the reader may access the address http://www.knowmo.ca/capacity/addictionmeasures/addictionmeasureslist.aspx?BlogTagID=e9193db3-b04d-4b3b-aecb-fdd7c507add8 at the Know Mo website, which stands for Alberta's hub for mobilizing knowledge about addictions and mental health.

96.2.3 Psychiatric Comorbidity and Relationship with Other Mental Disorders

The association of CBD with other psychiatric disorders is the rule rather than the exception, with comorbidity most often seen with mood, anxiety, substance use, eating, and other impulse control disorders (Christenson et al. 1994; McElroy et al. 1994; Schlosser et al. 1994; Black et al. 1998, 2000; Ninan et al. 2000; Black 2001; Mitchell et al. 2006; Mueller et al. 2009).

A bicentric study analyzed data from US and Germany treatment centers and found that approximately half of the sample had at least one current psychiatric comorbidity, mainly an anxiety disorder, and that 90 % fulfilled criteria for at least one Axis I diagnosis during the lifetime. The main diagnoses were mood disorder (74 %), anxiety disorder (57 %), and impulse control disorder (21 %) of which intermittent explosive disorder was most common (Mueller et al. 2010).

It is not uncommon for CBD patients to build up collections of similar items varying one single aspect, e.g., color, size, or design, to zealously stock and hoard them, not allowing other people to interfere with them. For this reason, a relationship with obsessive-compulsive disorder (OCD) has been speculated. However, only one study has found a relevant association, reporting that seven (35 %) out of 20 patients consecutively admitted for CBD treatment had a lifetime diagnosis of OCD (McElroy et al. 1994). Conversely, CBD has been described as a frequent comorbidity among OCD and eating disorder patients (Fernández-Aranda et al. 2008, 2006), with a suggestion that in OCD such an association represents a more impulsive subtype (approximately 10 % of the OCD patients – Hantouche et al. 1997; du Toit et al. 2001). The hoarding behavior seems to be the psychopathological link between the two disorders and for both of them a marker of a compulsive trait and severity (Frosts et al. 2009). For CBD, severity goes hand in hand with psychiatric comorbidity; thus, the presence of hoarding behavior is associated with mood, anxiety, and eating disorders (Kyrois et al. 2004).

On the other hand, the frequent comorbidity with depression and unrestrained expenditure have been pointed as evidences of a link between CBD and bipolar disorder and the former as a member of the so-called bipolar spectrum of disorders (Akiskal et al. 2000). In trying to clarify if CBD should be regarded as a sub-syndromal bipolar disorder, an OCD-related disorder, or a condition apart from the spectrums of both disorders, Filomensky and colleagues (2012) investigated 80 individuals undergoing outpatient treatment for either bipolar disorder, OCD, or CBD regarding impulsivity, obsessive-compulsive traits, hoarding, and mood spectrum of symptoms. Compared to the other two conditions, CBD patients scored significantly higher on all impulsivity measures and especially on the non-planning subdimension. In the hoarding spectrum, they scored higher for the acquisition subdimension, but not for difficulty discarding or cluttering subdimensions. Manic symptoms were distinctive of BD patients, while elevated scores on the contamination/washing and checking dimensions differentiated OCD patients. A discriminant model built with these variables correctly classified

79 % of the CBD outpatients, 71 % of the bipolar patients, and 77 % of the OCD. The authors concluded that given the high impulsivity involved and the intense acquisition desire, CBD, like pathological gambling, was closer to an impulse control disorder resembling a behavioral addiction. These findings establish an interesting parallel with a previous study that described two independent factors for the occurrence of a compulsive episode: an urgency/desire to buy and loss of control over buying (Nataraajan and Goff 1991).

Regarding the acquisition desire, other authors have described that in resisting a purchase CBD patients feel like they are wasting a "must have" opportunity, correlating this feeling to excessive materialism (Kyrios et al. 2004; Mueller et al. 2011) and underscoring the semblance with impulse control disorders. The relationship of CBD with other impulse control disorders needs to be further investigated. There are evidences of comorbidity with psychogenic excoriation, compulsive eating, and other compulsive/addictive behaviors (Christenson et al. 1994; Schlosser et al. 1994; Lejoyeux et al. 1997; Mueller et al. 2009, 2011).

With regard to personality disorders, very few studies have investigated Axis II disorders in the population of compulsive buyers. The two most important studies revealed that the disorders most observed were from clusters B and C: borderline, obsessive-compulsive, and avoidant personality disorders. The first study demonstrated that around 60 % ($N = 46$) of the compulsive buyer patients presented with at least one of the personality disorders mentioned above (Schlosser et al. 1994), and the second around 73 % ($N = 30$) (Mueller et al. 2009).

96.2.4 Clinical Manifestations and Subtypes of Compulsive Buyers

Black (2007) described four phases to characterize an episode of compulsive buying: the first is the anticipation, in which the compulsive buyer experiences thoughts, anxiety, or worry regarding the acquisition of a particular object or simply the act of buying itself. The second phase is the preparation, in which the person prepares him- or herself to go shopping, including researching the desired object, deciding on the clothes that will be worn while shopping, deciding when to go, where to go, and how to pay. This phase can be rather shortened depending on the degree of emotional instability. Negative emotions such as anger, anxiety, boredom, and self-criticism have been related to compulsive episodes of buying (Miltenberger et al. 2003). When pressured by an intense negative affective state, the CBD patient feels the need to quickly perform a purchase, regardless of the nature of the purchased object, or they may feel a need to purchase an object to which they are particularly fixated, e.g., a nail polish flask, a CD of their favorite artist, etc. The purchase, per se, is the third phase, in which compulsive buyers report the emotional experience of the act of buying and the ecstasy. Finally, the fourth phase is the consummation of buying, accompanied by immediate relief of the negative affective, but often shortly followed by self-deception and unpleasant feelings such as guilt or regret. Several authors underscore this narrow association between buying and the need to regulate negative affective sates.

Compulsive buyers divert their attention away from these internal negative emotions and onto external stimuli, which generates an increase in risky compulsive behaviors (Faber and Vohs 2004; Baumeister 1991; Claes et al. 2010; Mueller et al. 2011).

In the cognitive sphere, compulsive buying episodes have been associated with means of identity building, "all or nothing" attitudes toward money, hindsight appraisal of purchasing, and gift buying as a way to garner affection and avoid embarrassment (Mitchell et al. 2006; Filomensky and Tavares 2009). Dittmar and Drury (2000) propose that self-image image building is more related to women than men.

It is common for these episodes to occur in a solitary manner, routinely or in the form of purchasing binges. Sometimes to lessen the guilt, compulsive buyers will also buy for their partners, family members, or friends. When buying for themselves, they often – though not necessarily – hide the objects in closets, drawers, or the car trunk. Many of such purchases may never be used. There is no pattern to stores or commercial places in which these episodes of excessive spending occur; however, buyers do have their "favorite" shopping places, catalogues, and online sites. A study that evaluated excessive Internet use among compulsive and non-compulsive buyers concluded that buying through the Internet is more common among compulsive buyers. The same applies for purchases made through the television (Mueller et al. 2011).

DeSarbo and Edwards (1996) described two subtypes of compulsive buyers: one group in which the principal trigger of a compulsive episode was the materialism and desire for objects with a tendency to be more impulsive and the second group in which the compulsive episode was more motivated by internal emotions such as low self-esteem and little control over the desire to buy. This second group presented with a higher propensity to develop depression. Likewise, another study pointed to two distinct groups among compulsive buyers: one in which the motivation for the purchase was guided by positive reinforcement related to pleasant aspects of the purchase and the other in which the purchase occurred as a result of emotional suffering associated with financial problems, interpersonal relationships, and emotional questions, revealing a group with significantly higher levels of debt (Thornhill et al. 2012).

Therefore, like previously described for pathological gambling, CBD seems to encompass a double nature, an impulsive side related to purchase cravings and lack of planning and a compulsive side characterized by the avoidance of negative emotions and attempts to control one's affective state, both combined lead to loss of control over buying. The determination of the subtype depends upon which side prevails (Tavares and Gentil 2007).

96.2.5 Social-Cultural Issues

Social-cultural factors alone cannot be blamed for CBD occurrence; however, it is important to consider their influence. The easy access to growing amounts of credit

is a worldwide phenomenon, and in the last decades there have been a shift in advertising strategies from focusing on the qualities of the purchase to how good purchasing makes you feel. This is especially true for countries in which the economy is consumer based (Black 2007).

An almost universal selling strategy is to anticipate the pleasure of the acquisition through credit card shopping or other option and to delay the "pain" of payment, to which impulsive individuals may be particularly vulnerable. Indeed, several measures of compulsive shopping have a strong correlation with credit card use and credit card minimum payment (Faber and O'Guinn 1992; Ridgway et al. 2008). The credit card has become a cultural icon, going beyond a mere form of modern "plastic cash," something particularly noticeable in developing economies and most appealing to vulnerable women as a promise of more autonomy in societies largely dominated by men (Hanley and Wilhelm 1992).

96.2.6 Neurobiology, Genetics, and Risk Factors

Family studies of compulsive buyers show a heavy concentration of mood, anxiety and eating disorders, substance use, and other impulse disorders, including CBD itself. Evidence also exists showing that traumatic childhood events such as sexual abuse are factors that predispose the development of CBD (Black 2007; Black et al. 1998; McElroy et al. 1994). A study of 370 gynecology patients investigated the relationship between five traumatic experiences in childhood (before the age of 12) and CBD. The results indicated that childhood trauma is associated with compulsive buying behavior, particularly when the trauma was emotional in nature or involved witnessing violence (Sansone et al. 2013). However, there are no data on how childhood trauma and early adversities can build a specific vulnerability to consuming behavior or if it would be an unspecific vulnerability factor for various psychiatric syndromes.

There are few neurobiological studies of CBD, and most are concentrated on the loss of regulation over the serotonergic, dopaminergic, and opioid neurotransmission. Due to the diagnostic doubt that haunts CBD, researchers who note similarities between CBD and OCD use selective serotonin reuptake inhibitors (SSRIs), as it is a common and effective treatment for OCD, but so far its efficacy in CBD and the role of serotonin transmission in CBD remain undetermined (Black et al. 1997; Koran et al. 2003).

Potenza (2001) proposes that compulsive purchases, pathological gambling, and other self-indulgent behaviors are related to factors involving low dopaminergic activity, the so-called brain reward deficiency syndrome (BRDS). Thus, the preferred biological tools to intervene in CBD would be those directly or indirectly modulating dopamine transmission, through opioid and glutamate modulation, in the brain reward system. Few reports have suggested the benefits of treating CBD with the opioid antagonist naltrexone, raising speculations about the role of β-endorphin and opioid receptors in CBD (Grant 2003). A preliminary study with memantine, an antagonist of the N-methyl-D-aspartate receptor, resulted in reduced

glutamate excitability, in addition to improving the compulsive buying behavior of patients with CBD (Grant et al. 2012). In any case, proposals regarding neurotransmission remain up to now speculative, with no studies so far having directly examined the neurotransmitters involved in CBD, through either plasma levels or cerebrospinal fluid.

Comings et al. (1997) found a significant correlation between the polymorphism of the D1 receptor gene and Tourette's syndrome, pathological gambling, alcohol abuse, and CBD, corroborating the BRDS hypothesis. Another study investigating the polymorphism of the promoter region of the serotonin transporter gene did not find any association with CBD. However, it is important to note that this study involved a small sample and studied only the association with alleles of small effect (Devor et al. 1999). A recent study carried out by De Neve and Fowler (2010) identified an association between the polymorphism of the MAO-A gene and a higher probability of credit card debt. The MAO-A is implicated in the metabolism of serotonin and has one or both of the variant alleles of low efficacy associated with higher probability of addiction and impulsivity.

So far, no neuroimaging studies with CBD diagnosed individuals have been conducted. Nevertheless, one study using functional magnetic resonance imaging in a nonclinical sample observed activation of the nucleus accumbens when the subjects anticipated an advantageous purchase. This is the same structure over stimulated by drug addictions, which confirms the involvement of brain reward system in buying behavior. Conversely, disadvantageous offers, i.e., excessive prices, activated the insula and deactivated the mesial prefrontal cortex, indicating the involvement of different circuitries in the decision-making process related to purchasing. Interestingly, other studies have associated the insula activity with the experience of physical pain and its emotional component (Knutson et al. 2007).

96.2.7 Treatment

96.2.7.1 Psychotherapy

Over the past 5 years, studies regarding the treatment of CBD established important advances, as what existed were previous case reports aligned to the theoretical orientation of the authors. Still, controlled studies evaluating treatment efficacy for CBD, independent of therapeutic modality, remain scarce (Kellett and Bolton 2009; Benson and Gengler 2004; Mitchell et al. 2006; Steketee and Frost 2003).

Cognitive-behavioral models remain as the most tested and studied treatment programs. The first studies were by Lejoyeux et al. (1996) and Bernik et al. (1996), both of which suggested that cue exposure and response prevention may be useful in the treatment. Bernik and colleagues (1996) reported on two cases treated with clomipramine for panic attacks, who also presented with CBD. The medication did not improve compulsive buying behavior; however, both responded well to 3–4 weeks of buying cue exposure and response prevention, although no posttreatment information was provided.

One of the first to use the cognitive behavioral therapy group were Burgard and Mitchell (2000). A pilot study carried out by Mitchell et al. (2006) involved 28 patients with CBD diagnoses for the treatment with a cognitive-behavioral model and 11 controls on the waiting list. At the end of 12 weeks, the results showed significant advantages of cognitive-behavioral therapy, with subjects outperforming the waiting list controls in terms of the number of compulsive buying episodes and time spent buying. This improvement was maintained over the following 6 months. In 2008, Mueller et al., inspired by the Mitchell et al. (2006) study, treated 31 compulsive buyers with a 12-week cognitive-behavioral intervention and compared them with 29 control patients on the waiting list. The treatment sessions specifically dealt with problems related to compulsive buying, restructuring of negative thoughts and emotions regarding buying, control over buying behavior, and problem-solving skills. Throughout the next 6 months, the patients continued to present with improvements when compared with the control group.

Imaginary desensitization was also used to treat a female compulsive buyer with a treatment package that also included motivational interviewing, financial planning, leisure, and cognitive restructuring. The final evaluation was positive, showing a reduction in compulsive episodes (Donahue et al. 2011). Another uncontrolled study reported on a cognitive-behavioral group intervention with an emphasis on cognitive restructuring. Specific sessions were devised to deal with the most common cognitive distortions related to buying such as buying as a way of coping with emotions and building an identity and "all or nothing" type of thinking. The nine patients who participated all reported improvement of both cognitions and behaviors related to CBD (Filomensky and Tavares 2009).

96.2.7.2 Psychopharmacology

Similar to psychotherapeutic treatments, controlled clinical trials for CBD are scarce. Lejoyeux et al. (1995) suggest that depressive compulsive buyers have an increased chance of improving their compulsiveness when treated with antidepressants than compulsive buyers without depression. A clinical trial with ten patients evaluated the use of fluoxetine in compulsive buyers over 9 weeks. Nine of the ten patients showed improvement, suggesting that it is not necessary for patients to be depressed in order to benefit from antidepressants (Black et al. 1997).

Two randomized controlled clinical trials with fluoxetine were carried out soon after. The first treated 37 compulsive buyers over the course of 12 weeks and did not find a difference between fluoxetine and placebo (Ninan et al. 2000). The second studied a sample of 23 CBD inpatients without depression (Black et al. 2000). The participants were randomly distributed to fluoxetine ($n = 12$) or placebo ($n = 11$). At the end of 9 weeks and applying the Scale of Global Clinical Improvement, 50 % of the patients in the fluoxetine group and 64 % of those in the placebo group were classified as showing "great" or "very great" improvement. The positive response of the placebo group points to the need to undertake more randomly controlled trials with longer follow-up periods (Christenson et al. 1994; Black 2001).

A clinical trial with citalopram showed favorable results in the double-blind discontinuation study carried out by Koran et al. (2003). Twenty-four patients with

CBD were selected, and after 6 weeks of treatment, 17 patients presented with a significant reduction in spending and purchases and an improvement in global functioning. Then, these patients were randomly assigned to either citalopram or placebo maintenance for 9 more weeks. The seven patients that took citalopram did not relapse, while five of the eight patients who took the placebo relapsed. After 1 year, 73 % of the seven patients who took medication remained in remission from compulsive symptoms even after having interrupted medication. The authors suggested that citalopram treatment might have modified the natural course of the disorder. On the other hand, another study with a similar design using escitalopram found no significant effect (Koran et al. 2007).

Grant (2003) reported on the successful treatment of three patients with naltrexone, and recently memantine was tested in nine CBD patients with encouraging results (Grant et al. 2012).

96.2.8 Self-Help/Community Resources

Other treatments have been elaborated as complementary to those more traditional ones that could be useful. These include self-help books about CBD for individual clarification or group discussion. The Debtors Anonymous group, which was created with the same perspective of Alcoholics Anonymous, is a self-help group coordinated by laymen who have the same difficulties and who provide support and encouragement for those with substantial debt. Simplicity Circles, which exist in some American cities, is a group of volunteers who encourage people to adopt a simple lifestyle, to resist consumerism appeal, and to abandon CBD. Finally, couple and financial counseling may be beneficial as relationships and financial status of the family become stranded because of chronic CBD (Black 2007).

Contents

Abstract

Excessive sexual behavior or hypersexuality has been documented clinically in the western world since the eighteenth century. Individuals affected by such behavior have symptoms akin to those with substance dependence. The concept of sex addiction share features with substance dependence such as distress due to negative consequences of compulsive sexual behavior and impulsive sexual behavior. This chapter reviews the evidence for the concept of sex addiction and discusses the assessment, etiology, neurobiology, prevalence, comorbidity, and treatment approaches.

Keywords
Sex addiction • Compulsive sexual behaviour • Hypersexuality

97.1 Introduction

Phenomena of excessive sexual behavior have been documented clinically in the western world since the eighteenth century. Descriptions of "excessive and maladaptive" sexual behavior (Kafka 2010) served as precursors to what became known in the twentieth century as "Don Juanism," characterized by excessive sexual appetite and protracted promiscuity, and became codified in the International Classification of Diseases (ICD 2007) as excessive sexual drive (F52.7).

In the 1970s, 12-step recovery groups addressing "out-of-control" sexual behavior began to arise independently and spontaneously throughout a number of cities in the United States. Most of these groups were formed by members of Alcoholics Anonymous (AA) groups and followed 12-step format and principles. These groups placed excessive sexual appetites/behavior within the rubric of "addiction" (Irvine 1995). However, it was the publication of Patrick Carnes' *Out of the Shadows* in 1983 that signaled the emergence of "sex addiction" into the world of science and media, and the first inpatient treatment programs for "sex addicts" were introduced.

"Sex addiction" was a grassroots term that seemed to capture the experience of those struggling with seemingly "out-of-control" sexual behavior and emphasized commonalities between AA members' experience with sex and their experience with alcohol. Although the term was controversial, by the late 1980s, extensive media coverage popularized the idea of sex addiction, and since then it seems like every few years various celebrities would admit to sex addiction and enter treatment. Still, controversy remains over whether or not sex addiction exists, with concomitant impairments in cognition, impulse control, attachment, intimacy, and mood, or has simply been invoked as a convenient excuse for an individual's sexual indiscretions (Karim and Chaudhri 2012).

In the 1990s widespread access to the Internet lent a new dimension to sex addiction. Suddenly "an essentially unlimited range of sexually explicit texts, still and moving images, and audio materials" were available for immediate and secret consumption (Fisher and Barak 2001). As if the task of definition and classification were not complicated enough, technology further added to the complexity of what was described as compulsive sexual behavior. The Internet has become the arena of ever-varied forms of cybersex. Since the 1990s, "sex" has been the most widely used search term on the World Wide Web (Hertlein and Piercy 2008), and about a third of all data traffic on the Internet involves pornography (Anthony 2012).

The use of the Internet itself has become the focus of considerable attention in the literature, as it can also become problematic and excessive. Hertlein and Piercy (2008) noted that high levels of general Internet use accounts for lower levels of family communications and social interactions and higher levels of depression and

loneliness within families. It can be tricky to differentiate between general Internet use and online sexual behavior, however. For example, Young (2009) identified three subtypes of "Internet addiction": (1) excessive gaming, (2) online sexual preoccupation, and (3) email/text messaging. It is easy to see that all three subtypes (and not just the second) can have a sexual component to them. Role-playing games often involve sexual encounters between fantasy avatars; and email/text messaging can be and has been the means for sharing sexual preoccupations.

Thus, online sexual behavior could be a subset of Internet addiction or could be a technological variant of sex addiction (Ross et al. 2012); both of these also need to be distinguished from an online "affair," or Internet infidelity (Jones and Hertlein 2012). Indeed, as technology advances, the task of delineating boundaries around "sex addiction" becomes more complicated. "Cybersex" no longer denotes just viewing pornographic texts or images; there is now a significant interactive component to cybersex that defies straightforward classification. Dryer and Lijtmaer (2007) take a psychodynamic approach to the meanings of cybersexual encounters, noting that these interactive components (instant messaging, texting) add to these encounters a unique kind of "techno-intimacy." Their paper highlights the specific dynamics of this "twilight zone" of techno-intimacy, which in many ways constitutes a simultaneous virtual and real sexual "relationship," wherein the individual is able to be both "there" and "not there." Doubtless this twilight zone would require further exploration, as these virtual/real relationships also become more and more portable with the advent of smart phones.

Also in the early to mid-2000s, more attention was being paid to the effects of sex addiction on couples and families. The term "codependence," widely used with respect to partners of alcohol and drug dependents, came under criticism as a term that pathologized normal reactions to extreme situations (van Wormer 1990). Rather, partners are invited into treatment as those who have suffered a traumatic experience with the discovery or disclosure of compulsive sexual behaviors (e.g., Black and Tripodi 2012). In addition, an entire literature on managing disclosures has developed (e.g., Schneider and Levinson 2006).

The purported diagnosis of "sex addiction" was controversial from the beginning, in terms of both its existence and nosology. There have been arguments and evidence for and against conceptualizing a particular constellation of behaviors as an addiction, an impulse control disorder, an impulsive-compulsive behavior, or as symptoms of an underlying Axis I disorder; and the search for neurobiological substrates underlying each argument continues. As already noted, the emergence of the Internet has complicated matters further. Nevertheless, there seems to be consensus regarding the clinical presentation of such individuals, varied though they may be (Gold and Heffner 1998; Kafka 2010). As already noted, sex addiction (also known as compulsive sexual behavior, sexual impulsivity, or hypersexual disorder) is a controversial topic in both media and science (TIME 2011). Controversy is bound to occur when any class of behaviors, including sexual behaviors that are considered "normal," are medically pathologized (Money 1994).

Sexuality depends on many factors, including relationship variables, societal values, cultural norms, and ethnic and cultural beliefs; these need consideration

when discussing hypersexuality (Kaplan and Krueger 2010). The group of individuals easiest to diagnose with a form of sexual addiction are those (primarily men) who meet criteria for paraphilia disorders (Kafka 1994). This is due to societal and legal sanctions that consign these individuals to the legal system for punishment or medical system for treatment. Outside the paraphilias, sexual addiction typically presents with specific behaviors that are socially sanctioned but often cause significant distress with concomitant problems such as substance abuse or mental disorders (Schneider and Irons 2001; Carnes 1991).

There is a challenge in defining abnormal and pathological practices. Carnes and Wilson (2002) proposed that sexually addictive behaviors include compulsive masturbation, affairs and use of prostitutes, pornography, cybersex, voyeurism, exhibitionism, sexual harassment, and sexual offending. They divided the behaviors into three levels, in ascending order of potential serious concern. Level I behaviors, by far the most controversial category, include behaviors that are commonplace and widely accepted as being normal and unproblematic (masturbation, using pornography, visiting strip shows, prostitution). Carnes noted that these may have "devastating" consequences if compulsive or involving the "victimization of others." Level II behaviors "are sufficiently intrusive to warrant stiff sanctions." Such behaviors all involve some form of victimization and include exhibitionism, voyeurism, and indecent phone calls. Level III behaviors include the most serious forms of sexual victimization (child molestation, incest, rape, and violence). Goodman (1992), employing a contemporary definition of substance addiction (DSM IV Criteria), proposed to replace the word substance with sexual behavior and formulated criteria to describe sexual addiction disorder. Kafka (2010) proposed "hypersexual disorder" for consideration in the sexual disorders section for DSM V. It is conceptualized primarily as a nonparaphilic sexual desire disorder with an impulsivity component (Kafka 2010). The proposed diagnostic criteria for hypersexual disorder (American Psychiatric Association DSM V Development 2010) include recurrent and intense sexual fantasies, sexual urges, or sexual behaviors over a period of at least 6 months. This is in association with three or more of the five criteria related to repetitive sexual fantasies, urges, or behaviors and determined by the following: time consumed interfering with other important goals, activities, and obligations; engagement in response to dysphoric mood states or in response to stressful life events; unsuccessful efforts to control or significantly reduce these fantasies, urges, or behaviors; and disregard for the risk for physical or emotional harm to self or others.

These fantasies, urges, or behaviors are associated with clinically significant personal distress or impairment in social, occupational, or other important areas of functioning, and are not due to the direct physiological effect of a drug of abuse or a medication.

Kafka formulates "hypersexual disorder" as "a sexual desire disorder" characterized by an increased frequency and intensity of sexually motivated fantasies, arousal, urges, and enacted behavior in association with an impulsivity component – a maladaptive behavioral response with adverse consequences. "Hypersexual disorder" is associated with increased time engaging in sexual

fantasies and behaviors (sexual preoccupation/sexual "obsession") and a significant degree of volitional impairment or "loss of control" characterized as disinhibition, impulsivity, compulsivity, or behavioral addiction (Kafka 2010). Kafka avoided referring to "hypersexual disorder" as an addiction; however, his criteria are quite similar to those proposed by Goodman. The major difference between the two sets of criteria is the absence in "hypersexual disorder" of symptoms crucial to the addictive disorders concept, such as tolerance symptoms, and relief resulting from sexual behavior.

97.1.1 Relationship with Paraphilias

Paraphilias are characterized by intense, repetitive, deviant, sexually arousing fantasies and sexual urges and behaviors lasting at least 6 months and marked by personal distress or indications of significant psychosocial impairment related to sexual behavior. In contrast hypersexual behavior is characterized by excessive repetitive expression of culturally adapted normophilic sexual behaviors. As with other disorders, these disorders are not deemed mutually exclusive.

97.2 Management of Sexual Addiction

97.2.1 Assessment

Treatment begins with a comprehensive assessment. This includes current presentation and history of the "sexual addiction." The clinician must establish what precipitated the visit: what are the behaviors of concern, at what frequency do they occur, and under what circumstances do they occur? What is the sex and age of partners involved? What is the timeline of the behavior? When were the behaviors worst and what were the factors that contributed to their exacerbation? What has helped reduce the behaviors or the distress? Finally, what has been the impact of the behavior on various aspects of functioning? Particularly important would be a review of current relationships and the impact of the behaviors on family and friends.

With regard to history, the clinician must assess any sexual or physical abuse, or neglect, as well as review the medical history, including any treatments for sexually transmitted illnesses. The clinician must inquire into other addictive behaviors and their relationship with sexually acting out behaviors. In addition, assessing for any legal involvement, past and present, would be important, as well as mental health function and any comorbid psychiatric disorders.

A number of screening and assessment instruments are available, including the Sex Addiction Screening Test (SAST); the PATHOS, a short screening interview analogous to the CAGE for alcohol use; the Compulsive Sex Behavior Inventory; and the Sexual Compulsivity Scale. Carnes (1989, 1991) developed the SAST, a 25-item dichotomously answered self-administered questionnaire. The SAST has

demonstrated a single factor with high internal consistency in a sample of 191 sexually addicted, in comparison with 67 nonaddicted males. A cutoff score of 13 (out of 25) is likely indicating the presence of a sexual addiction in heterosexual males. The SAST was revised in 2010 (SAST-R) (Carnes et al. 2010).

The PATHOS (derived from the SAST and SAST-R) has been developed as a brief screening instrument to assist clinicians with identification of individuals who may have sex addiction (Carnes et al. 2012). A score of 3 out of 6 indicates further assessment for sex addiction.

PATHOS Questionnaire items are as follows:

1. Do you often find yourself preoccupied with sexual thoughts? (**P**reoccupied)
2. Do you hide some of your sexual behavior from others? (**A**shamed)
3. Have you ever sought help for sexual behavior you did not like? (**T**reatment)
4. Has anyone been hurt emotionally because of your sexual behavior? (**H**urt Others)
5. Do you feel controlled by your sexual desire? (**O**ut of Control)
6. When you have sex do you feel depressed afterwards? (**S**ad)

97.2.2 Etiology and Neurobiology

We do not have quality evidence supporting the etiology of sexual addiction. Most of the literature about etiological mechanisms is based on theory: endocrine dysfunction, incomplete monoamine hypothesis, developmental processes and a courtship disorder, social learning theory, and psychodynamic theories. Little is known about the brain pathways that regulate sexual behavior and cognition. Dopamine, serotonin, and androgenic hormones appear to play a critical role (Kafka 2003). Functional imaging with PET and MRI has corroborated that the amygdala, mesencephalic tegmentum, and septal nuclei are activated during sexual response (Arnow et al. 2002). PET scans of healthy volunteers during orgasm and ejaculation showed strong activation of dopaminergic mesodiencephalic junction and ventral tegmental area; the latter region of the brain is also activated with the "rush" experienced by heroin addicts (Park et al. 2001).

Neurobiological correlates of addiction start with the brain reward circuitry: specifically, the mesolimbic reward system (Di Ciara 1998), a region significant for understanding the origins of how addictive behaviors emerge. There is a paucity of literature on brain imaging during conventional or pathological sexual functioning. Reward circuits such as the dopaminergic and endogenous opiates systems have been implicated in the process of sexual behavior in much the same way as substance use (Goodman 2008). The role of the reward system in these disorders is derived from research into Parkinson's disease, whereby treatment with dopamine agonists leads to vulnerability to impulse control disorders such as pathological gambling, hypersexuality, compulsive shopping, and compulsive eating (Vilas 2012). Addiction has usually been defined as dependence on a drug that can "hijack" the reward system. Any stimuli (drug or behavior) that transform the

basic drive required for survival (like feeding, thirst, reproduction) into actions of craving/seeking behaviors or repetitive out-of-control behaviors may make it plausible that addiction can occur even in the absence of drug taking (Karim and Chaudhri 2012). Thus, behavioral addictions may share many of the same pathways associated with chemical dependence. Hence, the theory that "if one can alter neurocircuitry with illicit drugs and pharmacology, then one can alter it with behavior as well" (Holden 2001).

97.2.3 Prevalence

Kafka (1997) attempted to quantify sexually compulsive behavior and distinguish between socially conforming sexual behaviors and behaviors that are nonsocially conforming. They define "hypersexual desire" in men as the persistence of seven or more orgasms per week for a minimum duration of 6 months or more after age 15 (Kafka 1997). This definition characterizes 3–8 % of responses in nationally representative surveys of male sexual behavior in the United States (Kafka 1997, 2003; Black 2000) and Sweden (Langstrom 2006). The definition applies to males and may not be applicable to females, as fewer women engage in high rates of sexual behavior. In one national survey of women, 24.1 % reported sexual intercourse several times a week but only 1.1 % daily; 4.5 % reported masturbation several times a week and 1 % reported daily masturbation. There are no evidence-based estimates of the prevalence of sex addiction, nor reports of the incidence of the disorder.

97.2.4 Comorbidity

One of the consistent findings of studies of those with sexual compulsion was that the great majority have lifetime comorbid mood, anxiety, psychoactive substance use, and/or other impulse disorder diagnoses. ADHD (inattentive subtype) was identified as a co-occurring psychiatric diagnosis in sexual addicts (Blankenship and Laseer 2004). There is a high correlation between sex addiction and substance use disorders, up to 80 % in some studies. This tends to complicate the task of diagnosis and treatment.

With regard to Axis II comorbidity, Raymond et al. (2003) found that the most commonly co-occurring personality issues are Cluster C personality disorders (39 %), followed by Cluster B personality disorders (23 %). Reid et al. (2012) found that men with compulsive sexual behavior exhibited higher levels of emotional dysregulation, stress vulnerability, and interpersonal sensitivity; these characteristics generalized to hypersexual women. They concluded that personality traits associated with emotional problems, difficulties coping with stress, and interpersonal sensitivity may constitute a precipitating or perpetuating risk factor in the onset or maintenance of hypersexual behavior in adult men and women and

that treatment interventions targeting affect regulation, stress coping, interpersonal coping, interpersonal sensitivity, impulsivity, and manipulative tendencies are warranted for both hypersexual men and women.

Neuropsychiatric illness (Vilas 2001) may induce acute changes in sexual behavior; similarly, medications, typically dopaminergic agonists (Kafka 2003), may also contribute to hypersexual behavior. In these circumstances the hypersexual behaviors tend to be a mixture of normophilic and paraphilic-like sexual behaviors (e.g., inappropriate touching and exposing oneself, but not to strangers).

97.2.5 Treatment Approaches

97.2.5.1 Psychosocial Approaches

Patrick Carnes, whose autobiographical book *Out of the Shadows* (1983) brought sex addiction to public attention, has also been instrumental in the development of the most widely published therapeutic approach to compulsive sexual behavior (Herring 2013). Carnes' "task-centered approach," outlined briefly in his introductory workbook *Facing the Shadow* (2005), guides the "recovering addict" through 30 tasks. Each task has a list of "performables" meant to operationalize the task. For example, the first task is to "break through denial" and includes the following performables: make a problem list, make a secret list, make a list of excuses and rationales, complete a consequences inventory (list of consequences in various life areas), make a list of people hurt, find a therapist, find a sponsor, and make full disclosure to therapist and sponsor. Other tasks include such "performables" as reading about sex addiction, generating relapse prevention plans, and participating in a culture of recovery support.

The first seven tasks are meant to guide the "addict" through early sobriety; tasks 8–19 provide longer-term guidance in individual recovery and dovetail with tasks 19–30, which focus on "family recovery." The tasks make the most sense when used in conjunction with involvement with 12-step recovery groups; the "performables" can also serve as a menu of helpful worksheets regardless of therapeutic approach. While many of the "performables" can be directly linked to 12-step recovery (e.g., find a sponsor, complete a powerlessness inventory, share your first step), many others can also be used within the context of relapse prevention and cognitive-behavioral therapy (e.g., identify your relapse scenarios, complete a fire drill plan).

Young (2008) identified three categories of treatment for Internet sex addiction: the first category is Carnes' approach of symptom management and reflection, which initially involves "crisis management" – largely behavioral measures of contingency management, such as moving the computer to a public area and installing safety software – and later addressing underlying issues often related to early childhood development and family of origin. The second category identified involves formulating recovery plans based on "addicts" identifying behaviors which are out of bounds, behaviors which place them at risk, and behaviors that promote health. It must be noted that this work is included in Carnes' tasks as well.

The third category, which Young herself developed, is described as "an integrated recovery approach that combines cognitive-behavioral and insight-oriented therapies," which, based solely on her description, was frankly difficult to distinguish from Carnes' approach.

Carnes was instrumental in the establishment of the Society for the Advancement of Sexual Health (SASH), a nonprofit multidisciplinary organization "dedicated to scholarship, training, and resources for promoting sexual health and overcoming problematic sexual behaviors," such as "sex addiction, hypersexual disorder, out-of-control sexual behavior, sexual impulsivity, sexual abuse" (SASH 2013). SASH holds a conference yearly and recently started offering a certificate for "Advanced Training in Problematic Sexual Behavior."

Carnes also founded the International Institute for Trauma and Addiction Professionals (IITAP), which offers "premier training and cutting-edge educational resources for practitioners who treat people with addictive and compulsive sexual behaviors" and claims that its CSAT (Certified Sex Addiction Therapist) program is "one of the most highly regarded programs of its kind, offering a complete group of training, products and services" (IITAP 2013); Carnes also founded Gentle Path Press, which publishes many of the materials used for training as well as the books recommended through his task-centered approach.

While Stefanie Carnes, clinical psychologist and current president of IITAP, has remarked that the CSAT training is "very strongly research based" (personal communication, 28 March 2011), Rory Reid, research psychologist at the Department of Psychiatry and Biobehavioral Sciences at the University of California, Los Angeles, asserts that "having reference material that is 'research based' is not the same as having a treatment approach that is empirically supported by research" (personal communication, 28 March 2011). Indeed, Reid bemoans the fact that as of early 2011, there were only eight published treatment outcome studies related to the sex addiction population, half of which were single-subject design studies (personal communication, 6 February 2011).

When conceptualized as an addiction, there are many possibilities of extending already established therapies that help with addictive behaviors, such as motivational enhancement therapy, cognitive-behavioral approaches, emotional awareness, and mindfulness-based approaches. Participation in 12-step recovery groups is also routinely recommended in conjunction with psychosocial treatment. However, so far there is a paucity of research evidence to empirically support any one treatment approach for compulsive sexual behavior.

97.2.5.2 Pharmacological Approaches

Pharmacological treatment uses two main categories of medications: specific serotonin reuptake inhibitors (SSRIs) and antiandrogens (Guay 2009). In addition, patients with sexual addiction may present with dysphoric mood symptoms that may warrant antidepressant medications. This usually occurs in the initial phase of abstinence.

There are no randomized control trials for treatment of patients with antidepressants. However, case reports and open-label studies (Kafka 1994; Stein 1992)

indicate that SSRIs may be of use in the treatment of sexual addiction. This is based on the rationale that serotonergic dysfunction may underlie the condition. Madeo (2008) showed in a randomized control trial with citalopram that in healthy adult males, 4 weeks of treatment significantly increased the time to orgasm compared to men on placebo. However, the medications did not dampen sexual desire or penile tumescence measurements, suggesting that SSRIs may have differential effects on dampening libido and sexual function in men who are not depressed or who do not have compulsive sexual behavior. In a randomized control trial, gay and bisexual men with sexual addiction/compulsivity who were treated for 12 weeks with citalopram (20–60 mg a day) reported significant reductions in sexual drive, frequency of masturbation, and viewing of pornography in comparison to those treated with placebo (Weinberg et al. 2006). In summary there is some evidence supporting the use of the SSRI citalopram for sex addiction, especially in gay and bisexual men.

Naltrexone is an opioid antagonist approved for use in treating alcoholism and opioid dependence. It works by dampening dopamine release, thus reducing the euphorigenic effects of fantasizing and tension building which are considered the initial steps in compulsive sexual behaviors. There are no randomized trials of opioid antagonists for sexual addiction. Some open-label trials show that high doses of naltrexone reduced frequency of masturbation, sexual fantasies, and nocturnal emission (Bostwick and Bucci 2008).

Antiandrogen medications currently used for treatment of excessive nonparaphilic sexual behavior are cyproterone acetate (a synthetic steroid similar to progesterone which acts both as a progesterone and an antiandrogen) and medroxyprogesterone acetate. Medroxyprogesterone acetate diminishes libido in men and thus makes it easier to control sexually addictive behavior. The rationale of using hormone therapies in men with sexual addiction is based on eliminating sexual compulsivity and obsessions by stopping the production of testosterone. This approach is usually reserved for treating paraphilias in men that involve sexual offending involving children and violence (Thibaut et al. 2010; Gottesman and Schubert 1993). Antiandrogens diminish sex drive in women; hence, the use of antiandrogens in women to control hypersexuality may be of benefit.

Goodman (1998) has presented a psychotherapeutic stage model integrating pharmacotherapeutic, behavioral, and psychodynamic approaches. In the first stage (initial behavior modulation), individuals who engage in addictive sexual behavior learn how to modulate their behavior through a combination of inner motivation, psychological support, and affect-regulating medication; the second stage (stabilization of behavior and affect) addresses the question of relapse prevention, with a distinction between high- and low-risk forms of sexual behavior. Patients are taught to engage in "healthier" forms of sexual behavior.

97.3 Conclusion

Sex addiction as a concept carries a lot of controversy. In the last two decades, there has been an effort in defining the features of sex addiction. The proposed inclusion

of hypersexual disorder in the DSM V would help in furthering research in this field, provide a reference for clinicians, and help in the recognition and treatment of this disorder (Kafka 2010). There is frequent comorbidity with psychiatric disorders, especially substance dependence, bipolar disorder, and personality disorders. There is a paucity of research about the prevalence and incidence of the disorder. The treatment of the disorder encompasses a variety of treatment approaches including psychotherapeutic models and pharmacotherapeutic interventions (especially for concurrent psychiatric disorders). Twelve-step organizations are an integral part in helping individuals seeking help and recovery (Reid 2007; Carnes 1989).

Contents

Abstract

Obesity has become a worldwide pandemic with an estimated annual cost in related illnesses and loss of productivity over $100 billion and rising. Though not recognized as a psychiatric disorder, obesity has been linked to serious physical, psychological, and social consequences. Some forms of obesity are typified by the compulsive consumption of food, difficulty curbing further intake despite negative consequences, a desire to cut back, as well as needing increasing amounts of food to reach satiety, resembling a form of tolerance. These symptoms are remarkably similar to DSM criteria for substance use disorders. Research in both animals and humans has demonstrated food-related changes in the brain itself that are very similar to changes caused by drugs of abuse leading to the hypothesis that some forms of obesity and a related

contributing behavior, binge eating, may manifest secondary to or along with a "food addiction." This chapter seeks to describe the common elements and possible intersection of binge eating disorder, obesity, and addiction.

98.1 Introduction

This chapter seeks to describe the common elements and possible intersection of binge eating disorder, obesity, and addiction. The Diagnostic and Statistical Manual of Mental Disorders V (DSM-V) currently recognizes Anorexia, bulimia, binge eating disorder (BED), and FED-NEC secondary to the serious impairments and severe negative outcomes associated with these conditions (APA 2013). Unlike eating disorders, obesity is not currently recognized as a psychiatric disorder. However, obesity has been linked to serious physical, psychological, and social consequences. Some forms of obesity are typified by the compulsive consumption of food, difficulty curbing further intake despite negative consequences, a desire to cut back, as well as needing increasing amounts of food to reach satiety, resembling a form of tolerance (Volkow and O'Brien 2007; Taylor et al. 2010). These symptoms are remarkably similar to DSM criteria for substance use disorders. These symptoms are remarkably similar to the DSM-IV criteria for substance abuse and dependence: preoccupation, escalation, tolerance, denial, and a series of medical, psychological, and social consequences that relate directly to continued use (APA 2013; Gold et al. 2009), thereby leading to the hypothesis that some forms of obesity and a related contributing behavior, binge eating, may manifest secondary to or along with a "food addiction."

The concept of food addiction is a highly debated one (Avena et al. 2012b). One argument against the notion that food is addictive is, of course, that everyone eats. How can something that sustains life be considered addictive? It has been proposed, however, that only certain foods be considered addictive, specifically those high in sugars and fats. These "forbidden" foods are typically calorie dense, highly palatable, and the types of foods that people tend to overconsume most (Corwin and Grigson 2009). Studies using animal models have provided a great deal of empirical support for the concept of food addiction. Such studies have found that similar to substance addictions, the consumption of these types of foods increases dopaminergic activity in the brain's mesolimbic reward circuits and leads to increased intake over time, and when animals are deprived of these foods, a history of such consumption can precipitate symptoms of withdrawal (Avena et al. 2008). More recently, tools have been designed to assess food addiction in humans, and studies incorporating such tools are beginning to provide additional evidence of this construct. For example, more than half of obese individuals with binge eating disorder included in one study met the criteria for food addiction (Gearhardt et al. 2012). Using fMRI scanning, individuals with greater food addiction scores have also been shown to have greater activation of motivation-related brain regions when anticipating highly palatable food, similar to drug-addicted individuals when viewing cues associated with a drug (Gearhardt et al. 2011).

Disordered eating, such as that seen in binge eating disorder, bulimia nervosa, and some cases of obesity, poses a number of complications for the medical community. These conditions can be physically compromising and, in some cases, even fatal; however, their etiology is not well characterized. Expert speculations regarding the underlying risk factors for the development of disordered eating include a range of psychological, biological, and societal influences. Given the growing evidence of neurochemical and behavioral similarities between overconsumption of certain foods and substance addiction, and the urgent need to develop effective treatments to combat obesity and overeating, it may be time to consider food addiction as a possible contributing factor to these issues, as well as a target for treatment.

98.2 Feeding and Reward

Feeding behaviors are controlled by more than homeostatic mechanisms. As it has been pointed out, "if feeding were controlled solely by homeostatic mechanisms, most of us would be at our ideal body weight, and people would consider feeding like breathing or elimination, a necessary but unexciting part of existence" (Saper et al. 2002). The fact that this is not the case suggests that there is a role for the reward systems in the brain in promoting motivational, hedonically driven feeding. Thus, excessive food intake may be explained more by dysfunction in the reward circuitry than strictly dysfunction in the homeostatic mechanisms controlling feeding habits. Studies in both humans and animals have supported the hypothesis that brain reward circuitry may be dysregulated in cases of obesity, disordered eating, and more recently, food addiction.

The neurocircuitry underlying eating behaviors is quite complicated. Of the multiple regions of the brain involved in the processes of food procurement and ingestion, there are four regions that stand out as also being activated during drug addiction: the amygdala/hippocampus, insula, orbitofrontal cortex, and striatum. These areas of the brain play key roles in learning the rewards associated with food, allocating attention and effort toward procuring food, setting incentive for food, and integrating internal homeostatic information about energy stores and gut contents (Blumenthal and Gold 2010).

Sensory input from the mouth is relayed to the same cortical areas of the brain that receive satiety signals from the gut (Rolls 2007). Limbic structures such as the thalamus then integrate hypothalamic energy control signals, largely under the control of gut hormones such as ghrelin, leptin, insulin, and peptide YY (Leibowitz and Hoebel 2004). The hypothalamus has direct connections to the nucleus accumbens, which is the control center for reward behaviors such as exercise, sex, and feeding. Mesolimbic dopamine (DA) directly acts upon the nucleus accumbens thereby controlling motivational and hedonic feeding as well as serving as the point of action for endogenous opioids, serotonin, and acetylcholine (ACh). It should be noted that these are some of the same neurotransmitters and pathways that control motivation and reinforcement of behaviors typically associated with substance addictions. The endogenous opioids modulate DA

release thereby affecting the reward process. Similarly, ACh in the nucleus accumbens has been associated with satiety, though the precise mechanism of action needs further investigation (Avena and Rada 2012). 5-HT is also associated with the sensation of satiety and can be associated with weight loss and fat intake (Halford and Blundell 2000). Given the interplay between all of these neurotransmitters and the nucleus accumbens, it is possible that dysfunction at any of these key points could result in disordered eating. This also explains why many of the pharmacological therapies for eating disorders have been targeting these neurotransmitter systems.

98.3 Obesity

Obesity, defined as a body mass index >30, has increased dramatically over the last three decades and is now estimated to affect over 33 % of the US population. Obesity is classified as a medical condition as it places a patient at increased risk for cardiovascular disease, diabetes, cancer, and other diseases resulting in a 5–20-year reduction in life expectancy, as well as costing $70–$100 billion annually by conservative estimates. The seriousness of these health consequences highlights the urgent need for strong prevention efforts and the development of effective treatment approaches for individuals with this condition (Volkow and O'Brien 2007).

The cause of obesity remains largely unknown, but, similar to eating disorders, is likely multifactorial (Fig. 98.1). It has been suggested that the behavioral phenotype of overeating may be influenced by an interplay of genetics, development, and environmental factors (Brownell and Gold 2012). While separable in theory, the interplay of one's genes; the time, place, and culture in which one lives; and the development of one's obesity through non-homeostatic mechanisms are likely all simultaneously involved and thereby relevant to the problem (Devlin 2007).

Within genetic theories, the "*thrifty genotype*" hypothesis suggests that the neurocircuitry underlying food procurement and bodily storage evolved at a point in human history in which food was scarce as a means of promoting survival in times of famine (Volkow and O'Brien 2007). However, recent advances in technology have allowed for the creation and modification of foods, which artificially enhance palatability beyond what would be found in nature, especially with regard to sugar, fat, and caloric value (Taylor et al. 2010). These calorie-rich, highly palatable foods are abundant and easily accessible in the typical Western diet. This combination of factors may lead to the activation of reward circuitry, which evolved to reinforce feeding behavior, and desires to engage in pathologic overconsumption, which would have been advantageous in a time of famine but now, in a context of abundance, appear maladaptive (Brownell and Gold 2012).

In contrast, the "developmental origin" hypothesis suggests that our exposure to certain nutrients and calorie contents in utero may imprint upon our developing brain and influence food choices when outside of the womb. Evidence to support this hypothesis comes from studies investigating the effects of consuming certain

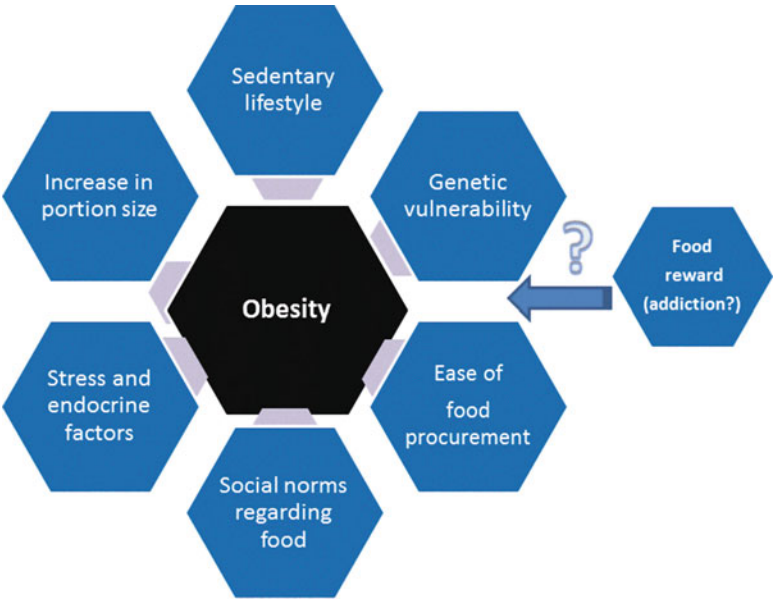

Fig. 98.1 Obesity is a multifaceted disorder with many contributing factors

diets during gestation on various outcome measures in the offspring. For example, recent research has found that the offspring of animals fed a high-fat diet during gestation are more likely to weigh more and consume more of a high-fat diet compared to controls (Bocarsly et al. 2012). While one hypothesis takes into account an evolutionary perspective and the other a more developmental view, both of these hypotheses may have value for understanding the current issues of obesity and disordered eating.

In regard to possible cultural and environmental influences of obesity, the past several decades have seen five major developments that are thought to have tipped the balance between caloric intake and energy expenditure to an unfavorable disproportion: (1) expanding labor market opportunities for women, (2) increased consumption of food outside of the home, (3) rising costs of healthy foods relative to unhealthy foods, (4) increasing quantities of caloric intake with declining overall food price, and (5) decreased requirements of occupational and environmental physical activity (Gold and Gold 2011). Other environmental factors implicated in the development of patterns of overeating include advertisements, sights, smells, and sounds, which have all been shown to induce food cravings and can result in overeating (Blumenthal and Gold 2010). Indeed, eating is more than a physiologic response; it can serve as a social lubricant, facilitating both personal and professional interactions, and is a prominent centerpiece for most individuals at holidays and celebrations (Gold et al. 2009).

These factors highlight the cultural aspect of obesity, but with them come a new set of challenges. During the Coronary Artery Revascularization in Diabetes (CARD) trial, which followed a population of 18–35-year-old patients over 10 years, the average patient showed a weight increase of at least 7 kg regardless of race and sex. This study demonstrated that significant weight gain over the course of adult life is now normative, suggesting a strong cultural component (Norman et al. 2003). In order to be classified as a disease, however, a condition must clearly differ from the norms of society. This conundrum has led some to refute claims that obesity should be included in the DSM-V as it may simply be a behavioral disturbance with an adverse medical outcome, not necessarily a psychiatric condition (Devlin 2007). While not all individuals who are obese may fit the existing criteria for food addiction, it is possible that individuals who do may represent a subcategory of obesity that is characterized in part by significant distress due to their thoughts and behaviors regarding food and/or exhibit comprised functioning as a result of these thoughts and behaviors. As such, these individuals may be recognized as having a psychiatric condition despite being within a weight range that may be considered relatively "normal" based on current trends within society. In fact, over- and/or normal-weight individuals also fit the criteria for food addiction.

Obesity is often described as an imbalance between caloric intake and energy expenditure. This simplified view has led some to suggest that obesity is the fault of the person due to excessive consumption, inadequate activity, or a combination of the two, resulting in much of the stigma that is associated with this condition (Devlin 2007). While decreased caloric consumption and increased physical activity can be effective in normalizing weight, these lifestyle modifications have proven very difficult to sustain (Volkow and O'Brien 2007). The failure of many lifestyle modifications to reduce obesity over the long term suggests that obesity may not be entirely a metabolic disorder, but likely has a neuropsychogenic component (Volkow and O'Brien 2007). While food addiction certainly does not explain all cases of obesity, the prevalence of people who eat for reasons other than obtaining energy suggests that other factors may play a role in motivating and/or reinforcing feeding behaviors. With the rapidly increasing number of cases of obesity, it may be time to consider new ways of understanding and approaching this problem.

Some hypothesize that obesity, at least in certain cases, is related to dysregulation of the brain's reward system. The hypothalamus is accepted as the primary brain region responsible for managing signals that regulate the intake of food, primarily through hormones such as ghrelin, leptin, and insulin which effect both the hypothalamus and the reward neurocircuitry in such areas as the caudate nucleus, hippocampus, and insula (Taylor et al. 2010). Food, especially when it is rich in fat and sugars, stimulates brain reward circuitry, in part, through the release of endogenous opioids, cannabinoids, and DA (Abizaid et al. 2006). Since these are some of the same neuropathways and neurotransmitters associated with drug addiction, as mentioned earlier, some have suggested that repeated exposure to certain foods in vulnerable individuals may result in compulsive food consumption, poor control, conditioning to food stimuli, and ultimately excess weight gain

(Volkow and O'Brien 2007). Further evidence of neurochemical similarities between substance addiction and obesity comes from studies showing that like individuals with drug addiction, obese individuals have decreased striatal D2/D3 receptor availability and demonstrate elevated levels of DA metabolism (Corwin and Grigson 2009; Wang et al. 2009). Such findings suggest dysfunction within the brain reward mechanisms of individuals with obesity.

Stimulant drugs such as methamphetamine or cocaine are known to curb appetite presumably by affecting the reward circuitry, while partial blockade of these same pathways by antipsychotics has been associated with overconsumption thereby increasing the risk for obesity and metabolic syndrome (Volkow and O'Brien 2007). Taken together, current evidence suggests that similar neurological pathways are associated with both addiction and obesity. Thus, medications used to treat drug addiction, including cannabinoid antagonists; opioid antagonists, such as naloxone; GABA agonists, such as baclofen; and corticotropin-releasing hormone antagonists, such as CRF-1, have been suggested for the treatment of obesity, as have some of the same behavioral interventions, including cognitive behavioral therapy (CBT), cognitive behavioral therapy with guided self-help (CBT-gsh), dialectical behavioral therapy (DBT), and interpersonal therapy (IPT), incentive motivation, and 12-step programs (Volkow and O'Brien 2007; Yarnell et al. 2013).

The addictive behaviors underlying some cases of obesity may be hardwired. There have been reports of a subset of patients who have undergone bariatric weight loss surgery for obesity and therefore are less likely to be able to consume food in excess, later developing other addictive behaviors such as gambling, substance abuse, and impulsive spending (Wendling and Wudyka 2011; Conason et al. 2012). Interestingly, sweet preference has also been shown to correlate with a paternal history of alcoholism. In fact, one study found that having a family history of alcoholism increased the chance that one preferred a stronger sweet taste by five times (Kampov-Polevoy et al. 2003). Though this association requires further investigation, the implication of these findings is that the tendency toward increased reward sensitivity, which may lead to addiction, may be intrinsic (Taylor et al. 2010).

98.4 Binge Eating

Binge eating disorder is now listed in the DSM V as a stand alone diagnosis. Binge eating is characterized by eating rapidly, eating more than was intended, eating alone, and feelings of disgust, guilt, or depression secondary to these binges. It has been reported that 3.5 % of adult women and 2 % of adult men within the US population suffer from binge eating disorder. These numbers are reported to be slightly lower for adolescents (2.3 % females, .8 % males) (Smink et al. 2012).

Bingeing has long been associated with bulimia nervosa, as binge eating is one of the major diagnostic criteria for this disorder, but it is also associated with obesity (APA 2013). The key difference between binge eating and bulimia

nervosa is that binge eating disorder patients do not engage in compensatory behaviors (i.e., vomiting, laxative use, excessive exercise) to expel calories after consumption. Thus, the excess caloric intake is not compensated for, which may result in weight gain. Indeed, one study found that nearly 70 % of participants with binge eating disorder were obese and 20 % were overweight (Grucza et al. 2007). A larger, national study found obesity to have a lower prevalence rate among individuals who had ever had binge eating disorder. However, this number was still relatively high, with approximately 40 % of these individuals considered either obese or severely obese (Hudson et al. 2007).

Many studies have attempted to elucidate the relationship between binge eating and obesity. Longitudinal studies have demonstrated a correlation between binge eating and significant non-developmentally appropriate weight gain in adolescents and young adults (Tanofsky-Kraff et al. 2006). Further, one study demonstrated a correlation between binge eating and both being obese and gaining weight over a 20-year span (Hasler et al. 2004). Another study also shows that cessation of binge eating is associated with weight loss, while continued binge eating is associated with ongoing weight gain (Devlin et al. 2005). Studies such as these strongly suggest a connection between uncompensated binge eating and weight gain and suggest that binge eating could ultimately contribute to obesity (Devlin 2007). It is thus reasonable to suggest that normal-weight individuals with binge eating disorder may be at risk for obesity.

In addition to the association between binge eating and obesity, binge eating has several similarities to addiction. Some of the criteria used to identify disorders characterized by binge eating are remarkably similar to those used to assess substance dependence. These include (1) binge-type intake, defined as consuming a larger amount of food than typically considered normal in a discrete period of time, (2) a sense of lack of control over eating during a binge episode, and (3) marked distress regarding binge eating. In fact, binge eating has been described as including "compulsion, marked change in affect, and long-term harm, " and it is noted that "physiologically based satiety tolerance enables escalation of food 'dose'" (Rogers 2011).

The types of foods consumed during binge episodes are typically those that should be consumed in moderation due to their high-fat, high-calorie, and high-sugar content (Kales 1990). Consuming foods rich in sugar and fat activates the reward circuitry of the brain, as mentioned earlier. Bingeing on both high-sucrose and high-fat foods has been shown to elicit DA release in the nucleus accumbens in animals (Avena et al. 2012a). Animal models have also shown that bingeing is associated with downregulation of D2-receptor mRNA and an increase in D3-receptor mRNA in the nucleus accumbens (Spangler et al. 2004). Interestingly, these dopaminergic changes seen in response to bingeing are the same as those observed in obesity and drug dependency (Johnson and Kenny 2010; Koob and Volkow 2010). This has led some to speculate that binge eating of palatable foods may result in neurochemical changes and subsequent addictive-like behaviors (Avena et al. 2012a).

Studies such as these have also led some to wonder if the dopaminergic system could provide a target for pharmaceutical intervention of bingeing behaviors. Indeed, one study using an animal model of binge eating found the D2 antagonist, raclopride, reduces binge intake of high-fat foods, while having no effect on ad libitum consumption (Corwin and Wojnicki 2009). Similarly, studies suggest that naltrexone, an opioid antagonist, can suppress bingeing behaviors (Corwin and Wojnicki 2009). Further, single-photon emission tomography (SPECT) studies have demonstrated that when compared to obese controls, decreased 5-HT transporter binding was found among obese binge eaters, suggesting that this may be another potential pharmaceutical target (Kuikka et al. 2001).

Within the brain, the ventral limbic circuit and the orbitofrontal cortex are important in the regulation of feeding behaviors as well as identifying emotional stimuli and facilitating a subsequent response, and atrophy or deregulation within these regions has been noted in persons with bingeing behaviors (Marsh et al. 2009). This suggests a link between emotions and binge eating. Indeed, one study found that 100 % of participants, all of whom were obese women who binge eat, reported that mood contributed to binge behavior. 68 % reported depression or sadness and 55 % reported boredom preceding a binge episode (Chua et al. 2004). It is not surprising, therefore, that the teaching of affect regulation skills through the use of dialectical behavioral therapy (DBT) has yielded promising results in this population (Telch et al. 2001).

98.5 Screening Individuals for Food Addiction

Given the potential magnitude and severity of food addictions, efforts have been made to develop screening tools for addictive-like eating. Gearhardt et al. (2009a) created the Yale Food Addiction Scale (YFAS), which consists of a series of questions based on the substance addiction criteria as outlined in the DSM-IV. This tool is designed to identify and better characterize signs and symptoms consistent with food addiction. Respondents use a yes/no format and 5-point Likert scale for questions regarding frequency. In early testing, the YFAS exhibited adequate internal reliability, good convergent validity with other measures of disordered eating, as well as good discriminant validity relative to related yet dissimilar conditions such as alcohol consumption and impulsivity (Gearhardt et al. 2009b). A recent study has shown a link between YFAS scores and mood disorders among obese patients with binge eating disorder. The YFAS has also been shown to be a good predictor of the frequency of binge eating episodes in this patient population (Gearhardt et al. 2012). As noted by the authors, the YFAS may help clinicians better identify disordered eating habits in their patients as well as allow researchers to better identify potential candidates for future studies. Future studies in this area may facilitate the development of screening tests for addiction to specific food ingredients, such as fat or sugar, which may lead to a better understanding of the types of foods that may be associated with food addiction, as well as the development of more specific approaches to treatment.

98.6 Management of Food Addiction

The study of food addiction is relatively new and specialized treatment approaches have not yet been developed. However, because of overlaps between binge eating, obesity, and food addiction, it is possible that strategies that are effective for treating binge eating and obesity may also prove helpful in the treatment of food addiction. Certain types of psychotherapy, including cognitive behavioral therapy (CBT), cognitive behavioral therapy with guided self-help (CBT-gsh), and interpersonal therapy (IPT), have shown success in the treatment of binge eating disorder (Devlin et al. 2005; Iacovino et al. 2012). As mentioned earlier, DBT has also been shown to be effective in treating binge eating behavior (Telch et al. 2001). Among existing pharmaceuticals, fluoxetine, desipramine, imipramine, and topiramate have been suggested to be effective in the treatment of binge eating disorder (Walsh et al. 1997), and phentermine, diethylpropion, and orlistat are often provided for obesity (Powell et al. 2011). For some, binge eating may become an ingrained behavior that serves as a form of self-medication in response to negative emotional states such as depression, anxiety, loneliness, boredom, anger, and interpersonal conflict. This highlights the role of behavior modification, in addition to pharmacological interventions, in the treatment of food addictions (Taylor et al. 2010). It should be noted that treatment of disordered eating can be a long and arduous process marked by alternating periods of relapse and recovery.

With regard to obesity, some patients turn to invasive procedures such as bariatric surgical treatments including gastric bypass and gastric banding. While these procedures do result in dramatic weight loss, they can be expensive and can have significant risks, including the development of gastric dumping syndrome and increased risk of bone fractures (Nakamura et al. 2011). As a result, much attention today is focused on developing better treatment options. Given the rise of obesity not only in the USA but around the world (Yach et al. 2006), a number of pharmaceutical companies are looking to develop new treatments for obesity based on the addiction hypothesis (Blumenthal and Gold 2010). Indeed, a number of new treatments are in both phase II and phase III clinical trials (Blumenthal and Gold 2010). The majority of these potential treatment options target the neuropathways and neurotransmitters discussed in this chapter, including raclopride, bupropion, and antipsychotics which target dopamine; naltrexone, naloxone, and nalmefene which target the opioid system; baclofen and topiramate which target the GABAergic system; SR141716, AM 251, and rimonabant which target cannabinoid receptors; as well as several new pharmaceuticals (Berner et al. 2011; Yarnell et al. 2013). However, these medications are not without risk; many of these drugs carry significant side effects including increased risk for depression, anxiety, obsessive-compulsive disorder, seizures, suicide, confusion, or memory deficits (Blumenthal and Gold 2010). Given the risks and side effects associated with these drugs, physicians will need to exercise great care when considering whether to prescribe these treatments and should carefully select their population base prior to prescribing (Blumenthal and Gold 2010).

98.7 Conclusion

As it stands, obesity and binge eating behaviors will continue to be a threat to global health (Avena et al. 2012c). As such, it is perhaps time to reevaluate the current food environment from many aspects while taking into consideration both the individual's perspective and society as whole. Societal measures may, in fact, be required at this time as dysfunctional eating behaviors affect not only the current generation but also its offspring due to the effects that consuming certain highly palatable foods may have on the developing brain in utero.

Given that some of the cultural factors discussed in this chapter are driven by economic factors that lie outside the control of the individual, the topic of obesity cannot simply be relegated to the domain of personal responsibility. Rather, economic incentives that may encourage people to make unhealthy food choices may need to be reevaluated on a larger scale. Indeed, any plan to combat the rise in obesity will need to address the economic, political, social, psychological, and biological factors that contribute to obesity, as well as factors such as taste, accessibility, convenience, cost, and level of promotion (Yach et al. 2006). Moreover, society may need to closely reevaluate the current state of food marketing. As mentioned earlier, one study has found that food-addicted persons respond at an even higher level to food cues than their nonaddicted counterparts (Gearhardt et al. 2011). This finding suggests that advertising cues may contribute, at least in part, to compulsive eating in at-risk persons. Further, societal changes such as reevaluating where government subsidies are allocated, taxation, publicly enforced well-care programs, and corporate-driven employee well-being programs may also be needed to address the issues of disordered eating and obesity. While these efforts are not expected to cure obesity, binge eating, or food addiction, they may help to reduce their prevalence and aid prevention efforts.

Acknowledgment The authors would like to thank Paula Edge and Eric Su for their assistance with the manuscript. Support was provided by the University of Florida and DA-03123 (NMA).

Medical Disorders and Complications of Alcohol and Other Drugs, Pain and Addiction: An Introduction

99

Jag H. Khalsa and Paul S. Haber

The health consequences of drugs are major problems throughout the world with billions of people using legal (tobacco and alcohol) and illegal drugs (amphetamines, cocaine, opiates, hallucinogens, and marijuana). Drug use is associated with burdensome social, economic, and health consequences, the latter involving almost every physiological/biochemical system. These may include psychiatric, cardiovascular, metabolic, and hepatic complications and infectious diseases. Although there is a myriad of problems related to drug use, it is the medical consequences that are the leading causes of death, and consequently, these are of great medical concern. It is evident that this section on medical consequences of drug abuse is an important component of a comprehensive textbook of addiction medicine that should describe, most if not all, these health effects and their clinical management. In general, the principles of assessment and management of these disorders are no different from people who do not abuse drugs or alcohol, but this section of the textbook describes particular patterns of morbidity and approaches to management that distinguish this population.

The typical patient with a substance use disorders has multiple problems rather than single pathology as described above, yet it is not generally feasible for multiple specialists to become involved. Consequently, the addiction medicine specialist needs a broad range of clinical skills to adequately manage patients with complex health problems including pain. Alcohol and other drugs particularly affect the

neurological and gastrointestinal systems but may involve all other systems. The chief medical comorbidities include infectious diseases, sleep, and pain disorders. Patients may be infected with infections including human immunodeficiency virus (HIV) and hepatitis C virus (HCV), tuberculosis, and sexually transmitted infections individually or in combination. Nutrition is important and nutritional disorders may impact on recovery from other co-occurring illnesses. Patients often require complex treatment with multiple medications, and consequently, pharmacokinetic/pharmacodynamic drug-drug interactions are a particular challenge in this population. Physicians with a background in mental health will welcome a concise description of the chief medical disorders to be encountered in their patients. In many cases with pathology that responds to management as recommended in this section, further specialist referral can be minimized.

Infectious diseases form the focus of several chapters in this section. An estimated one third of the global population of seven billion is living with one or more bacterial or viral infections (United Nations AIDS (UNAIDS) 2008). There are an estimated 200 million people who abuse illegal drugs regularly (United Nations Office on Drugs and Crime: World Drug Report 2007) in the world, and this population is at increased risk of blood-borne viruses and other infections. Legal and illegal substance abuse alone costs the American society an estimated 534 billion dollars annually (Office of National Drug Policy 2004), while diabetes and cancer cost an estimated $174 billion (American Diabetes Association 2003) and $263 billion (American Cancer 2008), respectively. Infections that occur in people who use substances lead to enormous social, economic, and health costs to the society. These infections are associated with inferior outcomes in drug users compared to nondrug users for a range of reasons including poor general health, poor engagement with health care, lower rates of treatment uptake, and higher rates of treatment dropout. Alcohol and drug use are also associated with impaired immune function that may increase infection risk. Infectious diseases complicating drug use can affect all systems of the body and are described throughout this section, but the blood-borne viruses are particularly important public health problems. There have been striking advances in the treatment of blood-borne virus infections particularly HCV and HIV. New antivirals have transformed HCV treatment and are poised to rapidly develop further in the coming decade. The complications and management of viral hepatitis in drug-abusing populations, particularly HCV, have been addressed by Giorgio Barbarini. HIV treatment continues to improve in efficacy and tolerability. It is important to note that the problem of drug interactions that appeared earlier between HIV antiretrovirals and methadone seems to be less with the newly approved buprenorphine. Khalsa and his colleagues have reviewed the medical consequences of substance abuse and co-occurring infections and how to clinically manage these health effects.

The cardiovascular complications of alcohol and other drugs have been addressed by Mori Krantz et al. This group has provided an overview on the

broad range of cardiovascular issues including both the pathophysiological approach and practical approach for clinicians. Patients who require surgery present particular challenges. Spies and colleagues provide an overview of the perioperative management problems in people with substance use disorders.

Neurological complications include neuropsychiatric complications such as anxiety disorders, severe depression, and suicidal attempts. Alcohol in particular is a major cause of many of the common neurological disorders including seizures, confusional states, stroke, and peripheral neuropathies. Bough and colleagues describe these disorders and their management. Crome and colleagues focus on memory and cognitive function, which is often the most critical functional impairment in the addicted patient.

Gastrointestinal and liver disorders are commonly seen in the substance-using population particularly in those that misuse alcohol. Alcoholic liver disease is the leading cause of death in those with alcohol dependence and is a major focus of the chapter by Haber and colleagues. Hepatitis C is now the leading indication for liver transplantation and a major public health problem. New antiviral treatment offers great promise over the next decade to increase the cure rate and reduce the morbidity associated with current interferon-based treatment.

There are myriad endocrine changes associated with alcohol and drug use. These include direct action of drugs on endocrine tissues and secondary effects related to infectious diseases, nutrition, and adverse effects from prescribed medications. All classes of abused drugs are associated with endocrine effects particularly alcohol, psychostimulants, and opioids as described by Dobs and Hallinan in respective chapters. Sexual dysfunction is a particular issue and is another clinical problem that may be overlooked in clinical practice. Hallinan describes the common disorders of sexual function and present a clinical approach to their management.

The kidney may be affected by substance abuse in a range of direct and indirect ways. Hennessy provides an overview of the clinically important syndromes and outlines their management.

Disturbed sleep is a very common yet sometimes overlooked complication of substance abuse. It may contribute to relapse and drug seeking as patients often increase use of their primary drug or use other drugs to restore adequate sleep. Varenbut and colleagues provide a sleep medicine overview, with specific emphasis on sleep physiology and the psychiatric and addictive disorders causing sleep concerns. Clinical and laboratory assessment is described. A practical approach is offered for the treatment of sleep disorders with both pharmacotherapy and cognitive behavioral therapy approaches.

In summary, drug abuse and co-occurring infections of HIV and HCV are associated with a wide variety of serious health effects. Although treatment of drug addiction, its medical consequences, and the dual infections of HIV and HCV are complex, good clinical outcomes are achievable with integrated programs of health care.

Cardiovascular Consequences of Addiction

100

Peter K. Moore, David Kao, and Mori Krantz

Contents

Abstract

Drugs of abuse often have important effects on the cardiovascular system, some of which are life-threatening. An understanding of the intersection between addictive and cardiovascular disorders, therefore, is increasingly relevant to general practitioners and psychiatrists. The effects of illicit drugs vary depending upon the agent, dose, route of administration, and its potential interaction with other prescription medications. Cardiovascular consequences can range from innocuous side effects, such as mild tachycardia and hypertension, to life-threatening ventricular arrhythmias and myocardial infarction.

Hemodynamic alterations are common with both active drug abuse and withdrawal and are frequently mediated by the autonomic nervous system.

Sympathomimetic drugs like amphetamines and cocaine often result in an increase in blood pressure and heart rate. In addition, they may cause substantial cardiotoxicity including arrhythmia, stroke, myocardial infarction, heart failure, and death. These stimulant drugs often increase the propensity for developing atherosclerosis. Some of this is mediated by increases in blood pressure and lipids, but may also occur due to proinflammatory effects or increased hypercoagulability. By contrast, some drugs such as opioids lead to small reductions in pulse and blood pressure. Most naturally occurring opioids do not alter cardiac rhythm; however, synthetic opioids, such as methadone, may result in QTc interval prolongation and torsades de pointes, a form of life-threatening ventricular arrhythmia. In this chapter we review the cardiovascular effects of common drugs of abuse including cocaine, amphetamines, nicotine, opioids, alcohol, marijuana, and anabolic steroids.

100.1 Introduction

Drugs of abuse have a myriad of cardiovascular effects. Depending on the drug, dose, and route of administration, cardiovascular consequences can range from innocuous side effects, such as mild tachycardia and hypertension, to life-threatening ventricular arrhythmias and myocardial infarction (Table 100.1). Hemodynamic alterations are common with drug use and most often are mediated through interactions with the autonomic nervous system (Ghuran and Nolan 2000). Sympathomimetic drugs like amphetamines cause an increase in release of peripheral catecholamines stimulating increases in heart rate, systemic vascular resistance, and cardiac contractility, thus resulting in augmentation of cardiac output and blood pressure. In contrast, several drugs are directly cardiodepressant in the acute setting, and many drugs of both types are cardiotoxic causing cardiomyopathy and congestive heart failure with long-term use.

Changes in the balance of myocardial oxygen supply and demand with drug use can lead to myocardial ischemia (Ghuran and Nolan 2000). For example, cocaine augments oxygen demand in the myocardium by increasing heart rate, afterload, and contractility while simultaneously decreasing supply by inciting epicardial coronary vasoconstriction. Modulation of lipid profiles, coagulation factors, platelet function, and inflammation further heighten the risk of cardiac ischemic events in patients using these drugs.

Many recreational drugs are arrhythmogenic in the acute setting or during abstinence/withdrawal. Mechanisms of arrhythmias are complex and likely result from interplay between the direct effects of drugs, electrolyte derangements, sympathetic nervous alterations, and cardiac ischemia. Of particular importance is the interaction of several drugs, especially the synthetic opioids, with a subunit of a voltage-gated potassium channel coded by the human Ether-à-go-go-Related Gene (hERG) (Katchman et al. 2002). Inhibition of this subunit causes alterations

Fig. 100.1 (**a**) Prolonged rate-corrected QT interval (QTc). (**b**) Torsades de pointes, a type of polymorphic ventricular tachycardia

in repolarization during phase 3 of the action potential, which can lead to acquired prolongation of the rate-corrected QT (QTc) interval, augmenting the risk of the ventricular arrhythmia, torsades de pointes, and sudden cardiac death (Fig. 100.1).

This overview highlights the variety of short-term and long-term cardiovascular consequences of abused drugs, with a particular focus on cocaine, opioids, and alcohol employing a clinical vignette format.

100.2 Mechanisms and Cardiovascular Consequences of Abused Drugs

100.2.1 Alcohol

Alcohol (ethanol) is widely used throughout the world with an estimated two billion users representing nearly half of the world's population. Light to moderate alcohol consumption has been associated with a reduced risk of atheroembolic vascular events including myocardial infarction and ischemic stroke, but chronic heavy alcohol use is clearly cardiotoxic and is associated both directly and indirectly with a number of cardiovascular consequences including hypertension, atrial fibrillation, stroke, and cardiomyopathy. Adverse cardiovascular effects begin to appear with consumption of two to three standard drinks/day or more and increase thereafter in a dose-dependent fashion (Lange and Hillis 2012). In comparison with moderate regular drinking, binge drinking is also associated with increased risk of complications such as atherosclerosis, atrial fibrillation (AF), and stroke (Liang et al. 2012). Alcohol is directly toxic to cardiomyocytes via a number of mechanisms including uncoupling of the excitation-contraction system, impairment of calcium sequestration in the sarcoplasmic reticulum, reduction of mitochondrial respiratory ratio, and increased interstitial protein synthesis (George and Figueredo 2011; Lange and Hillis 2012). In addition, alcohol increases sympathetic tone producing elevated heart rate and blood pressure (Mandyam et al. 2012), impairs vagal tone, may precipitate electrophysiologic changes in atrial tissue (Kodama et al. 2011), and is associated with endothelial dysfunction (Goslawski et al. 2013), each of which may contribute to adverse cardiovascular outcomes.

Abstinence often results in rapid improvement in many of cardiovascular consequences and in some cases may be the only intervention necessary in the long term to address alcohol-associated cardiovascular risk. However, acute alcohol withdrawal delirium tremens in particular can precipitate cardiovascular changes that may be fatal. Hypertension and tachycardia are classic symptoms of acute alcohol withdrawal, and though they improve within 3–4 days of alcohol cessation, they may precipitate ischemic or hemorrhagic stroke, acute decompensated heart failure, or cardiac ischemia in the setting of coronary artery disease. Fatal arrhythmias may also be precipitated by adrenergic surge, electrolyte deficiencies, or QT interval prolongation. Management of patients with acute alcohol withdrawal who have known cardiovascular disease is further complicated by potential exaggerated hemodynamic responses to beta-blockers, calcium channel blockers, and long-acting nitrates early in the course of withdrawal (Kahkonen 2006). There is little direct evidence regarding management of cardiovascular complications of acute alcohol withdrawal in the setting of specific cardiac conditions, but propranolol and clonidine are most commonly suggested to treat withdrawal-related autonomic instability as well as aggressive replacement of potassium, magnesium, and phosphate. Because of the potential exaggerated effects on cardiac output and peripheral vascular resistance of both medications, particular caution must be taken in the setting of dilated cardiomyopathy and valvular disease such as advanced aortic stenosis.

Vignette *A 48-year-old man is evaluated in the emergency department on January 2 for intermittent palpitations and chest pressure over the preceding 48 hours. He does not regularly receive medical care and takes no medications. He smokes cigarettes but uses no other drugs. He reports drinking up to 12 packs of beer per day normally and consumed up to double his normal amount during the week prior to presentation. He is noted to have an irregular heart rate of 130, a blood pressure of 140/90, and moderate pedal edema.*

100.2.1.1 Atrial Fibrillation

Atrial fibrillation (AF) is the most common arrhythmia among older adults and is categorized as paroxysmal (intermittent, not exceeding 7 days), persistent (episodes exceed 7 days or require treatment to terminate), and permanent (continuous, long standing) (Fig. 100.2). AF was the most common arrhythmia identified in 1978 as part of the "holiday heart syndrome" that was defined as hospital admission for dysrhythmia immediately following binge drinking in the setting of chronic alcohol use, classically following a weekend, vacation, or year-end holiday (Ettinger et al. 1978). Since then, moderate to heavy drinking has been associated with both new onset AF and exacerbation of existing paroxysmal AF, and it is suspected that alcohol is a causative factor in up to two-thirds of patients $\leq$65 years of age with AF (Samokhvalov et al. 2010; Kodama et al. 2011; Liang et al. 2012; Mandyam et al. 2012). However, the mechanisms underlying this association remain unclear, though clear electrophysiologic changes have been noted in atrial tissue exposed to ethanol including shortening of the action potential duration and refractory period, each of which may trigger dysrhythmia. The increased incidence of atrial fibrillation may also be due to other factors such as heightened sympathetic tone or electrolyte disturbances. Alcohol consumption is often associated with hypokalemia and hypomagnesemia, which both lead to QTc interval prolongation in experimental models. Heavy alcohol consumption has also been associated with left atrial enlargement and left ventricular enlargement (Singh et al. 2013), both of which may increase the risk of developing AF.

Acute AF related to alcohol and/or illicit drug use will often revert to sinus rhythm without requiring electrical cardioversion in young patients (Krishnamoorthy et al. 2009). However, if the patient is likely to continue to use alcohol, they will remain at an elevated rate of future episodes of paroxysmal AF that may become permanent. There are no specific recommendations regarding management of AF related to alcohol use. β-blockers have a theoretical advantage over calcium channel blockers for rate control in light of the adrenergic excess

Fig. 100.2 Atrial fibrillation

thought to contribute to alcohol-related AF. Alcohol and drug abuse have been associated with a lower likelihood of treatment with warfarin, and it remains important to risk stratify all patients using a validated risk score such as the $CHADS_2$ or CH_2ADS_2-Vasc score when deciding whether to initiate prophylactic antiplatelet or anticoagulation therapy (Camm et al. 2010). Unlike warfarin, newer agents such as rivaroxaban, dabigatran, or apixaban offer the advantage of not requiring routine monitoring, which may be useful in the setting of questionable compliance (Camm et al. 2012). These agents were associated with lower rates than warfarin of intracerebral hemorrhage and gastrointestinal bleeding, both of which occur more frequently in alcoholics than nonalcoholics, but there is no direct evidence to determine whether they provide a safe alternative for anticoagulation in AF in the setting of alcohol abuse.

100.2.1.2 Hypertension and Vascular Disease

Alcohol has been associated with dose-dependent increase in blood pressure both acutely and chronically in both men and women in several large studies (Marmot et al. 1994; Yoshita et al. 2005; Wakabayashi and Araki 2010). While the effect was seen at all ages, it was more prominent in the elderly where the propensity for hypertension is elevated. Furthermore, abstinence has been associated with clinically meaningful reductions in blood pressure comparable with effects of antihypertensive medications (Estruch et al. 2005). The mechanism of the association between alcohol and hypertension is incompletely understood, although evidence of vascular dysfunction has been observed even in young binge drinkers (Goslawski et al. 2013). Marked endothelial dysfunction is observed in alcoholics that is only partially reversed with abstinence, suggesting a persistent risk of cardiovascular morbidity and mortality. Furthermore, patients may continue to demonstrate exaggerated blood pressure response to stress for many weeks. Nevertheless, complete abstinence has been associated with reduction in systolic blood pressure of 7–12 mmHg approximating the effects of the most potent antihypertensive drugs. Therefore, abstinence remains a primary recommendation for all patients with hypertension who use alcohol.

The association between alcohol and vascular disease including coronary artery disease and stroke is J-shaped, with small to moderate amounts of ethanol producing reductions in several cardiovascular outcomes due in part to favorable effects on high-density lipoprotein cholesterol and apolipoprotein A–I levels, inhibition of platelet aggregation, increased antioxidant activity, decreased serum fibrinogen, anti-inflammatory effects, and improved fibrinolysis. However, heavy alcohol use is associated with increases in atherosclerotic coronary artery disease (McElduff and Dobson 1997; McClelland et al. 2008; Ruidavets et al. 2010), ischemic stroke, and cerebral hemorrhage (Leppala et al. 1999) compared with moderate drinkers. The mechanism of this association remains controversial but is likely due in part to increased serum triglycerides, hypertension, decreased nitric oxide synthesis, and increased inflammation (Cahill and Redmond 2012). In particular, risks of both coronary and cerebrovascular events have been repeatedly shown to be increased by binge drinking (Snow et al. 2009; Ruidavets et al. 2010), and an acute increase in

stroke risk within 1–24 h of heavy alcohol use has been observed. This may be due to reactive thrombocytosis and increased platelet aggregation during alcohol withdrawal, and we speculate that increased adrenergic activity may also play a role. Paradoxically, the observed association between alcohol and hemorrhagic stroke may relate to impaired coagulation function as well as weakening of cerebral arteries. The increased risk of both stroke and death due to ischemic heart disease appears to return toward baseline in former heavy drinkers (Hillbom et al. 1999; Roerecke et al. 2011), and apart from abstinence, there are no specific risk reduction strategies recommended apart from standard cardiovascular risk reduction. Elimination of tobacco abuse may be a particularly important risk factor given that it is often used in the setting of social alcohol consumption and is itself a potent atherosclerotic risk factor.

100.2.1.3 Cardiomyopathy

Although light to moderate alcohol consumption has been associated with a lower rate of heart failure than nondrinkers, chronic heavy alcohol use is a well-known cause of left ventricular diastolic and systolic dysfunction. In fact, alcohol may be the leading etiology of nonischemic dilated cardiomyopathy in industrialized nations. Most men who develop alcoholic cardiomyopathy have consumed $\geq$8 standard drinks/day for $\geq$5 years. Women appear to be more sensitive to the cardiotoxic effects of alcohol and may develop cardiomyopathy with a smaller comparative exposure. Evidence of cardiotoxicity may be apparent long before the emergence of symptoms, as 30–50 % of alcoholics have echocardiographic evidence of left ventricular hypertrophy and/or diastolic dysfunction and 30 % of asymptomatic alcoholics have evidence of systolic dysfunction as measured by reduced left ventricular ejection fraction (LVEF). Direct myocardial damage may be mediated by acetaldehyde, the first metabolite of ethanol. Acetaldehyde levels are particularly elevated in heavy drinkers, in part due to reduce hepatic aldehyde dehydrogenase activity (Zhang et al. 2004). Chronic activation of the renin-angiotensin-aldosterone system and sympathetic nervous system and nutritional deficiency (especially thiamine) may also contribute to progression of myocardial dysfunction by potentiating alcohol- and acetaldehyde-induced cell death.

Abstinence can result in significant improvement in left ventricular systolic function if achieved early during the progression of myocardial dysfunction. It has been shown that "controlled" intake of two to six standard drinks/day has also been associated with improvement in LVEF within months, but because controlled drinking is generally not possible for alcoholics, total abstinence remains the primary recommendation. Long-term survival in patients with alcoholic cardiomyopathy who achieve abstinence is the same or better than patients with idiopathic dilated cardiomyopathy, whereas patients who continue to drink have a lower survival (Prazak et al. 1996). As for all dilated cardiomyopathies, neurohormonal blockade with β-blockers and renin-angiotensin-aldosterone system inhibitors is the cornerstone of medical therapy. Additional considerations in the setting of alcoholic cardiomyopathy are nutritional and vitamin supplementation, particularly vitamin B12 and folate.

Vignette *During his hospitalization, the patient is noted to be in atrial fibrillation and to have reduced LVEF of 40 %. Cardiac catheterization reveals no coronary artery disease. He is counseled on abstinence; started on β-blockers, an angiotensin-converting enzyme (ACE) inhibitor, warfarin, and loop diuretics; and then discharged to an addiction treatment center. He leaves treatment after 21 days of a 30-day program and is found dead two weeks later in a hotel room. Although there are empty bottles of alcohol in his room, his blood alcohol level is found to be zero. Autopsy revealed an enlarged, hypertrophic heart but no evidence of acute ischemia, consistent with sudden cardiac death.*

100.2.1.4 Sudden Cardiac Death

Large studies have demonstrated an elevated risk of sudden death associated with heavy drinking (>6 drinks/day), even in patients without preexisting ischemic or structural heart disease (Wannamethee and Shaper 1992). Electrophysiologic studies have demonstrated that alcohol increases susceptibility to ventricular arrhythmias as well as supraventricular arrhythmias. However, sudden death may also occur during periods of abstinence or withdrawal. The QTc interval is may be prolonged in up to 63 % of cases during alcohol withdrawal (Cuculi et al. 2006) and normalizes with remission of abstinence symptoms. Electrolyte abnormalities, catecholamine excess, impaired vagal control of heart rate, myocardial fibrosis, and sleep apnea may also contribute to a heightened risk of arrhythmia (Laonigro et al. 2009).

In addition to correction of electrolyte abnormalities, particularly hypokalemia and hypomagnesemia, it is therefore important to consider cardiac monitoring of patients during the early stages of withdrawal, particularly in the setting of underlying structural heart disease and severe symptoms including delirium tremens. Furthermore, caution should be taken in administration of QTc-prolonging medications such as antipsychotics, even if the patient has previously been taking them, as there appears to be acute, transient prolongation of the QTc interval and increased QT variability during alcohol withdrawal. There is currently no recommendation for prophylactic antiarrhythmic therapy or continuing therapy after alcohol withdrawal has subsided.

100.2.2 Cocaine

Vignette *A 44-year-old man presents to the emergency department with complaints of mid-sternal chest discomfort of moderate severity, which has been unremitting for the past 3 hours and radiates to his shoulders. He notes palpitations, feelings of uneasiness, and resting dyspnea. He is a long-standing smoker and has untreated bipolar disorder. He denies illicit drug use but became more agitated when this line of questioning was pursued. Examination reveals an alert male somewhat apprehensive but with normal cognition. Blood pressure is 178/90 mm Hg and pulse rate is 95 beats per minute, while respiratory rate, temperature, and oxygen saturation are within normal limits. Cardiovascular exam reveals normal*

jugular venous pressure and a soft systolic murmur. Lung auscultation is normal. Urine toxicology is positive for benzoylecgonine. ECG demonstrates ST segment elevation in leads V2–V5 with peaked T-waves. QRS duration and rate-corrected QT (QTc) intervals are prolonged. Chest x-ray and serum chemistries (including cardiac troponin) are unremarkable. Upon sharing these results, the patient confides that he and his girlfriend consumed an "eight-ball" (3.5 grams) of cocaine by intranasal route.

Cocaine (benzoylmethylecgonine) is a crystalline alkaloid, derived from the coca plant that is among the most widely abused drugs worldwide. It is a consumed via intranasal insufflation, inhaled vapor from smoking a freebase combination with sodium bicarbonate, or the intravenous route. Cocaine incites a wide array of cardiovascular consequences ranging from acute alterations in hemodynamics to myocardial ischemia, ventricular arrhythmias, and dilated cardiomyopathy (Table 100.1). The extensive effects on the cardiovascular system result from its numerous mechanisms of action. Cocaine is a potent sympathomimetic that augments central sympathetic outflow and has the ability to increase peripheral catecholamine concentration. Cocaine also exhibits antiarrhythmic-like inhibition of voltage-gated sodium channels and potassium channels and has complex, poorly understood interactions with L-type calcium channels (Ramirez et al. 2012).

100.2.2.1 Hemodynamics

Cocaine incites a range of hemodynamic alterations. Sympathomimetic activity dominates at low to moderate doses resulting in tachycardia, systemic vasoconstriction, and coronary vasospasm. However, at higher doses, cocaine's sodium and potassium channel inactivation can lead to cardiodepression, tachy- and bradydysrhythmias, and even vasodilation (Egashira et al. 1991a; Schwartz et al. 2010).

When taken at low doses (~0.35 mg/kg) through the intranasal route, cocaine ingestion simply results in slight elevation of systolic blood pressure, while higher doses (~1.3 mg/kg) will cause an increase in systolic and diastolic blood pressure (~30/15 mmHg) and elevation of the heart rate (~20 bpm). The onset of these alterations occurs at 2 min and peaks at 5–10 min (Resnick et al. 1977). Moderate cocaine doses (2–3 mg/kg) have a positive inotropic effect, resulting in an increase in left ventricular contractility and cardiac index (Boehrer et al. 1992). In sum, low to moderate doses of cocaine result in tachycardia and in hypertension via a rise in both systemic vascular resistance and cardiac output.

The mechanism of catecholamine response is dependent on the route of cocaine administration. Experimentally, intravenous infusion of cocaine in humans blocks the reuptake of catecholamines peripherally, thereby increasing available norepinephrine in the heart and vascular smooth muscle (Muscholl 1961; Tuncel et al. 2002). However, when consumed by the intranasal route, peripheral norepinephrine levels are not elevated (Tuncel et al. 2002). Therefore, the mechanism of hypertension in acute cocaine intoxication following intranasal is due to an increase of central sympathetic outflow (Vongpatanasin et al. 1999).

Tachycardia is mediated through β-adrenergic receptor interactions as nonselective β-blockade with propranolol abolishes the increase in heart rate caused by cocaine (Kenny et al. 1992). Hypertension is partially mediated through α-adrenergic receptors as α-blockade with prazosin experimentally prevents vasoconstriction (Egashira et al. 1991a). However, positive inotropic effects facilitated through β-adrenergic stimulation contribute to hypertension caused by cocaine, as propranolol attenuates the rise in mean arterial pressure by diminishing the cocaine-mediated rise in left ventricular contractility. Combined α- and β-blockade with labetalol eliminates cocaine's chronotropic effect on the heart and significantly blunts the increase in blood pressure (Kenny et al. 1992).

Cocaine use has also been implicated in epicardial coronary artery vasospasm. Animal studies demonstrate that intravenous cocaine administration results in coronary vasoconstriction with a decrease in coronary diameter of 15–46 % (Benzaquen et al. 2001). In addition to α-adrenergic stimulation, cocaine causes vasospasm by increasing the expression of the potent vasoconstrictor endothelin and decreasing levels of nitric oxide (Mo et al. 1998; Wilbert-Lampen et al. 1998). Denuded endothelium that simulates atherosclerotic coronary artery disease exhibits a mean greater degree of narrowing compared to healthy coronary arteries experimentally (Egashira et al. 1991b). Human data have corroborated these observations. In several studies employing a recreational dose of cocaine (2 mg/ml) intranasally in humans, coronary caliber has been shown to decrease (Benzaquen et al. 2001). In a study of patients with and without coronary artery disease undergoing diagnostic catheterization, coronary diameter decreased more than twice as much in diseased arteries (>50 % stenosis) versus normal arteries (Flores et al. 1990). The time course of coronary vasospasm does not simply follow peak serum levels of cocaine. In fact, coronary vasoconstriction was found to occur at a greater magnitude at 90 min post administration when cocaine metabolites were highest compared to 30 min when serum cocaine levels peaked (Brogan et al. 1992). The degree of vasospasm is augmented by concurrent cigarette smoking with 19 % reduction in coronary diameter seen with simultaneous cocaine and smoking and 7 % reduction seen with cocaine alone in one study (Moliterno et al. 1994). The risk of coronary events is further heightened by cocaine's ability to activate platelets and provoke shear stress.

Cocaine infusion has been shown to be directly cardiodepressant in animal models and in vitro human cardiomyocytes (Egashira et al. 1991a; Perreault et al. 1993). This cardiodepression occurs independently of alterations in coronary blood flow (Morcos et al. 1993). The negative inotropic effect of cocaine is paralleled by a decrease in ventricular myocyte intracellular calcium concentration. The mechanism responsible for direct cardiodepression is hypothesized to result from decreased intracellular sodium concentration caused by voltage-gated sodium channel inactivation by cocaine. This results in less sodium available for the sodium-calcium exchanger in the sarcoplasmic reticulum, less calcium storage in the myocytes, and therefore lower intracellular calcium concentrations during depolarization (Perreault et al. 1993). In fact, it has been found that when cocaine's sympathomimetic action on the heart is blocked with β-adrenergic receptor

antagonists, cocaine's direct effect on the heart is unmasked and left ventricular contractility is significantly reduced (Kenny et al. 1992).

100.2.2.2 Myocardial Ischemia

Cocaine is responsible for 57 % of illicit drug-related emergency department visits in the United States, and chest pain is the most common presenting symptom (Finkel and Marhefka 2011). Cocaine-related chest pain is typically described as pressure-like in quality and is frequently associated with dyspnea, diaphoresis, nausea, palpitations, and anxiety (McCord et al. 2008). The reported incidence of acute myocardial infarction (MI) in patients with cocaine-related chest pain ranges between 0.7 % and 6 %. There is a 24-fold increased risk of acute MI within the first hour of cocaine use. However, myocardial injury can also occur hours after use presumably due to cocaine metabolites (Mittleman et al. 1999; McCord et al. 2008). Cocaine is estimated to play a role in one out of four MIs in patients between the ages of 18 and 45, and half of patients with cocaine-related MIs have no evidence of atherosclerotic coronary artery disease on angiography (Lange and Hillis 2001; Qureshi et al. 2001). All routes of administration appear to carry a similar risk of acute MI.

The diagnosis of myocardial infarction in those with recent cocaine use is difficult. There are no historical factors useful for distinguishing MI from chest pain without myocardial injury in this population. Specific characteristics of pain such as onset, location, quality, and duration are not predictive, nor are histories of chest pain, myocardial infarction, or risk factors for atherosclerotic coronary artery disease (Hollander et al. 1994). Furthermore, in the presence of cocaine, electrocardiograms (ECGs) can exhibit abnormal repolarization in the absence of ischemia. Presenting ECGs are abnormal in approximately 55–85 % of cocaine users, and up to 43 % of patients with cocaine-related chest pain meet diagnostic criteria for ST-elevation MI (as defined by >0.1 mV elevation in contiguous leads) (Gitter et al. 1991; Chakko et al. 1994; Hollander et al. 1994). The positive predictive value of ECG for MI in this population is reportedly only 18 % with a sensitivity of approximately 36 % (Hollander et al. 1994). Serum levels of creatinine kinase can be misleading presumably due to rhabdomyolysis (Gitter et al. 1991). However, serum troponin assays remain effective in detecting myocardial injury in cocaine users (Lange and Hillis 2001; Finkel and Marhefka 2011).

Myocardial ischemia is caused by misbalance of oxygen supply and demand. The sympathomimetic actions of cocaine augment myocardial oxygen consumption by increasing heart rate, blood pressure, and myocardial contractility (Lange and Hillis 2001). Simultaneously, coronary artery vasoconstriction, which occurs more dramatically in segments with significant atherosclerosis, decreases oxygen supply. Habitual cocaine use has been linked to premature coronary artery disease in postmortem studies, which is thought to result from increase vascular permeability to LDL and amplified expression of leukocyte adhesion molecules (Lange and Hillis 2001). Acute cocaine use is also associated with intracoronary thrombus formation, which may result from cocaine's ability to activate and trigger aggregation of platelets and augment levels of fibrinogen, von Willebrand factor, and

plasminogen activator inhibitor, without a corresponding increase in plasmin (Heesch et al. 2000; Lange and Hillis 2001; Siegel et al. 2002).

To our knowledge, there have been no randomized, placebo-controlled trials addressing improving outcomes in cocaine-related MIs (McCord et al. 2008). Those with chest pain in the setting of cocaine use should receive IV benzodiazepines as early management, as their use relieves chest pain and mitigates hemodynamic alterations. Nitroglycerin reverses cocaine-associated coronary vasoconstriction and should also been given as a first-line agent. Calcium channel blockers are recommended after benzodiazepines and nitroglycerin have failed. Although they can reverse coronary vasospasm, use of calcium channel blockers in ACS in the absence of cocaine has not been shown to improve survival and may even increase mortality rates in those with decreased left ventricular function. Phentolamine, an α-adrenergic blocker, may also be administered as a second-line agent, as it reverses coronary vasoconstriction.

Recent guidelines for unstable angina and non-ST-elevation MI caution against the use of β-blockers in patients using cocaine, because unopposed α-adrenergic stimulation can potentially exacerbate coronary vasoconstriction and worsen arterial hypertension (McCord et al. 2008; Anderson et al. 2011). β-blockers have been shown to reduce mortality when given orally in the first 24 h in acute coronary syndrome not related to cocaine. However, the mortality rate in cocaine-related MI is lower, which alters the risk/benefit ratio of this intervention (McCord et al. 2008). There have only been two studies that prospectively evaluated the effect of β-blockers on coronary artery vasoconstriction in the setting of cocaine use (Lange et al. 1990; Boehrer et al. 1993; Finkel and Marhefka 2011). These two small studies included only nine to ten patients each and evaluated the effects of only propranolol and labetalol, yet are the basis for the recommendation against β-blockers in cocaine-related chest pain patients (Finkel and Marhefka 2011).

In opposition, recent retrospective studies have evaluated outcomes in patients with cocaine-related chest pain who were given β-blockers prior to the discovery of their recent cocaine use. It was found that β-blocker therapy was associated with a lower incidence of MI without change in the rate of adverse outcomes or peak levels of troponin (Dattilo et al. 2008; Rangel et al. 2010; Ibrahim et al. 2013). In one study, there was a trend toward decreased post-hospital mortality in those receiving β-blockers (Rangel et al. 2010). The 2011 updated AHA guidelines state that it is reasonable to consider administering a combined α- and β-blocker like labetalol in situations when patients are hypertensive and tachycardic and have received a vasodilator such as nitroglycerin or a calcium channel blocker in close temporal proximity (Anderson et al. 2011). Much is still unknown about the potential benefit and harm of β-blockers in patients with cocaine-related myocardial ischemia, and caution should be taken with their use until further investigation has been conducted.

Due to the risk of coronary thrombus formation, patients should be given aspirin, and those with proven MI should receive unfractionated heparin or low molecular weight heparin if there are no contraindications (McCord et al. 2008). Fibrinolytics should be used with caution, as there are reports of devastating complications in

cocaine users, and the diagnosis of STEMI is challenging in this population due to baseline ECG abnormalities (Lange and Hillis 2001; McCord et al. 2008). Percutaneous coronary intervention is the preferred management of intracoronary thrombus, but fibrinolytics can be used in cases of persistent ST segment elevation after nitroglycerin and calcium channel blockers have been given if there are no contraindications and coronary angiography is not available (McCord et al. 2008; Anderson et al. 2011).

Outcomes are generally better in cocaine-related MI compared to MI not related to cocaine (McCord et al. 2008). The incidences of ventricular arrhythmias, congestive heart failure, and death are 4–17 %, 5–7 %, and <2 %, respectively (Lange and Hillis 2001). The better outcomes are presumably due to the overall younger age of patients experiencing MI while using cocaine. However, those who experience cocaine-related MI are at high risk for recurrent ischemic events as more than half will continue to use cocaine and up to 58 % will have recurrence of ischemia (McCord et al. 2008).

100.2.2.3 Cardiac Conduction and Arrhythmia

Cocaine can cause a wide range of electrocardiographic alterations owing to its sympathomimetic actions and antiarrhythmic properties (Ramirez et al. 2012). Cocaine acts similar to class I antiarrhythmic by blocking voltage-gated sodium channels (I_{Na}) in the inactive state. Cocaine also blocks the *hERG*-coded voltage-gated potassium channel responsible for the rapid delayed rectifier potassium current (I_{Kr}) that allows for repolarization. Together, the inhibition of I_{Na} and I_{Kr} slows the rapid upstroke of the action potential during phase 0 and prolongs the action potential duration by delaying phase 3. Electrocardiographically, this results in widening of the QRS complex and prolongation of the QT interval.

Clinically, cocaine use is associated with a variety of arrhythmias (Table 100.2) (Lange and Hillis 2001). The most common alteration is sinus tachycardia, but an assortment of other supraventricular rhythm disturbances has been temporally related to cocaine use, including nonsustained supraventricular tachycardia, atrial fibrillation, and sinus bradycardia (Ramirez et al. 2012). Excluding torsades de pointes, prospective studies on patients consuming cocaine have not consistently demonstrated an increase risk of ventricular arrhythmias other than frequent premature ventricular contractions. However, the literature contains frequent case reports of monomorphic ventricular tachycardia and ventricular fibrillation in cocaine users. These associations are often confounded by polysubstance use and electrolyte derangements, especially acidosis.

A prospective trial demonstrated that when habitual users smoke cocaine, the rate-corrected QT interval (QTc) modestly increases (Magnano et al. 2006). Furthermore, a retrospective report found that QTc interval prolongation is present in approximately 4 % of chronic cocaine abusers, 26 % of patients treated for cocaine toxicity in the ED, and 75 % of cases of cocaine-related mortality (Chakko et al. 1994). In addition to its ability to prolong the QT interval, cocaine has been shown to induce early afterdepolarizations, further increasing the risk of the ventricular arrhythmia torsades de pointes (Kimura et al. 1992). In the case report

Table 100.2 Arrhythmias and ECG abnormalities associated with cocaine

Arrhythmia	ECG abnormality
Sinus tachycardia	PR interval shortening
Sinus bradycardia	PR interval lengthening (first-degree AV block)
Supraventricular tachycardia	
Atrial fibrillation	QRS widening
Atrial flutter	Nonspecific intraventricular block
Second- and third-degree AV block	Right bundle branch block
Accelerated idioventricular rhythm	Left bundle branch block
Torsades de pointes	Left anterior fascicular block
Ventricular tachycardia	QT interval prolongation
Ventricular fibrillation	ST segment elevation/depression
Asystole	T wave peaking, flattening, inversion
	Acquired Brugada syndrome
	ST elevation, down-sloping ST segment, and T wave inversion

literature, QT prolongation is frequently reported, and associated torsades de pointes occurred in almost half of these cases (Ramirez et al. 2012).

Cocaine has seemingly contradictory interactions with atrioventricular conduction (Ramirez et al. 2012). Several small observational studies have shown that cocaine use is associated with PR segment shortening, which would suggest that cocaine enhances conduction through the AV node. However, the case report literature is incongruent with these results and contains several cases of PR prolongation with various degrees of AV block. QRS interval widening reportedly occurs in up to 6 % of patients using cocaine, which is most commonly due to nonspecific intraventricular conduction delay or right bundle branch block. It is important to note that many of these cases may be confounded by electrolyte derangements and concomitant ingestion of other substances.

There have been cases of acquired Brugada pattern associated with cocaine use (Ramirez et al. 2012). However, electrophysiologic testing did not induce sustained ventricular arrhythmias in any of these cases, and it is unknown if cocaine-associated Brugada pattern confers any additional risk of sudden cardiac death.

100.2.2.4 Other Effects: Cardiomyopathy, Endocarditis, Aortic Dissection, and Stroke

Cocaine can cause left ventricular hypertrophy and systolic dysfunction (Lange and Hillis 2001). Administration of cocaine in animal models acutely results in left ventricular dilation and decreased contractility, while intracoronary administration in humans has been shown to be negatively inotropic (Perreault et al. 1993; Schwartz et al. 2010). There are reports of dilated cardiomyopathy in long-term cocaine users as well as acute, reversible, profound left ventricular dysfunction after acute cocaine binge use (Lange and Hillis 2001). Additionally, transient left

ventricular apical ballooning syndrome (takotsubo cardiomyopathy) has been temporally related to acute cocaine intoxication (Schwartz et al. 2010). One study found that left ventricular dysfunction is present in 7 % of apparently healthy, asymptomatic cocaine users (Bertolet et al. 1990).

In those with congestive heart failure, stimulant use (cocaine and amphetamines) is associated with an increased incidence of hospitalization and reduced ejection fraction (Diercks et al. 2008). Cocaine cessation leads to improved cardiac function, and cocaine relapse can cause recurrence of decompensated heart failure (Schwartz et al. 2010). The possible mechanisms of cocaine's effects on myocardial systolic dysfunction include myocardial ischemia/infarction, repetitive sympathetic stimulation of the myocardium (similar to cardiomyopathy associated with pheochromocytoma), hypersensitivity to adulterants or infectious agents leading to myocarditis, alteration of intracellular calcium concentration, and stimulation of cytokine production resulting in remodeling and myocyte necrosis (Lange and Hillis 2001).

As with any substance used by the intravenous route, there is a risk of bacterial endocarditis with IV cocaine use (Lange and Hillis 2001). For unknown reasons, cocaine seems to increase the risk of endocarditis compared to other drugs. Left-sided valves are more frequently involved with cocaine than other IV drugs.

Aortic dissection is well described in the setting of cocaine intoxication (Eagle et al. 2002). The prevalence of cocaine use in aortic dissection has been found to range from 0.5 % in a larger multicenter review to 37 % of aortic dissections at a single inner-city hospital. Cocaine-related aortic dissections primarily affect young, black, hypertensive individuals, and there may be a higher risk with crack cocaine use compared to other routes of administration. The mechanism of cocaine's association with aortic dissection is thought to involve arterial hypertension and tachycardia with a resulting increase in arterial shear stress. Cocaine is associated with decreased aortic elasticity, increased smooth muscle cell apoptosis, and premature atherosclerosis, all of which play a role in increasing dissection risk (Eagle et al. 2002; Finkel and Marhefka 2011).

Cocaine use confers a twofold increase in the risk of ischemic and hemorrhagic stroke (Schwartz et al. 2010). Compared to the general population, former cocaine users experience a higher proportion of subarachnoid hemorrhage, while current cocaine users have higher ratios of both subarachnoid hemorrhage and intracerebral hemorrhage. Subarachnoid hemorrhage most commonly results from rupture of arterial aneurysms, and intracerebral hemorrhagic strokes are thought to result from large spikes in blood pressure. Compared to those not using cocaine, cocaine users with hemorrhagic strokes have worse functional outcomes and increase mortality (Martin-Schild et al. 2010). Overall, cocaine is widely considered the most cardiotoxic among drugs of abuse.

100.2.3 Amphetamines

Amphetamines are a group of drugs that are derived from a β-phenylethylamine core structure, a structure also shared by catecholamines. They cause an increase in

catecholamines concentrations both centrally and peripherally by stimulating their release, blocking their reuptake, and inhibiting their metabolism by monoamine oxidase (Fleckenstein et al. 2007). The degree of peripheral and central sympathetic activation varies between the different types of amphetamines (Kaye et al. 2007). Given their sympathomimetic mechanism of action, it is not surprising that amphetamines share many of the adverse cardiovascular effects associated with cocaine. This section focuses on three commonly abused amphetamines: amphetamine, methamphetamine, and 3,4-methylenedioxymethamphetamine (MDMA).

As would be expected with a sympathomimetic drug, amphetamines cause tachycardia, vasoconstriction, and hypertension (Carvalho et al. 2012). In healthy subjects, oral amphetamine administration results in a dose-dependent increase in both systolic and diastolic blood pressure that peaks in 1–2 h (Mas et al. 1999). There is a biphasic heart rate response; the baroreceptor reflex blunts the initial rise in heart rate, but heart rate quickens again 3–4 h later when blood pressure begins to lower.

The most common clinical presentations of amphetamine users requiring hospitalization are chest pain syndrome, cardiac arrhythmias, palpitations, and hypertension (Kaye et al. 2007). Acute coronary syndrome and acute MI are particular concerns in this population. One series found that 25 % of patients using methamphetamine that presented with chest pain to the emergency department were diagnosed with an acute coronary syndrome (Turnipseed et al. 2003). Indeed, there are an abundance of reports of acute MI in amphetamine users presenting to the ED and in postmortem series (Kaye et al. 2007; Carvalho et al. 2012). Furthermore, patients suffering acute MI associated with amphetamine use are often young. For example, a 15-year-old boy with no previously known cardiac abnormalities had an MI after starting extended-release amphetamine salts for attention deficit disorder (Sylvester and Agarwala 2012). The pathogenesis of cardiac ischemia in the setting of amphetamines results from an increase in myocardial oxygen demand, through augmentation in chronotropy, wall stress, and afterload, with a reduction in coronary blood flow secondary to vasoconstriction (Kaye et al. 2007; Carvalho et al. 2012). The risk of ischemia may be further increased in long-term users, as postmortem and angiographic data suggests that amphetamines may cause premature coronary atherosclerosis (Kaye et al. 2007).

Amphetamines have been associated with sudden cardiac death and ventricular arrhythmias (Bennett and Walker 1952; Kaye et al. 2007; Carvalho et al. 2012). Specifically, in animal models, methamphetamine has been shown to inhibit the channels responsible for the transient outward potassium current, inward rectifying potassium current, and L-type calcium current (Liang et al. 2010). In humans, methamphetamine has been shown to prolong the QTc interval in humans increasing the risk of torsades de pointes (Haning and Goebert 2007).

Aortic dissection has been strongly associated with methamphetamine intoxication in case reports (Kaye et al. 2007). In fact, one autopsy series found that after hypertension, methamphetamine use was the most common risk factor for fatal acute aortic dissection (Swalwell and Davis 1999). The pathogenesis of aortic dissection is proposed to be secondary to hypertension, but methamphetamine may also have a direct degenerative effect on the aortic wall (Kaye et al. 2007).

Amphetamine use is linked to cardiomyopathy in the acute and chronic setting (Kaye et al. 2007; Carvalho et al. 2012). Amphetamine-associated cardiomyopathy is usually manifest as the gradual onset of a dilated cardiomyopathy with systolic dysfunction. In some cases, the cardiomyopathy may reverse with abstinence. Additionally, takotsubo cardiomyopathy has been described in the setting of acute amphetamine use (Carvalho et al. 2012). The pathogenesis of cardiomyopathy in these patients is probably multifactorial with contributions from catecholamine-induced toxicity, oxidative stress, and ischemia (Kaye et al. 2007; Carvalho et al. 2012). As with other cardiomyopathies, the cornerstone of therapy is neurohormonal blockade with β-blockers, renin-angiotensin-aldosterone system blockade with angiotensin-converting enzyme inhibitors, angiotensin receptor blockers and/or aldosterone antagonists, and possibly vasodilators including long-acting nitrates and hydralazine. β-blockers are not recommended for use in the setting of acute cocaine intoxication, and the safety of their long-term use in patients who continue to use sympathomimetic recreational drugs is unknown. Because of the lack of prospective data, β-blocker therapy may be considered only after careful risk-benefit assessment and ideally after documentation of sustained abstinence (Schwartz et al. 2010). Where available, ivabradine may be an alternative to β-blockers in the setting of ongoing cocaine or amphetamine abuse, as it lowers the heart rate and has been shown to improve outcomes via mechanism unrelated to the adrenergic receptor (van Bilsen et al. 2009).

100.2.4 Opioids

Opioids exert their principal clinical actions of analgesia and euphoria via agonist activity at the μ-opioid receptor in the central nervous system (CNS). Respiratory depression occurs in a dose-dependent manner and represents the principle cause of opioid-related mortality. By contrast, cardiovascular effects tend to be relatively mild, with no direct effect of most opioids on cardiac rhythm or myocardial contractility. However, orthostatic hypotension may occur, presumably secondary to histamine release and vasodilation of peripheral arteriolar vessels. In patients with acute coronary syndromes, opioids are often used intravenously for relief of chest discomfort. Intravenous morphine is most frequently utilized in acute myocardial infarction. It leads to mild venodilatation, which decreases preload and myocardial oxygen consumption in the setting of left ventricular systolic dysfunction and pulmonary edema. Intravenous opioids also result in a small decrease in pulse and blood pressure in the acute coronary syndrome patient. Opioids may also improve myocardial energetics at the cellular level and have been associated with enhancement of "ischemic preconditioning." This phenomenon entails repetitive episodes of noncritical ischemia, which may provide myocardial protection to patients chronically treated with opioids. In support of this theory, an autopsy study evaluated age and gender matched decedents stratified by the presence of opioid detected at autopsy (Marmor et al. 2004).

The authors found a lower burden of coronary artery disease among opioid users and postulated that this may relate to ischemic preconditioning.

By contrast to the potential protective effects of opioids with regard to atherosclerotic coronary artery disease, more recent evidence suggests that synthetic opioids may adversely influence cardiomyocyte electrophysiology and occasionally lead to malignant arrhythmia. Specifically, synthetic opioids may block the delayed rectifier potassium ion current known as I_{Kr}, which is encoded by the *hERG* gene. This blockade may lead prolongation of the QTc interval in vivo, which is the requisite substrate for drug-induced torsades de pointes, a type of polymorphic ventricular tachycardia (Fig. 100.1).

Vignette *A 34-year-old law school student presents to your psychiatry office with complaints of fevers, malaise, occasional rigors, and fatigue for 10 days. He has been previously treated for major depression but takes no prescription drugs. He has a 7-year history of intermittent recreational opioid abuse. Over the past 6 months he reports escalation in abuse of prescription opioids including oxycodone and hydrocodone cough syrup with dextromethorphan. When he is unable to use opioids, he develops withdrawal symptoms, and 2 weeks ago he admits to a period of intravenous, black-tar, heroin use. His last opioid consumption was 2 hours ago. The patient is in no acute distress. Examination is notable for a temperature of 38.5 degrees Celsius. Blood pressure is 135/70 mm Hg, and pulse is 112 beats per minute. Cardiovascular exam is notable for a grade III systolic murmur at the lower left sternal border accentuated following inspiration. He reluctantly rolled up his sleeves, revealing the presence of healed track marks and a small abscess in the left antecubital fossa. The remainder of his examination is normal.*

100.2.4.1 Heroin

Diacetylmorphine or heroin was originally formulated as an antitussive agent. It is derived from the opium poppy and was extensively marketed by Bayer Corporation before its addictive potential was recognized in the early 1900s (Marmor et al. 2004). Heroin is often injected after heating a liquid solution but increasingly is smoked or nasally insufflated. Like all opioids, its principal medical complication is central nervous system (CNS) depression and respiratory depression.

The effects of heroin on the cardiovascular system are not extensive, which may in part reflect its close derivation from the natural opium poppy. Heroin abuse is associated with acute pulmonary edema, but this is generally non-cardiogenic in origin. The typical hemodynamic findings include normal pulmonary-capillary pressure and a normal or increase cardiac output (Barceloux 2012), suggesting the absence of direct myocardial toxicity. Although moderately elevated pulmonary artery pressures have been described, this is most likely due to direct pulmonary toxicity in the setting of injected impurities or in overdose with hypoxemia leading to subsequent increased pulmonary-capillary leakage.

The most feared cardiovascular complication of heroin abuse is the development of infective endocarditis. Infective endocarditis is diagnosed using the Duke criteria based on a combination of major (bacteremia and valvular vegetation seen on echocardiography) and minor diagnostic criteria including fever, intravenous drug use history, and vascular embolic findings such as nail bed or "splinter" hemorrhages (Durack et al. 1994). Heroin may also result in embolic stroke due to systemic embolization of cardiac valvular vegetations to the brain. Infective endocarditis of the right-sided heart valves (tricuspid and pulmonic) should always alert the clinician to the possibility of surreptitious intravenous drug abuse. Moreover, the type of bacterium isolated from blood cultures may be pathognomonic for intravenous drug abuse. Pyogenic species such as *Staphylococcus aureus* are commonly isolated as this bacterium may be carried on the skin of intravenous drug abusers. In addition, Pseudomonas and even fungal organisms have been reported given the potential for suspending heroin in contaminated water. In suspected cases of endocarditis, a complete skin examination is mandatory that includes the neck, groin, and feet, as patients are not always forthcoming in exposing pathognomonic skin lesions associated with injection drug use. Careful cardiac auscultation is essential, and both systolic (tricuspid and mitral valve destruction) and diastolic (aortic and pulmonic valve destruction) regurgitant murmurs may be detected. Cases of potential endocarditis should be confirmed immediately by transthoracic echocardiography, which is often diagnostic particularly for right-sided valvular vegetation. If there is a high clinical suspicion for this disorder, transesophageal echocardiography is increasingly utilized as it offers enhanced visualization, particularly of left-sided valvular structure.

Since the early 1970s, a high incidence of sudden death has been noted among heroin users, some of whom were receiving methadone treatment. One study suggested that QTc interval prolongation occurred more often among individuals receiving methadone (Lipski et al. 1973). However, this study was not designed to prospectively address the effects of methadone, heroin, or both medications on cardiac repolarization. More recently, in a study of 115 active heroin users admitted to an opioid treatment center, the median QTc interval was not significantly different compared with 57 healthy controls (Lysenko et al. 2008), which suggests that heroin is unlikely to be directly associated with cardiac arrhythmia. This clinical finding is consistent with its pharmacologic classification as a natural (esterified morphine), rather than a synthetic, opioid.

Vignette (Continued) *The patient is effectively treated for tricuspid valve endocarditis with 6 weeks of intravenous antibiotics with resolution of symptoms. He returns to school but eventually begins to relapse and abuse heroin. He asks for assistance and it's decided to induce him onto methadone maintenance therapy. It is initiated on 30mg/day and up-titrated to 90 mg daily at which point he feels well and discontinues illicit opioids entirely. One month later he is at the opioid treatment center in a group counseling sessions and develops the sudden onset of tonic-clonic seizures and loss of consciousness. He regains awareness and is referred for neurologic evaluation. Computed tomography of the brain is normal.*

Subsequently, magnetic resonance imaging is performed without focal lesion and an electroencephalography study is similarly unremarkable. He started on low dose anti-epileptic therapy but one month later is involved in a motor vehicle accident after passing out while driving.

100.2.4.2 Methadone and Synthetic Opioids Used in Addiction Treatment

Methadone is the most commonly utilized medication for treating heroin addiction worldwide given its low cost and long terminal elimination half-life. This allows patients to break the cycle of frequent, daily heroin use. Methadone is a synthetic diphenylpropylamine compound with a chemical structure similar to propoxyphene (Marmor et al. 2004). Propoxyphene was recently removed from the market in the United States and a number of other countries due to reports of QTc interval prolongation and ventricular arrhythmias (Food et al. 2011).

To investigate the effect of synthetic opioids on arrhythmia risk, the principal focus is on cardiac repolarization. Repolarization describes the phase in the cardiac cycle where myocytes "reset" and is clinically characterized by the QTc interval on the surface electrocardiogram. Opioids have generally been considered devoid of cardiac activity. However, the cardiac repolarization changes associated with synthetic opioids were characterized in human cells stably transfected with the hERG gene which encodes the I_{Kr} current (Katchman et al. 2002). The ratio of the concentration of drug that blocks 50 % of I_{Kr} channels (IC50%) was divided by the expected maximal plasma concentration (Cmax) in man for the individual drugs yielding the IC50/Cmax. This ratio predicts the likely occurrence of QTc prolongation, with higher numbers suggesting the greatest margin of safety. The IC50/Cmax observed with codeine and morphine (and by extension diacetylmorphine or heroin) was >400 uM. These "naturally occurring" opioids therefore are not associated with QTc prolongation and torsades de pointes. By contrast, the synthetic opioids fentanyl, meperidine, and buprenorphine exhibited modest blockade with IC50/Cmax ranging from approximately 50 to 200. Notably, the most potent I_{Kr}-blockade was observed with methadone and levacetylmethadol (LAAM), with ratios of 2.7 and 2.2, respectively. This creates a challenging paradox: while synthetic opioids clearly reduce the harm of injection drug use including the risk of hepatitis, HIV infection, and endocarditis, they also have a cardiac safety liability in susceptible individuals.

From a clinical perspective, LAAM was first shown to have a dose-dependent relationship with cardiac repolarization in 2001 (Huber et al. 2001). LAAM, a long-acting methadone derivative was discontinued from the market in Europe, Australia, and the United states in 2003 due to its association with cardiac arrhythmia. This leaves methadone and sublingual buprenorphine as the primary therapeutic choices for opioid-dependent patients. In 2002, a case series of torsades de pointes associated with high-dose oral methadone was first described (Krantz et al. 2002). In the case presented within the clinical vignette, it is likely that the patient's grand mal seizures and syncope were manifestations of torsades de pointes. Torsades de pointes is a self-terminating arrhythmia in most cases, though it may degenerate

into ventricular fibrillation and lead to sudden cardiac death. A case of methadone-induced arrhythmia masquerading as epilepsy has been previously described (Krantz et al. 2005). This highlights the fact that ventricular arrhythmia if prolonged may result in marked reduction of cardiac output and cerebral hypoxemia and subsequent seizures. Thus, seizures are not always due to epilepsy and should alert clinicians to the possibility of life-threatening arrhythmia.

Many addiction clinicians are unaware of the cardiac arrhythmic properties of synthetic opioids used in treating opioid dependency (Krantz et al. 2007). However, a recent registry study found that ventricular arrhythmia and cardiac arrest are now the most frequent FDA-reported class of methadone-associated adverse events, and reports of QTc prolongation and torsades de pointes have increased sharply in the past decade (Kao et al. 2013). In this study, methadone was associated with a disproportionate signal of torsades de pointes reporting similar to that of drugs with established proarrhythmic properties (such as dofetilide). By contrast, propoxyphene, which was recently withdrawn from the market due to QTc prolongation and dysrhythmia, was not associated with disproportional arrhythmia reporting. Because available evidence definitely suggests that both oral and intravenous methadone hydrochloride cause QTc interval prolongation and torsades de pointes, a consensus guideline suggesting QTc interval screening was developed (Krantz et al. 2009). The guideline emphasized five recommendations for physicians prescribing methadone (Table 100.3). Because the arrhythmia risk associated with methadone is a direct consequence of its effect on cardiac repolarization, the recommendations are applicable to patients either receiving current treatment with methadone or being considered for initiation of methadone treatment for addiction or pain management. Because methadone is now considered an essential medication by the World Health Organization, its utilization is expected to rise, highlighting the need to enhance its cardiac safety.

Table 100.3 Consensus recommendations for QTc interval screening in methadone treatment (Krantz et al. 2009)

Recommendation 1 (disclosure)	Clinicians should inform patients of arrhythmia risk when they prescribe methadone
Recommendation 2 (clinical history)	Clinicians should ask patients about any history of structural heart disease, arrhythmia, and syncope
Recommendation 3 (screening)	Obtain a pretreatment ECG for all patients to measure the QTc interval and then a follow-up ECG within 30 days and annually. Additional ECG is recommended if the methadone dosage exceeds 100 mg/d or if patients have unexplained syncope or seizures
Recommendation 4 (risk stratification)	If QTc interval is >450 ms but <500 ms, discuss potential risks and benefits with patients and monitor them more frequently. If the QTc interval exceeds 500 ms, consider discontinuing methadone or reducing the methadone dose; eliminating contributing factors, such as drugs that promote hypokalemia; or using an alternative therapy
Recommendation 5 (drug interactions)	Clinicians should be aware of interactions between methadone and other drugs that possess QT interval-prolonging properties or slow the elimination of methadone

100.2.5 Nicotine

Cigarette smoking is the leading risk factor for developing cardiovascular disease, increasing risk of coronary artery disease by up to 80–100 % (Law et al. 1997). Secondhand smoke exposure is also harmful, potentially increasing risk of coronary artery disease by up to 30 % (Whincup et al. 2004). Furthermore, pipe smoking, smokeless tobacco, and cigars are all associated with increases in cardiovascular morbidity and mortality (Katsiki et al. 2013). Nicotine is the addictive and primary active component in tobacco products and causes many of the adverse cardiovascular effects of smoking. Nicotine acts in part by stimulating release of norepinephrine from sympathetic nerves and by release of epinephrine from the adrenal glands, which produce increases in heart rate and blood pressure shortly after exposure. Although the precise role of nicotine relative to other components of cigarette smoke is unclear, cigarette smoking is also associated with vasomotor dysfunction mediated by reduced availability of nitric oxide, systemic inflammation that increases adherence of leukocytes to endothelial cells, increases in serum low-density lipoprotein and triglycerides with decreases in high-density lipoprotein, platelet dysfunction, and alteration of thrombotic factors (Ambrose and Barua 2004). Consequently, cigarette smoking is associated with increased rates of all-cause and cardiovascular mortality, first myocardial infarction, recurrent infarction or revascularization in patients with coronary artery disease, sudden death, and stroke (Foody et al. 2001; Prescott et al. 2002; Rodriguez et al. 2002; Goldenberg et al. 2003).

Cessation of smoking is associated with rapid decreases in cardiovascular events including myocardial infarction, stroke, and sudden death, with rates returning to near that of nonsmokers within 3–4 years in many cases (Rea et al. 2002; Gellert et al. 2013). Although the increased risk of cardiovascular events associated with smoking appears to increase with age, the benefits of cessation are independent of age. Despite the clear risks of smoking and benefits of smoking cessation, smoking rates remain relatively stable, and the rate at which physicians in the United States advise patients to stop smoking has actually decreased over the last 10 years (Kruger et al. 2012). Intensive support including structured behavioral modification counseling and pharmacotherapy with either nicotine replacement therapy and/or bupropion appears superior to one-time counseling in patients hospitalized for coronary disease or heart failure, although even a brief statement to outpatients of the risks associated with smoking can result in increases in smoking cessation (Lin et al. 2013).

The acute hemodynamic effects of nicotine withdrawal are poorly characterized, but appear minimal. Blood pressure and heart rate are likely to decrease compared with ongoing tobacco use (Morrell et al. 2008), and withdrawal symptoms are primarily limited to psychosocial changes including prominent irritability. Consequently, abrupt smoking cessation as may occur during hospitalization for myocardial infarction or heart failure is unlikely to adversely affect an individual's hemodynamic status. Theoretical concerns regarding vasoconstrictor activity of nicotine and rare anecdotal reports of myocardial infarction in patients

taking nicotine replacement therapy, particularly those who continue to smoke, have resulted in caution in using nicotine replacement therapy in patients with known coronary artery disease, including immediately post-myocardial infarction (Hubbard et al. 2005; Woolf et al. 2012). However, large studies have failed to show an increased risk of cardiovascular events or death following initiation of nicotine replacement therapy in the setting of cardiovascular disease. Furthermore, effects of continued smoking on platelet activation, hypercoagulability, and other factors suggest that any small increase in atheroembolic risk associated with nicotine replacement therapy is far outweighed by the potential benefits of smoking cessation. There are very few drug-drug interactions between nicotine replacement therapy and cardiovascular medications. Bupropion appears safe to use in patients hospitalized for acute myocardial infarction, but may not be as effective as in chronic, stable outpatients (Eisenberg et al. 2013). Varenicline has not been studied specifically in the acute post-myocardial infarction setting. The use of varenicline in patients with cardiovascular disease is controversial due to some evidence of trends toward a small increase in cardiovascular events in unselected populations (Ware et al. 2013), and the FDA issued an advisory in 2011 that varenicline may increase the risk of adverse cardiovascular events in patients with known cardiovascular disease (US Food and Drug Administration 2011). However, these findings have not been verified, and it is likely that any increased risk is quite small (Prochaska and Hilton 2012). Nonetheless, given the paucity of safety data with varenicline in patients with known cardiovascular disease, patients using varenicline should seek medical attention promptly if their cardiovascular symptoms worsen.

The effects of smoking ordinances that reduce secondhand smoke exposure and the risk of myocardial infarction are an important albeit controversial international public health issue. The biologic effects of secondhand smoke have been well characterized and mirror those of direct tobacco exposure. In particular, coronary arterial plaque destabilization is triggered by nicotine in secondhand smoke; this stimulates the matrix metalloproteinase enzyme that degrades the fibrous cap in coronary plaques (Carty et al. 1996). Secondhand smoke is also associated with impaired coronary endothelial function, increased aortic stiffness (Mahmud and Feely 2003), as well as reduced heart rate variability (15), a marker of abnormal sympathetic nervous system activity. Early studies examining the effect of smoking ordinances found unexpectedly large reductions in myocardial infarction as high as 40 % in Helena, Montana, United States (Meyers et al. 2009). Larger statewide and countrywide smoking studies have been completed including Scotland, England, Italy, the Netherlands, New Zealand, Ireland, and the United States, suggesting an attenuated impact from smoking legislation. In particular, one US analysis found that in contrast to smaller regional studies, smoking bans were not associated with statistically significant short-term declines in mortality or hospital admissions for myocardial infarction or other diseases (Shetty et al. 2010). Regardless of the ultimate impact of smoke-free policy on cardiovascular events, it remains clear that nicotine is among the most highly active substance in tobacco leading to adverse cardiac physiology.

100.2.6 Cannabis

Cannabis (marijuana) is generally thought to be relatively benign by the community despite growing evidence that implicates it in several serious cardiovascular complications including myocardial infarction and ischemic stroke (Bachs and Morland 2001). Cannabis is most commonly smoked and rapidly absorbed through the lungs with physiologic changes appearing shortly after use (Ghuran and Nolan 2000). When consumed through the enteral route, absorption is slower and less predictable. The primary active constituent of cannabis is Δ-9-tetrahydrocannabinol (THC), which interacts with G-protein-coupled cannabinoid receptors (CB1 and CB2) (Pertwee 2006). CB1 receptors are found primarily on neuronal tissue, and their activation at peripheral nerve terminals inhibits neurotransmitter release (Pertwee 2006). In addition, there may be cross talk between CB1 and α_2-adrenergic receptors on the presynaptic autonomic nerves.

THC causes a biphasic autonomic response. The sympathetic nervous system is activated at low to moderate doses and the parasympathetic nervous system predominates at higher doses (Ghuran and Nolan 2000). This results in tachycardia and augmented cardiac output at lower doses and hypotension and bradycardia at high doses. Even at low doses, cannabis can cause both hypertension and hypotension. Blood pressure alterations during cannabis use are often positional; blood pressure increases while in the seated or supine position and drops while standing (Pratap and Korniyenko 2012). Hypotension can also occur during the act of smoking due to rapid changes in autonomic nervous system output, and orthostatic hypotension with resulting syncope is not an uncommon occurrence. Autonomic changes are generally well tolerated in healthy individuals, and cannabis-induced hypotension usually resolves spontaneously or responds to intravenous fluid boluses (Ghuran and Nolan 2000).

Cannabis use increases myocardial oxygen demand by increasing heart rate, wall stress, and sometimes blood pressure. Additionally, when smoked, it decreases oxygen supply through carboxyhemoglobin formation (Aronow and Cassidy 1974). Cannabis use has been shown to decrease threshold to symptomatic angina pectoris. Furthermore, one study demonstrated that the risk of acute MI is 4.8 times higher within the hour following cannabis use (Mittleman et al. 2001). A follow-up study of these MI patients found that continued marijuana use of more than once per week was associated with a 4.2-fold increased risk of death over a 3.8-year period (Mukamal et al. 2008).

In addition to cardiac ischemia, evidence is emerging that implicates cannabis use with inciting ischemic stroke (Wolff et al. 2013). As of 2013, there have been 59 reported cases of stroke associated with cannabis use. All but one were ischemic in origin and the patients were often young. Cannabis use has been particularly strongly associated with two specific etiologies of ischemic stroke: reversible cerebral vasoconstriction syndrome (RCVS) and multifocal intracranial stenosis (MIS). In a prospective study evaluating cannabis' role in ischemic stroke, a single center enrolled every patient under 45 years of age that presented with ischemic stroke (Wolff et al. 2011). It was found that cannabis use was highly associated with

ischemic strokes caused by multifocal intracranial stenosis. In this study, ten of 11 multifocal intracranial stenosis stroke patients had used cannabis for years, and all had binge-smoked cannabis the day prior to their ischemic events. Caution must be taken with attributing these events solely to cannabis, as all patients also smoked tobacco regularly and half of these patients had binged on alcohol shortly before their ischemic events.

Epidemiological data demonstrates that cannabis users are more likely to feel palpitations than nonusers, which is usually caused by sinus tachycardia (Petronis and Anthony 1989). However, other arrhythmias have also been temporally related to cannabis use such as sinus bradycardia, atrial fibrillation, atrial flutter, ventricular extrasystoles, and second-degree AV block (Fisher et al. 2005; Pratap and Korniyenko 2012). The onset of arrhythmias can begin within a few minutes of cannabis use, peaks at about 30 min, and can last as long as 90 min (Johnson and Domino 1971). The majority of these arrhythmias revert spontaneously to sinus rhythm. If persistent, the American Heart Association and European Society of Cardiology management protocols should be followed (Fisher et al. 2005). There are two cases of cannabis-induced Brugada pattern, neither of which were associated ventricular arrhythmias (Pratap and Korniyenko 2012). Although reports of ventricular arrhythmias are not common with cannabis use, a postmortem case series carried out on six patients with unexplained sudden death with recent cannabis use concluded that causes of death were "acute cardiovascular events," possibly representing fatal arrhythmias (Bachs and Morland 2001).

100.3 Anabolic Steroids

Anabolic steroids have varying degrees of androgenic properties and are frequently utilized by athletes, weightlifters, and bodybuilders to enhance athletic performance and strength. Anabolic steroids are associated with direct effects such as left ventricular hypertrophy and myocardial fibrosis and indirect effects, including dyslipidemia, hypertension, arrhythmia, and myocardial infarction (Higgins et al. 2012). It is likely that chronic exposure to these agents can result in significant alterations in the cardiovascular system, beyond the expected increase in salt and water retention leading to elevations in blood pressure in susceptible patients.

Cardiomyocytes have testosterone receptors, which may explain the propensity to muscular hypertrophy in the setting of supraphysiologic doses. The most feared complication of anabolic steroids, however, is the increased risk of ischemic cardiovascular events. Numerous reports of myocardial infarction have been described in the literature even among young patients. In addition, there is further concern that anabolic steroids may accelerate the overall atherosclerotic process with ongoing abuse. A framework for understanding this risk has been put forward (Melchert and Welder 1995). Four mechanisms are suggested: (1) atherosclerosis-dyslipidemia model given marked reductions up to 70 % in high-density lipoprotein (HDL) cholesterol, which is responsible for reverse cholesterol transport and >20 % increases in the atherogenic low-density lipoprotein (LDL) cholesterol;

(2) vasospasm model given alterations in the vascular nitric oxide system; (3) thrombosis model involving alterations in platelet and clotting function including increases in plasminogen activator activity; and (4) direct myocardial injury model including impaired myocardial relaxation and diastolic dysfunction. Another factor that enhances the risk of myocardial infarction is polycythemia associated with anabolic steroids. This increases blood viscosity and the risk of thrombosis. As such, a complete blood count should be obtained in patients using anabolic steroids who present with ischemic complications. Beyond the risk of acute myocardial infarction, these agents have been associated with cerebrovascular accident (Garcia-Esperon et al. 2013), suggesting that atheroembolic complications may affect all vascular territories. Furthermore, anabolic steroid use has been associated with supraventricular and ventricular ectopy, atrial fibrillation, ventricular fibrillation, and ventricular tachycardia, and cardiac pathology has been frequently observed in deceased anabolic steroid abusers (Thiblin et al. 2000).

Anabolic steroid use should be considered in young athletes with evidence of hypertension, very low serum HDL and elevated LDL cholesterol levels, atrial or ventricular arrhythmias, and/or left ventricular hypertrophy by electrocardiogram or echocardiogram. There is little data regarding cardiovascular risk reduction associated with anabolic steroid use apart from abstinence. The actual prevalence of significant coronary artery disease among anabolic steroid users is not known, and cardiovascular risk reduction should conform to standard age-appropriate guidelines until additional data is available. Blood pressure and lipid abnormalities will generally resolve after 6–12 months of abstinence, but there is evidence that pathologic left ventricular hypertrophy may persist for years after discontinuation of steroid use, although this persistence may be due to sustained or ongoing strength training (Achar et al. 2010). If blood pressure abnormalities are particularly severe, or do not resolve with abstinence, pharmacologic intervention should be considered. Statin therapy should be initiated for sustained LDL cholesterol levels $\geq$160 mg/dL in accordance with current guidelines. Rosuvastatin in particular appears more effective in raising HDL levels than other statins. Omega-3 fatty acids and niacin have also been associated with increases in HDL cholesterol, but their efficacy in reducing risk of cardiovascular effects is uncertain. Antihypertensive therapy should be considered if the blood pressure is consistently $\geq$140/90 in accordance with currently guidelines. The optimal antihypertensive agent for steroid-associated hypertension is unclear, although the stimulation of the renin-angiotensin-aldosterone system observed in anabolic steroid users suggests that ACE inhibitors or angiotensin receptor blockers may be particularly effective and are often tolerated well by young patients. β-blockers are typically not used as monotherapy for hypertension, but may be considered if coexisting arrhythmias are present. There is currently no evidence or recommendation for antiplatelet therapy for primary prevention in anabolic steroid use. There is no clear evidence for pharmacologic treatment of LV hypertrophy, although dilated cardiomyopathy as a result prolonged steroid use and/or ischemic events should be treated in accordance with heart failure guidelines using neurohormonal blockade with β-blockers and renin-angiotensin-aldosterone system inhibitors along with vasodilators and/or diuretics according to patient symptoms.

Abstract

Acute and chronic gastrointestinal manifestations are common in the setting of alcohol, tobacco, prescription, and recreational drug use. Excessive alcohol use is associated with injury to all parts of the gastrointestinal tract. Within the gastrointestinal tract, alcoholic liver disease, alcoholic pancreatitis, and gastrointestinal cancer are important causes of morbidity and mortality related to excessive alcohol use. Tobacco use is associated with gastroesophageal reflux, peptic ulceration, and gastrointestinal cancer but appears to protect against ulcerative colitis. Opioids have important effects on gastrointestinal secretion and motility. Narcotic bowel syndrome may develop in the setting of escalating doses of opioid analgesia. Cannabinoid hyperemesis syndrome should be considered in the setting of heavy cannabis use and recurrent vomiting. The body packing syndrome is rare but challenging when encountered.

101.1 Introduction

This chapter describes gastrointestinal effects of gastrointestinal disorders secondary to the effects of alcohol, tobacco, prescription, and recreational drugs.

Excessive alcohol use is associated with injury to all parts of the gastrointestinal tract. Several detailed reviews have been published (Bujanda 2000). The gastric mucosa is a target for alcohol-related toxicity but also contributes to the oxidation of alcohol. Within the gastrointestinal tract, liver disease and pancreatitis are important causes of morbidity and mortality related to excessive alcohol use. Symptoms of intestinal dysfunction are common among people with alcohol dependence and include diarrhea and malabsorption.

Tobacco use is associated with gastroesophageal reflux, peptic ulceration, and gastrointestinal malignancy but appears to protect against ulcerative colitis. Opiates have important effects on gastrointestinal secretion and motility. Other drugs of abuse such as cannabis and cocaine uncommonly affect the gastrointestinal tract. The body packing syndrome is rare but challenging when encountered.

101.2 Alcohol

The relative risk of alcohol-related GI toxicity appears to differ between affected tissues and between benign and neoplastic disorders. Similarly the pattern and type of beverage have not been consistently shown to predispose to any specific GI effects of alcohol.

101.2.1 Parotid Glands and Oral Cavity

Painless symmetrical enlargement of the parotid glands (termed sialosis or sialadenosis) is common in patients with alcoholic liver injury (Proctor and Shori 1996). Abelson et al. (1976) found 61 % of patients with alcohol cirrhosis had

enlarged parotid glands. Sialosis is characterized by the triad of acinar cell hypertrophy, myoepithelial degeneration, and neural degeneration. Salivary secretion is reduced in experimental animals given alcohol. These effects may contribute to progressive dental caries and poor oral mucosal health. The effect of alcohol abuse on salivary function in humans is controversial with reports of increased, unaltered (Silver et al. 1986), and decreased salivary flow (Proctor and Shori 1996). Moreover, alcoholics may suffer from inflammation of the tongue (i.e., glossitis) and the mouth (i.e., stomatitis). It is unclear, however, whether these changes result from poor nutrition or reflect a direct effect of alcohol on the mucosa.

101.2.2 Esophagus

Both acute and chronic alcohol consumption are associated with symptomatic gastroesophageal reflux disease (GERD). Dysfunction of the lower esophageal sphincter (LES) and esophageal peristalsis and abnormal gastric acid secretion may be involved in the pathogenesis of alcohol-related GERD. Exposure of the esophagus and stomach to alcohol may cause direct damage to esophageal and gastric mucosa. In addition, acetaldehyde generated from alcohol may affect the function of the esophagus and stomach. Systemic investigations concerning this matter are still inadequate and further well-designed prospective studies are needed to clarify the effect of alcohol on GERD. An Irish study concluded that alcohol consumption in early adulthood may lead to the development of reflux esophagitis. More recent alcohol consumption does not appear to confer any increased risk of reflux esophagitis, Barrett's esophagus, or esophageal adenocarcinoma. In fact, wine consumption may reduce the risk of these esophageal disorders (Anderson et al. 2009).

Reflux episodes were increased by 60 g of ethanol given with a meal to healthy subjects without alcohol dependence (Kaufman and Kaye 1978). These episodes were measured by measurement of esophageal pH for three hours after a standard meal and most were asymptomatic. A number of mechanisms have been identified that may contribute to these effects of alcohol (Lieber 1992b). Direct application of 30 % ethanol, but not lower concentrations, causes injury to the esophageal mucosa. An acute dose of alcohol reduces lower esophageal sphincter pressure (LESP) (Hogan et al. 1972) and reduced maximal LESP stimulated by a meal (Mayer et al. 1978). Chronic excessive alcohol use is also associated with manometric abnormalities relevant to GERD that recover with a month of abstinence (Keshavarzian et al. 1987; Silver et al. 1986). These abnormalities were found regardless of the presence or absence of peripheral neuropathy. These studies provide evidence to support the time-honored advice to reduce alcohol consumption in the presence of symptomatic GERD.

Upper gastrointestinal bleeding (UGIB) is more frequent in alcoholics, especially those with cirrhosis. In a 2007 UK audit of 6,750 patients with acute UGIB, 9 % had known cirrhosis and 26 % a history of alcohol excess (Hearnshaw et al. 2011). A Czech prospective study of 137 cirrhotic patients presenting with acute UGIB found the following causes: esophageal varices (57.7 %), peptic gastric and duodenal ulcers (18.2 %), portal hypertension gastropathy (9.5 %), gastric

varices (5.1 %), reflux esophagitis (2.9 %), Mallory–Weiss syndrome (2.9 %), and erosive gastropathy (1.5 %). The mortality in all bleeding cirrhotic patients was 14.6 % (Svoboda et al. 2012). Mallory–Weiss syndrome is characterized by massive bleeding caused by tears in the mucosa at the cardio-esophageal junction after vomiting. The syndrome accounts for 5–15 % of all cases of bleeding in the upper GI tract. Mallory–Weiss syndrome prevalence varies; it is uncommon in China (Yin et al. 2012). In one series, almost 50 % of these patients, the disorder was caused by increased gastric pressure resulting from repeated retching and vomiting following excessive acute alcohol consumption (Kortas et al. 2001).

101.2.3 Stomach

101.2.3.1 Alcoholic Gastritis

The clinical term "alcoholic gastritis" is nonspecific and is often used to refer to a broad range of upper gastrointestinal symptoms experienced by people who drink alcohol excessively. It has been surprisingly controversial despite considerable study (Feinman et al. 1992; Konturek et al. 1996). The term gastritis is used to denote inflammation associated with mucosal injury. Epithelial cell damage and regeneration without associated inflammation are referred to as "gastropathy" (Dixon et al. 1996). It is often difficult to establish with certainty that a particular agent, such as alcohol, has caused gastropathy. Exposure of the gastric mucosa to 20 % alcohol induces gastric mucosal injury. Lower concentrations are not toxic, whereas higher concentrations lead to extensive hemorrhagic injury (Konturek et al. 1996).

101.2.3.2 Dyspepsia and Ulcer

In humans admitted for treatment of alcohol dependence, gastric hemorrhagic and erosive lesions and ulcers were commonly seen (Segawa et al. 1987). Interestingly, Brown et al. (1981) found that gastritis was not more common in patients with cirrhosis than healthy controls. Gastritis in people with alcohol dependence is strongly associated with *H. pylori* infection, with histological and symptomatic relief after eradication of the organism but no improvement with abstinence from alcohol (Uppal et al. 1991). This finding has been confirmed by another group (Hauge et al. 1994). The presence of alcohol dehydrogenase (ADH) activity in *H. pylori* organisms may tend to protect the alcohol drinking host from infection as exposure to alcohol leads to generation of acetaldehyde that may be bactericidal. Alcohol abuse is associated with reduced medication compliance and delayed healing (Reynolds 1989), but healing of established ulcers is not retarded by moderate alcohol consumption (Battaglia et al. 1990). The available evidence does not convincingly support the conclusion that alcoholic beverages cause chronic chemical gastropathy (Cheli et al. 1981). Moreover, there does not appear to be a link between chronic atrophic gastritis and alcohol consumption (Adamu et al. 2011) and indeed the risk was reduced among moderate drinkers in Germany (Gao et al. 2009).

Other causes may be account for gastritis-like symptoms. Fatty liver may cause upper abdominal discomfort and nausea. It has been proposed that alcohol may

directly induce vomiting by central stimulation of the chemoreceptor trigger zone in the area postrema of the floor of the fourth ventricle in the absence of peripheral disease (Shen 1985). In addition, bacterial overgrowth has been reported to be more common in people who drink alcohol excessively and may also contribute to upper abdominal symptoms and diarrhea (Hauge et al. 1997).

101.2.4 Alcoholic Pancreatitis

Approximately 10 % of chronic alcoholics develop attacks of clinically acute pancreatitis. Conversely, alcohol is responsible for approximately 30 % of cases of acute pancreatitis in the USA (Yang et al. 2008). In a large cohort study from the USA, alcohol was estimated to account half of the cases of chronic pancreatitis and the incidence has increased in the past 20 years (Yadav et al. 2011). Likewise, UK data reveal a correlation between rising total community alcohol consumption and the number of hospital admissions for chronic pancreatitis (Johnson and Hosking 1991).

101.2.4.1 Definitions

The term acute pancreatitis refers to an acute inflammatory process of the pancreas, with variable involvement of other regional tissues or remote organ systems. Chronic pancreatitis is characterized by chronic inflammation, glandular atrophy, and fibrosis. Clinically, it manifests pain with exocrine or endocrine insufficiency. The revised classification of acute pancreatitis identified two phases of the disease: early and late. Severity is classified as mild, moderate, or severe. Mild acute pancreatitis, the most common form, has no organ failure and local or systemic complications and usually resolves in the first week. Moderately severe acute pancreatitis is defined by the presence of transient organ failure, local complications, or exacerbation of comorbid disease. Severe acute pancreatitis is defined by persistent organ failure, that is, organ failure >48 h. Local complications are peripancreatic fluid collections, pancreatic and peripancreatic necrosis (sterile or infected), pseudocyst, and walled-off necrosis (sterile or infected) (Banks et al. 2013).

101.2.4.2 Etiology

The most common associations of acute pancreatitis in Western societies are gallstones and heavy alcohol use which together account for approximately 75 % cases. A Danish cohort study showed gallstones as the most common cause (up to 34 %) for acute pancreatitis and alcohol was the most common cause (up to 68 %) for chronic pancreatitis (Nøjgaard et al. 2010). Yadav et al. (2011) found that while alcohol was the most common etiology in men (59 %), it was a less common etiology in women (28 %). In women, both nonalcoholic and idiopathic etiologies were more common (37 % and 35 %, respectively). Nonetheless, only a minority of heavy drinkers develop clinically evident pancreatic disease.

The association between alcohol and pancreatitis appears to be dose related. Pancreatitis typically occurs in subjects who have consumed greater than 100 g alcohol per day for at least 5–10 years and rarely if ever follows an isolated alcoholic debauch.

Kristiansen et al. (2008) reviewed 17,905 Danish men and women with pancreatitis and found hazard ratios associated with drinking 1–6, 7–13, 14–20, 21–34, 35–48, and >48 drinks/week were 1.1 (95 % confidence interval (CI): 0.8, 1.6), 1.2 (95 % CI: 0.8, 1.8), 1.3 (95 % CI: 0.8, 2.1), 1.3 (95 % CI: 0.7, 2.2), 2.6 (95 % CI: 1.4, 4.8), and 3.0 (95 % CI: 1.6, 5.7). The risk of pancreatitis may be increased in developing countries as impurities within country-made alcoholic products may cause pancreatic injury (Barreto et al. 2010). In a Swedish cohort study, the risk of acute pancreatitis was associated with the amount of spirits consumed on a single occasion but not with wine or beer consumption (Sadr Azodi 2001). Acute gallstone pancreatitis occurs more often in women, while alcoholic pancreatitis occurs more often in men. Once the disease is established, episodic heavy drinking often precipitates relapses. Relapses have been described after only 1 day of recurrent drinking. Pancreatitis is common among people with HIV particularly in association with heavy alcohol use (Dutta et al. 1997; Whitfield et al. 1997). Many patients with acute alcoholic pancreatitis progress to chronic pancreatitis, with continued alcohol abuse being a key prognostic factor (Ammann 1996).

Other than gallstones, relatively common causes for pancreatitis that should be considered include hypercalcemia of any cause and severe hypertriglyceridemia. Hypertriglyceridemia (greater than 10 mmol/l (approximately 1,000 mg/dl) with lipemic serum) of any cause is associated with recurrent attacks of pancreatitis (Greenberger et al. 1966). Although alcohol abuse is a known cause of hypertriglyceridemia, the majority of cases of alcoholic pancreatitis are not associated with marked hyperlipidemia (Haber et al. 1994). Other causes include pancreatic trauma, duct pathology, and a number of drugs. In most series, about 10 % of cases are idiopathic.

101.2.4.3 Predisposing Factors

Numerous investigators have attempted to account for this individual susceptibility by studying associations between alcoholic pancreatitis and potential risk factors. These studies have been previously reviewed (Haber et al. 1995) and have focused on the amount, type, and pattern of alcohol consumption, genetic markers, diet (Wilson et al. 1985), hypertriglyceridemia (Haber et al. 1994), tobacco consumption (Haber et al. 1993), and pancreatic ischemia. The genetic markers that have been studied include blood groups, HLA phenotypes (Wilson et al. 1984), a1-antitrypsin phenotypes (Haber et al. 1991), cystic fibrosis genotypes (Norton et al. 1998), cytochrome P450 2E1 (CYP2E1) genotypes, and ADH isoenzyme genotypes. A number of these studies are difficult to interpret due to small sample sizes, inappropriate controls, and inconsistent findings between studies. There remains insufficient evidence to consider that any of the above factors are well established. A mutation of the gene coding for pancreatic secretory trypsin inhibitor (SPINK1) has been described in 5.8 % of a cohort with alcoholic pancreatitis compared with 1 % of alcoholic controls and this important observation has been independently replicated (Witt et al. 2007). Recently, mutations in chymotrypsin C (CTRC) have also been identified in pancreatitis (Rosendahl et al. 2008).

These two studies support the concept that genetic factors influence susceptibility to pancreatitis, but given that only 6 % and 3 % of the subjects carried these mutations, respectively, individual susceptibility to this disease remains largely unexplained. Two other important genetic mutations are linked to pancreatitis, but not the alcoholic form. Gain-of-function mutations in the serine protease 1 gene (PRSS1) on chromosome 7q35, which encodes cationic trypsinogen, results in an autosomal dominantly inherited form of hereditary pancreatitis. Mutations in the cystic fibrosis gene (CFTR) have been associated with an autosomal recessive form of pancreatitis.

101.2.4.4 Pathogenesis

Two important factors leading to tissue injury in pancreatitis are autodigestion and oxidant stress. Several lines of evidence indicate that activated digestive enzymes play an important role in pancreatitis (Haber et al. 1997): (a) Mutations of the cationic trypsinogen gene that increase pancreatic content of trypsin underlie hereditary pancreatitis (Whitcomb et al. 1996). (b) Activated digestive enzymes are found in both clinical and experimental pancreatitis and can produce cellular necrosis when instilled into pancreatic tissue. (c) Protease inhibitors reduce the incidence of post-ERCP and experimental pancreatitis. Oxidant stress is characterized by the production of reactive oxygen species that are atoms or molecules containing oxygen with an unpaired electron in the outer shell (free radicals). Free radicals are highly reactive and bind to lipids, proteins, and nucleic acids leading to cellular injury (Freeman and Crapo 1982). Free radicals are generated during experimental pancreatitis (Nonaka et al. 1989) from infiltrating leukocytes (Slater 1984) or possibly within acinar cells (Braganza et al. 1995).

Several mechanisms have been proposed to explain why alcohol-induced pancreatitis occurs only after many years of alcohol abuse and not after a single binge in humans. These include the role of progressive pancreatic fibrosis related to activation of pancreatic stellate cells by acetaldehyde and oxidative stress (Haber et al. 1999) and the potential for endotoxin to precipitate pancreatitis in the alcohol-exposed gland (Vonlaufen et al. 2007). Chronic alcohol intake is associated with increased gut permeability and translocation of Gram-negative bacteria across the mucosal barrier. Thus, bacterial components (endotoxins) can enter the circulation and reach the pancreas. Plasma LPS levels have been shown to be significantly higher in drinkers (either after chronic alcohol intake or a single binge) compared to nondrinkers and in patients with alcoholic liver disease compared to those with liver disease of other etiologies (Bode and Bode 2005).

101.2.4.5 Diagnosis

A confident diagnosis of pancreatitis can often be made on the basis of an attack of severe abdominal pain and tenderness with elevation of the serum amylase more than three times the upper limit of normal and with imaging studies suggestive of inflammation in and around the pancreas.

The diagnosis of alcoholic pancreatitis is occasionally difficult. The amylase level does not rise significantly in approximately 10 % of cases of acute pancreatitis, including many with alcoholic pancreatitis (Spechler et al. 1983) or in those with delayed presentation. Determination of serum lipase, which remains elevated longer than the serum amylase, may be helpful and is supplanting amylase in some centers (Gomez et al. 2012). A previous report that an increased lipase/amylase ratio was specific for alcohol-induced pancreatitis (Gumaste et al. 1991) has not been confirmed (Pezzilli et al. 1993; King et al. 1995). Newer tests that may be more specific for acute pancreatitis include trypsinogen activation peptide and trypsinogen-2 but are not widely available.

Gallstones should be excluded by ultrasound examination. In cases with a negative ultrasound, serum alkaline phosphatase or transaminase levels raised at least two-fold suggest associated gallstones which may be detected by repeat ultrasonography or endoscopic retrograde cholangiopancreatography (ERCP) (Goodman et al. 1985; Venu et al. 1983). Magnetic resonance cholangiography (Soto et al. 1996) and endoscopic ultrasound are increasingly supplanting ERCP for diagnosis of gallstones in this setting. Dilated common bile duct has been recently described in patients on methadone and with opioid dependence in the absence of gallstones (Sharma 2002).

101.2.4.6 Assessment of Severity

Several clinical findings, including thirst, poor urine output, progressive tachycardia, tachypnea, hypoxemia, agitation, confusion, a rising hematocrit level, and a lack of improvement in symptoms within the first 48 h, are warning signs of impending severe disease. If such symptoms develop, admission to an intensive care unit should be considered. Enzyme levels do not correlate well with disease severity. A number of clinical and laboratory scoring systems have been developed to identify patients at risk of complications so that they may be treated more intensively at an earlier stage.

Contrast-enhanced CT scan is now widely performed to detect pancreatic necrosis and complications of severe pancreatitis such as fluid collections, pseudocysts, and abscesses (Kivisaari et al. 1983). Some concern has been raised about possible adverse effects of contrast-enhanced CT scanning (McMenamin and Gates 1996). Studies of intravenous contrast in experimental animals have yielded conflicting findings (Foitzik et al. 1994; Kaiser et al. 1995; Schmidt et al. 1995). Caution in the unrestricted use of contrast-enhanced CT scans appears warranted. CT scanning without contrast can detect most diagnostic features of pancreatitis and is often performed. MRI is an option that may spare radiation exposure.

101.2.4.7 Treatment

Overall, about 20 % of patients with acute pancreatitis have a severe course, and 10–30 % of those with severe acute pancreatitis die. Despite improvements in intensive care treatment during the past few decades, the rate of death has not significantly declined (McKay and Imrie 2004). Severe cases, particularly those associated with respiratory or renal failure, require treatment in an intensive care unit.

Initially, patients are treated with bed rest, analgesics, intravenous fluids, and fasting. Adequate pain control requires the use of intravenous opiates, usually in the form of a patient-controlled analgesia pump. Fentanyl is being increasingly used due to its better safety profile, especially in renal impairment.

Meperidine (pethidine) has been favored over morphine for analgesia in pancreatitis because studies showed that morphine caused an increase in sphincter of Oddi pressure. However, there are no clinical studies to suggest that morphine can aggravate or cause pancreatitis or cholecystitis. It is important to note that meperidine has a short half-life and repeated doses can lead to accumulation of the metabolite normeperidine that causes neuromuscular irritation and, rarely, seizures. Morphine is more effective analgesic, is less susceptible to abuse, and is usually the drug of choice.

Ebbehøj et al. (1985) showed the use of indomethacin suppositories (50 mg twice daily) reduced opioid requirements in 30 patients with acute pancreatitis without risk of gastrointestinal bleeding. An Iranian double-blind randomized control trial showed that rectal indomethacin given immediately before ERCP reduced the incidence and severity of post-ERCP pancreatitis (Sotoudehmanesh et al. 2007).

Intravenous fluids are given aggressively to restore vascular volume and renal perfusion and hour by hour monitoring is required. Patients are initially fasted, partly for symptomatic reasons but also because early refeeding seems to cause clinical relapse. Nutritional support is required if oral intake is not likely to be restored within several days. Total parenteral nutrition (TPN) and enteral feeding (nasogastric or nasojejunal) have been evaluated. Enteral feeding is safer and less expensive and there is some evidence it may be more effective than TPN (Pandol et al. 2007). Provision of early enteral nutrition is therapeutic, changing the patient's hospital course in a favorable manner (McClave 2013).

Protease inhibitors may limit the damage done by activated digestive enzymes. In clinical practice, it is not possible to commence treatment early enough in the attack of pancreatitis for protease inhibitors to be effective, except for post-ERCP pancreatitis, where some benefit has been reported. Peritoneal lavage might improve the outcome by removing toxic inflammatory products from the peritoneum but the results of controlled studies have been conflicting (Mayer et al. 1985; Stone and Fabian 1980). Other approaches that may prove more effective include extended lavage (Ranson and Berman 1990) and retroperitoneal lavage using operatively placed cannulas (Pederzoli et al. 1990). Antibiotics have not been shown to be beneficial for unselected cases of acute pancreatitis for which the prognosis is already excellent (Bradley 1989). In severe pancreatitis, infectious complications contribute to morbidity and mortality, and several controlled trials of prophylactic antibiotic therapy have been undertaken, (Pandol et al. 2007). The results have been inconsistent and the use of antibiotics in acute pancreatitis remains controversial.

A number of antioxidant therapies have been evaluated for both acute and chronic pancreatitis given the role of oxidative stress in the pathogenesis of these diseases and encouraging results from early small trials. However, a well-conducted

recent trial in acute pancreatitis found no benefit from antioxidant supplements in predicted severe acute pancreatitis (Siriwardena et al. 2007). Similarly, the evidence is conflicted in chronic pancreatitis (see below).

ERCP with endoscopic sphincterotomy has been shown to reduce the morbidity of patients with unremitting severe gallstone pancreatitis in two randomized controlled studies (Fan et al. 1993; Neoptolemos et al. 1988). In general, ERCP should be performed within 72 h in those with a high suspicion of persistent bile duct stones (i.e., visible common bile duct stone on noninvasive imaging, persistently dilated common bile duct, jaundice, or rising liver chemistries) but plays no role in alcoholic pancreatitis.

Surgery is uncommonly required, the main indication being necrotizing pancreatitis (McFadden and Reber 1994). Observational data support delaying surgical debridement of necrotic tissue for at least two weeks if possible while the patient's medical condition is optimized and viable pancreatic tissue becomes evident. This approach appears to improve survival and maximize organ preservation. Pancreatic abscess carries a very high mortality and is an absolute indication for drainage by open surgery or percutaneous techniques. In fulminant cases, multiple procedures may be required. Small pseudocysts may resolve spontaneously but large or symptomatic ones usually require drainage via endoscopic, percutaneous, or operative techniques (Maule and Reber 1993).

101.2.4.8 Chronic Pancreatitis (CP)

Recurrent episodes of acute pancreatitis, clinical or subclinical, may lead to chronic pancreatitis. Chronic excessive consumption of alcohol is the most common cause and accounts for approximately 75 % of cases in Western societies. Interestingly idiopathic pancreatitis is the most common type in India (tropical pancreatitis) and China, accounting for approximately 70 % of all cases of CP (Garg and Tandon 2004).

101.2.4.9 Clinical Features

The main clinical problem is usually pain and this may be very challenging. Like that of acute pancreatitis, the pain of chronic pancreatitis is typically diffusely located in the upper abdomen and may radiate to the back when severe. Pain tends to increase with meals and decreases appetite and food consumption and often results in weight loss. A minority present without pain. The other manifestations are diabetes mellitus and steatorrhea. Weight loss is common but typically is mild. Vitamin deficiency is generally subclinical. Investigations may reveal malabsorption of fat-soluble vitamins and osteopenia. Other complications include pseudocyst formation, bile duct or duodenal obstruction, pancreatic ascites or pleural effusion, splenic vein thrombosis, pseudoaneurysms, and pancreatic cancer.

101.2.4.10 Treatment

Complete abstinence from alcohol is essential to minimize progression of the disease. Reassurance that the disorder is benign with a tendency to slowly remit is helpful. In patients who continue to drink alcohol, a Japanese study of 12 patients

treated with bromhexine for 6 months, eight reported symptomatic improvement, and all patients showed improvement in the levels of pancreatic enzymes (Tsujimoto et al. 2005). Non-narcotic analgesia may suffice, but opioids are often required and should not be unreasonably withheld. Olesen et al.'s (2011) Danish randomized double-blind clinical trial of 64 patients found that pregabalin compared with placebo was a more effective analgesic after 3 weeks of treatment (36 % vs. 24 %; mean difference, 12 %; 95 % confidence interval, 22–2 %; $P = .02$). Analgesic dependence or possible misuse should be carefully managed according to principles described elsewhere in this volume (Hung et al. 2001). Antidepressants should be tried. Celiac plexus injection helps about 60 % of patients but pain may recur. The procedure is not often performed due to limited efficacy, frequent recurrence, and significant complications. Pancreatic enzyme supplements have been evaluated for the treatment of pain but the evidence is mixed. A trial of 1 month is sufficient to determine whether this works in practice. Octreotide is not effective. An emerging treatment option for resistant cases of pain is total pancreatectomy with islet autotransplantation (IAT) which has shown favorable outcomes with regard to pain reduction. Concurrent IAT enabled 46 % of patients to be independent of insulin supplementation at 5 years (Bramis et al. 2012).

There is mixed evidence concerning antioxidant therapy in chronic pancreatitis. One study using a combination preparation that contained selenium, beta-carotene, vitamin C, vitamin E, and L-methionine found reduced pain and improve quality of life (Kirk et al. 2006). Antioxidants were considered useful in a subset of patients with idiopathic and obstructive but not alcoholic chronic pancreatitis in a non-randomized study (Burton et al. 2011). Recent randomized trials yielded conflicting results but antioxidant therapy was disappointing in alcoholic pancreatitis (Siriwardena et al. 2012; Braganza 2013; Bhardwaj et al. 2009).

The relationship between pancreatic duct obstruction and pain is not clear but relief of obstruction is frequently clinically associated with relief of pain. Endoscopic approaches to dilate pancreatic duct strictures and remove calculi have been developed and surgery is typically reserved for refractory cases. Extracorporeal shock wave lithotripsy (ESWL) creates millimetric fragmentation of pancreatic stones, which has improved the results of endoscopic therapy and may have additional indications in the treatment of patients with chronic pancreatitis. Whipple procedures or modified Whipple procedures are the most commonly performed procedure. The Puestow procedure (lateral pancreaticojejunostomy) involves decompression of a dilated pancreatic duct and side-to-side anastomosis onto a Roux-en-Y loop of jejunum. Two small randomized trials comparing endoscopic and surgical drainage of dilated pancreatic duct in chronic pancreatitis showed that surgery was associated with better long-term analgesia and quality of life (Cahen et al. 2007; Dite et al. 2003).

Exocrine failure is treated by dietary modification, vitamin therapy, and pancreatic enzyme replacement. Reduction of dietary fat intake reduces steatorrhea. Pancreatic enzymes are required with each meal and snack. The newer enteric-coated microsphere preparations are more potent and are preferred as they release enzymes only in the duodenum, reducing inactivation of lipase by gastric acid.

Lipase inactivation is also due to failure of pancreatic bicarbonate secretion and proton pump inhibitors may increase effectiveness of treatment. Normalization of fecal fat levels does not typically occur. Diabetes mellitus is treated with dietary modification, treatment of malabsorption, and specific therapy. Some patients respond to oral hypoglycemic agents but most require insulin. The diabetes is "brittle" in that the patient is susceptible to hypoglycemia due to loss of both insulin and glucagon secretion. Long-term surviving patients with this form of diabetes are prone to diabetic complications and should be monitored accordingly. Patients with substantial steatorrhea may require fat-soluble vitamins. The 25-hydroxylated form of vitamin D (calcifediol) is more polar than vitamin D2 or D3 and is therefore more easily absorbed in patients with fat malabsorption. The serum calcium should be monitored for the first few weeks of therapy with this naturally occurring analogue since it is more potent than vitamin D2 or D3 and can more easily produce hypercalcemia.

Small Intestine

Diarrhea is common among those who drink alcohol excessively, both acutely and chronically. Multiple factors contribute to this problem including altered motility, permeability, and nutritional disorders. Small intestinal mucosal injury can occur after acute or chronic administration of alcohol. Perfusion of the hamster jejunum with 4.8 % ethanol caused separation of the tip of the villus epithelium forming blebs (Beck 1996). These blebs may rupture leading to denudement of the epithelium. The villus core contracts and loses height within 1 min of ethanol exposure. This effect is independent of any action on the microcirculation (Dinda et al. 1994) and may be mediated by leukocytes (Dinda et al. 1996) via release of histamine from mast cells and by oxidant stress (Dinda et al. 1994).

Mucosal blood flow is acutely increased with increased endothelial permeability (Beck 1996). Acute administration of alcohol leads to increased gut permeability resulting both in abnormal absorption of luminal content (such as endotoxin, which contributes to the pathogenesis of alcoholic liver disease; see previous chapter) and abnormal leakage of mucosal contents (such as albumin). Ethanol also inhibits absorption of actively transported sugars, dipeptides, and amino acids. Many defects in absorption have been reported in people with alcohol problems, including water (Krasner et al. 1976a, b), carbohydrate, lipid, vitamins (notably thiamine, folate), and minerals (calcium, iron, zinc, and selenium) (Beck 1996). Folate deficiency, common among people with alcohol problems, causes intestinal injury leading to malabsorption and diarrhea and further loss of folate. Ethanol may exacerbate lactase deficiency, especially in non-Caucasians (Perlow et al. 1977).

Colon

Portal hypertension may manifest uncommonly with hemorrhoids and rarely with colonic varices. Colonic varices appear as filling defects on barium enema and may occur in any part of the colon, most commonly in the rectum (Feinman et al. 1992). Alcohol has also been reported to cause non-ulcerative inflammatory changes in

human colonic epithelium (Brozinsky et al. 1978). These changes resolved during a 2-week period of abstinence and were not explained by folate deficiency. This form of colitis has the potential to contribute to diarrhea but is not usually recognized clinically as pathology elsewhere in the gut tends to dominate the clinical picture.

Inappropriate alcohol enema has been reported to cause a chemical colitis (Herrerias et al. 1983) and this may result from a toxic effect similar to the direct toxicity of alcohol on the gastric mucosa. Alcohol use has a recognized association with colorectal cancer as indicated below. Finally, alcohol consumption may have at least one beneficial effect on the colon in that it has been linked to a reduced incidence of ulcerative colitis in one study (Boyko et al. 1989).

101.2.5 Alcohol and Gastrointestinal Cancer

Alcohol use is a recognized risk factor for several gastrointestinal neoplasms, including tumors of the tongue, mouth, pharynx, larynx, esophagus, stomach, pancreas, colon, and liver (Franceschi 1999; Longnecker 1995; Ringborg 1998). The effect of alcohol on cancer risk appears to be dose related. A recent comprehensive Australian overview of the literature reports that relatively modest average daily consumption, 25 g per day, within the guidelines for men in many countries including the USA, is associated with increased risk of gastrointestinal cancer. For example, consumption of 25 g per day was associated with a relative risk of 1.76 for oropharyngeal cancer and 1.52 for esophageal cancer, approximately 1.05 for colon and rectum and 1.17 for liver (Lewis et al. 2008). Cancer risk rose from zero alcohol consumption with no safe level, suggesting that the less alcohol consumed, the lower the risk of cancer.

The pathophysiology of ethanol-associated gastrointestinal malignancy is varied. Current understanding suggests that alcohol and its metabolites (in particular acetaldehyde) affect the generation of reactive oxygen species (ROS), transforming growth factor-b signaling pathways, the immune system, and cell death and apoptosis and have direct toxic effects, among them the ability to produce aberrant methylation of DNA, with an impairment of its self-repair capacity (Haas et al. 2012). Ethanol-induced induction of CYP2E1 that increases carcinogen activation, potentiation of oxidant stress, diminished DNA repair, suppression of immune responses, and nutritional depletion such as folate deficiency (Mufti 1996). For example, alcohol-fed rats given N-nitrosomethylbenzylamine developed more esophageal tumors than control rats (Mufti et al. 1989). In addition, nonalcoholic components of alcoholic beverages may in turn add to carcinogenesis. Interestingly, racial differences appear to affect the risk of carcinogenesis. In Asia, a large proportion of individuals carry a mutation of acetaldehyde dehydrogenase (ALDH) 2 which has very low activity. ALDH2 is responsible for the breakdown of acetaldehyde and thus its inhibition or reduced activity leads to an accumulation of total acetaldehyde and increased duration of exposure. Homozygotes of the

ALDH2 mutation develop severe side effects with small amounts of alcohol and hence are protected against alcohol-related disorders and alcohol overuse. In Japan, heterozygosity is prevalent in alcoholics and is significantly associated with oropharyngolaryngeal (OR 11.14), esophageal (OR 12.50), and esophageal cancer concomitant with oropharyngolaryngeal and/or stomach cancer (OR 54.20) (Yokoyama et al. 1998).

101.2.5.1 Oropharynx and Esophagus

Alcohol use is associated with an increased incidence of esophageal (and oropharyngeal) cancer, especially in those who also smoke. A Chinese population-based case–control study of esophageal cancer with 902 cases and 1,552 controls showed the combined effect of heavy smoking and drinking among men was pronounced: OR was 12.0 for those who smoked more than 1 pack per day and drank more than 750 g of ethanol per week (Gao et al. 1994). Blot et al. (1988) reported a 5.8-fold increased risk among those who drink alcohol, a 7.4-fold increased risk among smokers, and a 38-fold increased risk among those who both drank and smoked. The risk of oral, oropharyngeal, and esophageal cancer is further increased in South American countries where there is a high prevalence of concurrent alcohol, tobacco, and mate use (Wünsch-Filho 2002). A recent large meta-analysis of 20 case–control and four cohort studies including a total of 5,500 cases concluded that there was no association between alcohol drinking and esophageal adenocarcinoma risk, even at higher levels of consumption (Tramacere et al. 2012). Moderate and high alcohol intake was associated with risk of esophageal SCC. Light alcohol intake appears to be associated to ESCC mainly in studies in Asia, which suggests a possible role of genetic susceptibility factors (Islami et al. 2011). While in SCC of esophagus, the type and quantity of alcoholic beverages consumed may affect the risk of esophageal SCC. Hard liquor may have a higher risk than wine or beer; however, the cumulative amount of alcohol rather than the type is probably more important (Tuyns et al. 1979).

101.2.5.2 Stomach

The association between gastric cancer and alcohol consumption appears to be mild. Tramacere et al..'s (2012) meta-analysis of 34,557 patients provided definitive evidence of a lack of association between moderate alcohol drinking and gastric cancer risk. There was, however, a positive association with heavy alcohol drinking (RR 1.14 (95 % CI 1.08–1.21) for 50 g/day). Gastric noncardia adenocarcinomas were more common than gastric cardia cancers. This is supported by the European Prospective Investigation into Cancer and Nutrition (EPIC) cohort study which also showed beer but not wine or spirits to be positively associated with gastric cancer (Duell et al. 2012). Genetic susceptibility also appears to be important, especially in Asian populations. A Korean study showed ALDH2 polymorphisms were found to modify the susceptibility to the development of gastric cancer associated with alcohol intake, especially in case of ALDH2 *1/*2 genotype (Shin et al. 2011).

101.2.5.3 Colonic

A large pooled analysis found that those who consumed 30 to less than 45 g per day of alcohol had a relative risk (RR) of colorectal cancer of 1.16 (95 % CI 0.99–1.36) and those who consumed more than 45 g per day had an RR of 1.41 (CI 1.16–1.72); the relative risks in men and women appeared similar, and the association was seen for cancers of all portions of the colon and rectum (Cho et al. 2004). This data is reflected in the Netherlands Cohort Study which showed alcohol consumption 30 g/day or more was associated with a hazard ratio of 1.3 (hazard ratio: 1.32, 95 % CI: 1.06–1.65) [46]. Of note, cancer risk appeared to increase from proximal colon through rectum (hazard ratio: 1.29, 95 % CI: 0.85–1.96 for proximal colon cancer; hazard ratio: 1.41, 95 % CI: 0.94–2.11 for distal colon cancer; hazard ratio: 2.07, 95 % CI: 1.03–4.18 for rectosigmoid cancer; and hazard ratio: 1.69, 95 % CI: 1.08–2.64 for rectal cancer) (Bongaerts et al. 2008).

101.2.5.4 Pancreatic

The role of alcohol in pancreatic cancer pathogenesis appears to be significant. Retrospective analysis of the Swedish Inpatient Register suggested that excess risk for pancreatic cancer among alcoholics is small and could conceivably be attributed to confounding by smoking (Ye et al. 2002). High lifetime ethanol intake from spirits/liquor tends to be associated with a higher risk, but no associations were observed for wine and beer consumption (Rohrmann et al. 2009; Gapstur et al. 2011).

101.3 Prescription Medications

101.3.1 Opioids

It has long been recognized that opioids affect gastrointestinal motility. Opioids act on gut function in a complex fashion via all three receptor classes in the brain, spinal cord, and enteric nervous systems. Low doses act at enteric nervous system sites and higher doses also act within the CNS. These effects usually are manifest as constipation, but bloating, early satiety, and pain are possible. Occasionally, patients develop ileus or a syndrome characterized by a relatively high level of abdominal pain. When pain is significant, the term “narcotic bowel syndrome” has sometimes been applied (Fig. 1). It is attributed to the effects of opioid drugs on bowel function and opioid-induced hyperalgesia (Grunkemeier et al. 2007). A US survey of 98 patients with chronic non-cancer pain treated with opioids revealed constipation prevalence was 46.9 %, nausea 27 %, vomiting 9 %, and gastroesophageal reflux disease 33 %. Chronic abdominal pain was reported by 58.2 % and 6.4 % fulfilled the criteria of NBS. Prevalence of constipation increased with duration of treatment. Health-related quality of life was low in patients with chronic abdominal pain (Tuteja et al. 2010).

Opioids induce bowel dysfunction through several expected effects: blockade of propulsive peristalsis, inhibition of the secretion of intestinal fluids, and an increase in intestinal fluid absorption. Opioids decrease the activity of both excitatory and inhibitory neurons in the myenteric plexus. In addition, they increase smooth-muscle tone and inhibit the coordinated peristalsis required for propulsion, leading to disordered, nonpropulsive contractile activity, which contributes to nausea and vomiting as well as constipation. Longer gastrointestinal transit time causes excessive water and electrolyte reabsorption from feces, and decreased biliary and pancreatic secretion further dehydrates stool (De Schepper et al. 2004).

Concurrent use of other constipating drugs (e.g., tricyclic antidepressants), dehydration, advancing age, immobility, metabolic abnormalities (e.g., hypercalcemia), chemotherapy (particularly treatment with the vinca alkaloids), and tumor-related bowel obstruction may also contribute. Not all opioid formulations are equally constipating. Although the results of randomized trials are conflicting, a systematic review concluded that there is less constipation with transdermal fentanyl than with oral sustained-release morphine (Tassinari et al. 2009).

Among methadone maintenance patients, constipation is common and tends to be worse early in treatment (Langrod et al. 1981; Yaffe et al. 1973). The high prevalence of persisting constipation suggests that tolerance to the gut effects of opioids occurs to only a limited extent. In one study, 58 % of subjects in methadone maintenance experienced some degree of constipation and 10 % had severe problems (Yuan et al. 1998). Fecal impaction, and even stercoral perforation, has been described (Haley et al. 1998) and usually responds to increased fluid intake and fiber supplementation to correct for poor dietary intake. Laxatives are not often required but osmotic agents such as lactulose are the laxatives of choice.

Two peripherally acting opioid-receptor antagonists are available for the management of opioid-induced constipation: methylnaltrexone and alvimopan. They do not cross the blood–brain barrier and have no antianalgesic effect. Methylnaltrexone was approved by the US FDA in 2008 as a subcutaneous injection for the treatment of opioid-induced constipation in patients with terminal illness requiring palliative care (Thomas et al. 2008). Randomized trials report some effectiveness for oral alvimopan in the treatment of opioid-induced constipation in patients with chronic pain (Paulson et al. 2005).

101.3.2 Laxative Misuse

Surreptitious laxative misuse is among the more common causes for unexplained chronic diarrhea. It represents an intriguing form of substance misuse but is rare and is typically observed in people without other substance misuse issues. These patients present to family physicians and gastroenterologists. Some are associated with bulimia. Others tend to be older women and the disorder can be viewed as a form of Munchausen's syndrome. The diagnosis rests on identification of laxatives by stool alkalinization, osmolality studies, or a bag search in the hospital (Fine 1998).

101.3.3 Misuse of Anticholinergics

In high doses, anticholinergic drugs alter mood and are occasionally misused, particularly when prescribed to relieve extrapyramidal symptoms in the mentally ill (Caplan et al. 2007) and among those with limited access to other drugs of abuse. Amitriptyline and other tricyclic antidepressant drugs are commonly misused by people on opioid maintenance treatment (Peles et al. 2008). Clonidine and/or buscopan prescribed for opioid withdrawal may also be misused. Patients develop marked constipation and abdominal pain as well as dry mouth and blurred vision. In the author's experience, patients have had previous drug-dependence problems and have welcomed an explanation of their symptoms and participated in structured withdrawal.

101.4 Tobacco

Tobacco use is associated with a number or benign and malignant disorders of the gastrointestinal tract.

101.4.1 Gastroesophageal Reflux

Smoking has been linked to exacerbations of reflux symptoms and cessation of smoking is one of the lifestyle changes traditionally recommended in the treatment of reflux (Pandolfino and Kahrilas 2000). At a practical level, smoking cessation is difficult to achieve and has not been shown to induce remission of reflux or healing of esophagitis. Nicotine has been shown to reduce lower esophageal sphincter pressure and promote gastroesophageal reflux in response to straining during coughing and deep breathing (Kahrilas and Gupta 1990). People who smoke cigarettes have also been shown to have delayed acid clearance from the esophagus (Kahrilas and Gupta 1989). Not all studies have yielded consistent findings. One recent study found that smoking did not influence basal lower esophageal sphincter pressure or esophageal motility (Bhandarkar et al. 2000). From the foregoing, it is clear that smoking cessation cannot be recommended as sole treatment for reflux, but there is sound evidence that smoking contributes to reflux. It is reasonable to advise patients with GERD to quit smoking based upon the association with reflux, the expectation that GERD might respond favorably to quitting and to prevent the myriad of other adverse effects of smoking. Snus is a form of smokeless tobacco commonly used in Scandinavia. A Swedish study found snus significantly alters the histology of the distal esophagus but does not impact on gastrointestinal symptoms or peptic ulcer disease (Aro et al. 2010).

101.4.1.1 Peptic Ulceration

Tobacco smoking increases the risk of both gastric and duodenal ulcers as compared with non-exposed persons (Ostensen et al. 1985). Smoking increases risk of

ulcer according to the number of cigarettes smoked. Heavy smoking is associated with delayed ulcer healing and the risk of recurrence is increased (Sonnenberg et al. 1981; Korman et al. 1983). Smoking increases the risk of complications from peptic ulcer (Piper et al. 1985). Finally, the overall ulcer-related mortality is increased in those who smoke compared to those who do not (Ross et al. 1982; Kurata et al. 1986). The mechanism by which smoking exacerbates peptic ulcer disease remains unclear given several pathophysiological studies were carried out prior to the *Helicobacter pylori* era.

101.4.1.2 Pancreatic Disease

Evidence from a number of countries provides a clear link between smoking and pancreatic cancer. Several studies have consistently found a moderately increased risk (about threefold) of pancreatic cancer among smokers (Chowdhury and Rayford 2000; Talamini et al. 1999).

There have been inconsistent findings concerning the relationship between smoking and pancreatitis (Chowdhury and Rayford 2000). A case–control study compared tobacco use in a group with alcoholic pancreatitis and a control group who drank at least as much alcohol yet did not develop pancreatitis and found no association with smoking (Haber et al. 1993). A French study of 108 patients concluded that tobacco intake accelerates the course of alcoholic chronic pancreatitis in a dose-dependent fashion with a threshold at 20 pack-years (Rebours et al. 2012). Overall, it would seem appropriate to recommend patients with alcoholic pancreatitis quit smoking, in addition to other risks of smoking.

101.4.2 Inflammatory Bowel Disease

A curious relationship exists between smoking and inflammatory bowel disease. A meta-analysis of 22 studies showed an association between current smoking and Crohn's disease (OR, 1.76; 95 % confidence interval [CI], 1.40–2.22) and former smoking and ulcerative colitis (OR, 1.79; 95 % CI, 1.37–2.34). Current smoking had a protective effect on the development of UC when compared with controls (OR, 0.58; 95 % CI, 0.45–0.75) (Mahid et al. 2006). Smoking status is also strongly associated with microscopic collagenous and lymphocytic colitis. The risk is higher in current smokers and is not significantly affected by gender or alcohol consumption (Yen et al. 2012).

Smokers are more than twice as likely to develop Crohn's disease as nonsmokers (Silverstein et al. 1989). Smoking may also increase the risk of recurrence of Crohn's disease. At least one study suggested that patients who stop smoking for more than 1 year can decrease the risk of flares (Cosnes et al. 2001). Tobacco smoke appears to interfere with epithelial integrity and immune responses to pathogenic bacteria but research in this area is ongoing (Verschuere et al. 2012).

Patients with ulcerative colitis who begin smoking after the diagnosis of their disease present a significant reduction in the number of recurrences (Fraga et al. 1997), and hospitalization and surgical procedure occur most frequently in heavy smokers who quit smoking before the onset of ulcerative colitis (Boyko et al. 1988). This suggests nicotine may have a therapeutic potential for this disease. Nicotine influences immune cellular function, increases mucin production, relaxes colonic smooth muscle, increases endogenous glucocorticoids, and influences rectal blood flow and intestinal permeability (Thomas et al. 2005). Less toxic approaches to this form of therapy have been sought and include topical colonic administration of nicotine. These approaches remain experimental at this time (Lunney and Leong 2012). McGrath et al.'s Cochrane Review (2004) of transdermal nicotine patches for the treatment of mild to moderate ulcerative colitis has suggested that these agents can improve ulcerative colitis compared to placebo but have significant adverse events and have not been shown to be more effective than other effective treatments.

101.4.3 Gastrointestinal Malignancy

Smoking has been strongly linked to cancers of the upper gastrointestinal tract and pancreas as discussed above. The link between smoking and stomach cancer is weaker but is present in most studies (Neugut et al. 1996; Trédaniel et al. 1997). A Swedish population-based prospective cohort of 17,118 twins with up to 30 years of follow-up showed long-term heavy smoking was associated with a statistically significant threefold increased risk of colorectal cancer compared with never smoking (relative risk 3.1, 95 % CI 1.4–7.1). Examining colorectal cancer sub-sites separately, a nonsignificant 60 % increased risk of colon cancer was observed only for heavy smokers and a statistically significant fivefold increased risk was observed for rectal cancer (Terry et al. 2001).

The risk is related to total number of cigarettes smoked and the duration of smoking. Pipe and cigar smoking have a higher risk compared with cigarette smokers (Franceschi et al. 1990). Interestingly, a recent meta-analysis of smokeless tobacco (snus or snuff) available in Scandinavia has shown to be not associated with cancers of the oropharynx, esophagus, stomach, and pancreas once the effects of smoking are removed (Lee 2011).

Tobacco smoke contains multiple mutagenic and carcinogenic compounds including nicotine, nitrosamines, and polycyclic hydrocarbons. Mouse and cell models reveal a direct promoting action of nicotine on the growth of gastric tumor and neovascularization through sequential activation of the ERK/COX-2/VEGF signaling pathway (Shin et al. 2004). The effects of tobacco and alcohol appear to be synergistic. Smoking increases the acetaldehyde burden following alcohol, and alcohol enhances the activation of various procarcinogens via cytochrome P450 induction.

101.5 "Body Packing"

Persons smuggling illicit drugs may ingest large amounts of cocaine, heroin, or other drugs aiming to retrieve the packages after reaching their destination (Traub and Kohn et al. 2003a). This is referred to body packing, cocaine packing, or body stuffing syndrome (Malbrain et al. 1994). Multiple packages made from latex condoms, wax, or plastic bags are either swallowed or placed retrogradely into rectum or vagina. The incidence of this practice is unknown. Most cases present in police custody raising ethical and potentially funding challenges of managing an involuntary patient. Some people may be coerced to smuggle drugs. Cases involving children and pregnant women have been described (Traub et al. 2003a, b). Hospitals close to international airports may encounter these cases and should consider developing a management policy for this challenging problem. An early report describes 10 cases diagnosed only after death in which as many 147 packages were found (Wetli and Mittlemann 1981). Lethal drug absorption through rubber condoms may occur without rupture. The body packer may present with life-threatening symptoms of intoxication, including seizures and cardiorespiratory collapse, as well as mechanical obstruction from the ingested drug packets. The distal ileum was the most common site of obstruction, whereas rupture tended to occur in the upper gastrointestinal tract (East 2005). The largest series comprises 61 cases from Milan, Italy, of which only two cases required laparotomy, one each for obstruction and nonfatal drug toxicity (Aldrighetti et al. 1996).

Plain X-ray is the method of choice to detect drug-filled packets within the gastrointestinal tract of body packers (Hergan et al. 2004). Dilute contrast has been reported to assist identification of the packages (Gherardi et al. 1990). In some cases, CT is required, with potential concerns regarding radiation exposure if repeated examinations are needed. Extensive dose reduction makes low-dose CT a valuable alternative imaging modality for the examination of suspected body packers and might replace conventional abdominal radiographs as the first-line imaging modality (Maurer et al. 2011).

Clinical monitoring comprises frequent clinical and neurological assessment and abdominal examination daily to the detected complications of acute drug intoxication or bowel obstruction or perforation. The patient should be kept in hospital until all drug packages have cleared due to the risk of life-threatening overdose if any rupture. Traub et al. (2003) presented a detailed review and clinical approach to management. A light solid diet with free liquids may be given. Oily or polyethylene glycol laxatives can be given repeatedly to accelerate passage of packages (Hoffman et al. 1990). Symptomatic cases may require early surgery (Silverberg et al. 2006). The risk of careful endoscopic removal from the esophagus is probably exaggerated, and in any case, the risk of endoscopic removal is almost certainly less than that of any other surgical approach to the esophagus. The rigid esophagoscope appears to have an advantage over the flexible instrument because of the wide lumen which will accommodate most average-sized pellets. Intact pellets in stomach and small bowel may be retrieved endoscopically or are evacuated through a single gastrotomy and/or enterotomy. Non-obstructing pellets in the colon pose an

interesting dilemma. Removal through a colotomy will expose the patient to the risk of sepsis. The risk of rupture of pellets already in the colon must be very low as there are no noxious enzymes here and the pellets are subject to less turbulence within formed stool than they would be in the small intestine (East 2005).

Methamphetamine body stuffers have similar demographics to those of body stuffers of other stimulants but tended to ingest fewer baggies with larger masses and had a higher percentage of severe outcomes (29 %) than previously reported with other stimulants. Increases in presenting pulse rate and temperature (pulse rate 120 beats/min or 38.0 °C) are common in patients who will develop end-organ damage (West et al. 2010).

101.6 Psychostimulants

Gastrointestinal disorders are uncommon in patients with stimulant use. Juxtapyloric perforation has been described after the smoking of crack cocaine in 50 (95 % male) consecutive patients (Feliciano et al. 1999). Cocaine abuse can cause mesenteric ischemia and gangrene, which result in small and large bowel perforation as well as intraperitoneal hemorrhage (Tiwari et al. 2006). This is thought to be related to cocaine-induced arterial vasospasm or vasoconstriction leading to intestinal ischemia with mucosal and transmural necrosis as well as mesenteric vascular thrombosis. The use of preoperative angiography is vital in detecting occlusive lesions that are amenable to revascularization (Hoang et al. 1998). The usual management of small or large bowel gangrene or perforation is by resection and primary anastomosis.

101.7 Cannabis

Our understanding of cannabis and cannabinoid substances has changed since the discovery of the endocannabinoid system (ECS). Cannabinoid receptors are widely expressed throughout both the upper and lower GI tract and are also expressed on hepatic stellate cells. Consequently, cannabinoids may influence a range of GI functions in health and disease (Pertwee 2001). Cannabinoids have been implicated in the pathophysiology of satiety, nausea/emesis, gastrointestinal secretion, gastrointestinal motility, gastrointestinal sensation, as well as inflammation (Izzo and Sharkey 2010). Nausea and vomiting are side effects of many chemotherapeutics and reduce the quality of life of patients with diabetes, cancer, and acquired immune deficiency syndrome. Cannabis (marijuana) and other cannabinoids appear to be effective antiemetics. The antiemetic effect has been demonstrated in an animal model and is related to the expression of CB1 receptors in the dorsal vagal nucleus (Van Sickle et al. 2001). Cannabinoids are also involved in inhibition of gastric emptying and gastric acid secretion.

Cannabis has also been linked to a series of cases with hyperemesis (Allen et al. 2004). Cessation of cannabis, as confirmed by a negative urine drug screen for

cannabinoids, led to cessation of the cyclical vomiting illness and a return to regular cannabis use heralded a return of the hyperemesis weeks to months later. The hyperemesis is often relieved by frequent hot showers (Sontineni et al. 2009). The mechanism is not understood. A further similar case was described in the UK (Roche and Foster 2005) and a small series has now been reported in the USA (Soriano-Co et al. 2010). Most recently, a series of 98 cases was reported from the Mayo Clinic (Simonetto et al. 2012). Cannabinoid hyperemesis should be considered in younger patients with long-term cannabis use and recurrent nausea, vomiting, and abdominal pain.

nonurban areas) a constant progression of drug addiction is reported, liver diseases induced by this behavior represent a growing challenge for all clinicians confronting a patient with liver injury. Drug-induced liver injury can present in a clinical pattern similar to acute hepatitis, chronic hepatitis, acute liver failure, biliary obstruction, or fatty liver disease; furthermore, the link of drug addiction with HBV and HCV infection, very common among drug abusers either IV or not IV, can make liver diseases worse; so today, drug addicts have to be considered at very high risk of liver damage. The literature on drug-induced liver injury is large, sometimes controversial, but dispersed to publications in many disciplines, often appearing as short reports or letters; in the classical textbooks on drug-induced liver diseases, most of the considered drugs, except alcohol, are commonly medically prescribed drugs, even if several hundreds of them have been linked to liver damage.

102.1 Introduction

In the human body, the liver is the most susceptible organ to injury by foreign molecules, as a consequence of its primary role in their metabolism and of its position as the first organ encountered by ingested substances after absorption. When any drug or toxin is abused heavily, the liver can be overwhelmed with the task of processing it out of the body, resulting in liver damage and liver failure. Because in any urban area worldwide (but in many countries also in nonurban areas) a constant progression of drug addiction is reported, liver diseases induced by this behavior represent a growing challenge for all clinicians confronting a patient with liver injury. Drug-induced liver injury can present in a clinical pattern similar to acute hepatitis, chronic hepatitis, acute liver failure, biliary obstruction, or fatty liver disease; furthermore, the link of drug addiction with HBV and HCV infection, very common among drug abusers either IV or not IV, can make liver diseases worse; so today, drug addicts have to be considered at very high risk of liver damage. The literature on drug-induced liver injury is large, sometimes controversial, but dispersed to publications in many disciplines, often appearing as short reports or letters; in the classical textbooks on drug-induced liver diseases, most of the considered drugs, except alcohol, are commonly medically prescribed drugs, even if several hundreds of them have been linked to liver damage. In the first part of this chapter, we try to summarize the most relevant informations available today about liver injury due to the use/abuse of cocaine, ecstasy, heroin, marijuana, methamphetamine, steroids, inhalants, and alcohol; in the second part, we analyze the impact of HBV, HCV, and HDV infection on the liver of drug addicts.

102.2 Liver Toxicity of Considered Drugs

102.2.1 Cocaine

Cocaine is one of the most addictive and dangerous drugs of abuse; its medical complications can include cardiovascular, cerebrovascular, renal, muscular, and

liver injuries. Cocaine-induced hepatotoxicity may be sometimes fatal, usually hours to a few days after an overdose, generally following or accompanying other major organ involvement (myocardial infarction, stroke, rhabdomyolysis, and renal failure are the most frequent); the cause of death is generally not due only to an acute liver failure but to a multi-organ failure. Clinically, the pattern of cocaine-related hepatic injury is usually an acute necrosis (centrilobular and periportal necrosis with diffuse micro- and macrovesicular fatty infiltration have been histologically demonstrated) with very high levels of serum aminotransferases and a rapid decrease of prothrombin value (possible DIC). Cocaine is believed to cause liver damage by conversion to a toxic metabolite as a result of P450 metabolism. Liver damage is more common, and the risk of a sudden death is estimated 18 times greater, when cocaine and alcohol are used together than when cocaine is used on its own. In the most part of cases, the liver injury due to cocaine is self-limited and resolves rapidly; there is no specific therapy or antidote for acute cocaine hepatotoxicity. Because the liver damage cocaine-related is similar to the one due to acetaminophen, infusions of N-acetylcysteine are often given in these situations. Also crack can produce a very similar hepatotoxicity, and some years ago also cases of fulminant hepatitis B were observed after crack use. Chronic hepatic damage linked only to cocaine use, without alcohol and without HBV and HCV infection, has not been sufficiently demonstrated.

102.2.2 Ecstasy (MDMA)

Many cases of acute liver failure after ecstasy use have been reported in recent past years, with a Zenit in the second half on the 1990s. The clinical features may differ from acute liver failure with hyperthermia to acute liver failure without hyperthermia or to mild hepatitis. The mechanism of MDMA-induced hepatic damage is unclear because histological changes varying from a mild to moderate lobular hepatitis to massive hepatic parenchymal collapse with areas of nodular regeneration and cholestasis have been described; the severity of liver failure does not seem to correlate with the amount or the frequency of ingested MDMA, suggesting an individual susceptibility for the related hepatic damage (single cases of recurrent hepatitis after ecstasy exposure have been reported). Ecstasy users may be also at increased risk of heatstroke because of the direct effect of MDMA on thermoregulation via central serotonergic nerve terminals, in addition to high exercise levels, inadequate fluid replacement, and the high temperatures often present at "raves." In acute liver failure with hyperthermia, it is difficult to establish if ecstasy is directly hepatotoxic or if liver injury results from the hyperthermia; the clinical resulting failures generally need liver transplantation. In acute liver failure without hyperthermia in the most part of described cases, liver damage can progress often to severe and liver transplantation is needed. In mild liver failure without hyperthermia, the patients can recover themselves without developing severe coagulopathy or encephalopathy. MDMA is generally not detectable in the urine or blood of patients admitted to the hospital for liver failure after ecstasy use,

because of the short half-life of the drug and the usual ingestion and presentation. In young patients admitted to the hospital, presenting an unexplained acute hepatic damage, it is important to verify the possible drug history, both oral and intravenous. The mechanism by which MDMA causes liver disease is unknown, but all amphetamines undergo extensive hepatic metabolism particularly by hepatic P450 system (CYP 2D6) with generation of a liver toxic metabolite.

102.2.3 Heroin

The liver damage due to pure heroin is relatively small, not significant; this drug is metabolized very quickly and does not affect liver functions in a big way. Heroin itself is also nontoxic to the liver like to any other internal organs; however, additives and dilutants with which street heroin is generally "cut" can cause after prolonged use of IV heroin some damage to the liver. The most important effect of heroin on the liver is due to HBV and HCV infections, very common among IVDA; drug users' liver failure is often linked to their physical health because it is notorious that the most part of them are malnourished and generally unhealthy. Only in very few papers, a direct hepatotoxicity of heroin, consisting in vesicular hepatotoxic changes and fatty changes not linked to alcohol or hepatitis viruses, has been demonstrated, but not confirmed in subsequent research.

102.2.4 Marijuana

The prevalence of cannabis use among young people everywhere in the world is no less than 10–20 %; just a few days ago, data from the Italian Public Health Ministry revealed a percentage of 25 % of regular cannabis users among young students aging from 14 to 18. Medical consequences of regular cannabis usage are still debated; today, cannabis is known to have some therapeutic potential in treating multiple sclerosis, asthma and breathing difficulties, migraine headaches, and severe pains. Cannabis is used in some countries, including the USA and Canada, as antiarthritic, antidepressant, and/or anticonvulsant. In a controversial study published (2008) in Clinical Gastroenterology and Hepatology, Norah Terrault and colleagues demonstrated a significant association between daily versus non-daily cannabis use and moderate to severe fibrosis, especially in HCV-positive patients and in HIV/HCV-coinfected people; the Liver Transplant Center of Michigan University (David Nicholas Ranney and coll.) concluded, upon a multivariate analysis, that survival in transplanted subjects is associated not only with MELD score and HCV infection but also with marijuana use, considered a significant negative factor. Other studies however showed beneficial effects of cannabis use in people treated for HCV with antiviral specific therapy (PEGIFN plus Ribavirine) helping the patients to maintain the adherence to the therapy. Just less than one year ago, a poster by Italian researchers at EASL annual conference postulated that a cannabinoid receptor (CB2-63 QQ Variants) is associated with a more severe liver damage in HCV-positive people.

102.2.5 Amphetamines

In several clinical trials, amphetamines (not MDMA, previously described) have not been associated with serum aminotransferase elevations; nevertheless, some cases of hepatic injury have been reported in international literature but usually only after amphetamine, often used intravenously, overdoses. The liver injury due to amphetamines is generally self-limited and resolves rapidly.

102.2.6 Anabolic Steroids

Synthetic androgenic steroids, medically used for male sex hormone replacement, are widely assumed for body building because of their anabolic effects; many of them can cause cholestatic liver injury, and after a long-term use, they can be associated with liver tumors. The C-17 alkylated androgenic steroids have been implicated either in the acute or in the chronic liver injuries, while the esterified testosterones have not been implicated in the acute, but only in a lower rate of chronic liver diseases. The mechanism of hepatic injury is not well defined for the acute cholestatic disease, while an unregulated growth stimulus to hepatocytes is the cause of nodular regeneration and hepatic tumors. The onset of acute liver damage after anabolic steroids is often insidious, with nausea, fatigue, and itching, followed by dark urine and jaundice. Jaundice and pruritus can be prolonged also after a promptly steroid discontinuation; AST, ALT, and ALP levels may be often normal also with a high bilirubinemia. Liver histology shows a typical bland cholestasis with minimal inflammation and hepatocellular necrosis; bile duct injury is generally mild and vanishing bile duct syndrome rare. Chronic injuries related to anabolic steroid abuse are peliosis hepatis, nodular regeneration, hepatic adenomas, and hepatocellular carcinoma. Peliosis hepatis is a rare syndrome, with normal or mildly elevated serum enzyme levels, in which there are blood-filled enlarged sinusoids and cysts throughout the liver. Patients may complain of right upper quadrant discomfort with hepatomegaly or abdominal pain and vascular collapse due to hepatic rupture and hemoperitoneum. Peliosis hepatis associated with anabolic steroid abuse generally reverses, at least in part, stopping drug assumption. Nodular regeneration has been described as a marked nodular regenerative hyperplasia with portal hypertension and splenomegaly, often found in "normal livers"; generally, the course of this illness is asymptomatic or associated with mild abdominal discomfort linked to hepatomegaly. Hepatic tumors are typically found in subjects on long-term anabolic steroids (5–15 years, but onset within 2 years of drug use has been described); histologically, they may look as hepatic adenomas, as "well-differentiated" hepatocellular carcinomas or as hepatic adenomas with areas of malignant transformation. Clinical presentation usually shows right upper quadrant discomfort and a hepatic mass on imaging procedures; routine liver tests are often normal before an extensive spread of the tumors. It is often possible to obtain a spontaneous regression of adenomas after stopping anabolic steroid use.

102.2.7 Inhalants

Chronic inhalant abuse can cause significant damage to the liver, depending on the time duration of the drug abuse. The hepatic injury seems to resemble alcoholic disease; carbon tetrachloride has such a strong association with liver damage that is today used to induce liver injury in some animal models.

102.2.8 Alcohol

The association of alcohol abuse and liver damage is well known and documented from the times of ancient Greeks and Ayurveda's system of medicine. Because there is evidence suggesting that fermented beverages existed at least as early as the Neolithic period (app. 10,000 BC), alcoholic liver disease (ALD) should be considered the oldest form of liver injury known to mankind. In the 1830s, the link between alcohol consumption and fatty liver was described in European medical literature, but the pathogenesis of this disease has been associated almost exclusively with a secondary protein and choline deficiency. Only in the last 1940s the direct toxicity of ethanol, its metabolism, and its metabolites have been demonstrated to represent the pathogenetic stimulus for alcoholic liver damage; nevertheless, today also we have to admit that our knowledge of ALD pathogenesis is not complete. In fact, the susceptibility to develop ALD is strictly individual and the reason unknown; the basic mechanism behind alcohol-induced cell death has not been unfolded, although the direct hepatotoxicity of ethanol has been established in experimental animals. Alcohol is the most common cause of liver diseases in the Western countries, but everywhere in the world, the percentage of alcoholic hepatic damages is still growing. In 2004, 3.8 % of all global deaths were attributable to alcohol, 6.2 % for men and 1.1 % for women, in 30 % of them due to liver failure. The harmful use of alcohol is the leading risk factor for death in men aged 15–59; the highest proportion of alcohol-attributable mortality is in the Russian Federation and neighboring countries, where 5 % of deaths among men and 6 % among women are attributable to the harmful use of alcohol. Relatively high numbers of alcohol-attributable deaths were revealed also in economically expanding middle-income countries, such as Brazil and China. Worldwide, alcohol consumption in 2005 was equal to 6.13 l of pure alcohol consumed per person aged 15 years or older. Analysis from 2001 to 2005 showed that countries in the WHO Americas, European, Eastern Mediterranean, and Western Pacific regions had relatively stable consumption levels during that time, while marked increases were seen in Africa and Southeast Asia. The main causative factors in alcoholic liver disease are as follows:

102.2.8.1 Quantity and Duration of Alcohol Use

Among susceptible people, risk increases markedly for men drinking >40 g (particularly >80) of alcohol/daily for >10 years; if consumption exceeds 230 g/daily, the risk of cirrhosis is about 50 %. The type of consumed alcohol may influence the risk to develop ALD; in a survey of more than 30,000 subjects in

Denmark, drinking beer or spirits was more likely to be associated to ALD than drinking wine. Nevertheless, only some chronic alcohol abusers develop liver disease; also variations in alcohol intake do not fully explain variations in susceptibility, suggesting that other factors are involved.

102.2.8.2 Sex

Women are more susceptible to alcoholic liver injury, even after adjustment for body size; they require half quantity of alcohol (20–40 g/daily) than for men to be at risk which may be increased if their alcohol dehydrogenase (ADH) level in the gastric mucosa is less.

102.2.8.3 Genetic Factors

Alcoholic liver disease often runs in families worldwide. Asians, who have lower levels of acetaldehyde dehydrogenase (ALDH), are more susceptible to toxic acetaldehyde effects. In the USA, the rates of alcoholic cirrhosis are higher in African/American and Hispanic males than in Caucasian, and the mortality rates are the highest in Hispanics.

102.2.8.4 Nutritional Status

Undernutrition (specially for protein), diets high in unsaturated fat, and obesity increase the susceptibility to ALD.

102.2.8.5 Other Factors

HBV, HCV, and HDV hepatitis and iron accumulation in the liver are concomitant high risk factors for the development of ALD.

Fatty liver, **alcoholic hepatitis**, **cirrhosis, and hepatocellular carcinoma** are the spectrum of alcohol-related hepatic injury, often as separate, progressive manifestations, but sometimes not necessarily distinct stages of evolution, simultaneously present in a given individual. The pathophysiology of ALD is linked to the metabolism of alcohol; ethanol is readily absorbed from the stomach and the small intestine and catabolized in the liver (only a small amount is degraded in transit through the gastric mucosa) involving ADH, cytochrome P450, and microsomal enzyme oxidation system (MEOS). ADH, a cytoplasmic enzyme, oxides alcohol into acetaldehyde subsequently oxidized to acetate by ALDH, a mitochondrial enzyme. These oxidative reactions generate hydrogen, which converts nicotinamide-adenine dinucleotide (NAD) to its reduced form (NADH), increasing the redox potential (NAD/NADH) with an inhibition of fatty acid oxidation and gluconeogenesis and promoting fat accumulation in the liver. Hepatic fat accumulation may predispose to oxidative damage subsequently increased by endotoxins, released in the gut, which stimulate liver macrophages (Kupffer cells) to release free radicals. Oxidative damage is increased also by liver hypermetabolism, due to alcohol consumption; by reduction in protective antioxidants (e.g., glutathione, A and E vitamins); by binding of alcohol oxidation products, such as acetaldehyde, to liver cell proteins, forming neoantigens and resulting in inflammation; by accumulation of WBCs attracted by lipid peroxidative damage and neoantigens; and finally by inflammatory

cytokines secreted by WBCs. As a result, cell necrosis and apoptosis with hepatocyte loss and subsequent fibrosis, stellate cells, lining sinusoids (blood channels) in the liver, proliferate and transform in myofibroblasts, with an excess of collagen and extracellular matrix that narrow the sinusoids limiting blood flow. Fibrosis narrows the terminal hepatic venules, contributing to portal hypertension; extensive fibrosis is associated with an attempt at regeneration, resulting in liver nodules that represent the first step of cirrhosis. Clinically, ALD shows an initial fatty liver (steatosis), with a macrovesicular fat hoard, potentially reversible, followed by alcoholic hepatitis (steatohepatitis), a combination of fatty liver, diffuse liver inflammation, and liver necrosis (balloon degeneration and Mallory bodies) with subsequent extensive fibrosis that disrupts the normal liver architecture evolving in cirrhosis. Symptoms are usually absent in patients with fatty liver, may appear (fatigue, fever, jaundice, tender hepatomegaly) during alcoholic hepatitis and compensated cirrhosis, ranging from mild to severe, and are evident in decompensated cirrhosis (ascites, portal-systemic encephalopathy, variceal bleeding, liver failure with hypoglycemia, coagulopathy, and hepatorenal syndrome). Hepatocellular carcinoma develops in 10–15 % of patients with alcoholic cirrhosis; the percentage is more elevated if other factors (hepatitis virus infection, hemochromatosis) are concomitant.

102.2.9 Hepatitis Viruses and Drug Use

Injection drug users (IDUs) are, from many years, the subjects at highest risk for acquiring hepatitis B, C, and D virus infection not only in developed but also in developing countries; in fact, there is a high efficiency transmission of these viruses via blood exposure. Declines in use of drug preparation and injection equipment have been observed in the HIV era (1990s) and have been associated with reduction over time in HCV-HBV-HDV infection among IDUs. However, injection-risk behavior has not totally been eliminated and sharing of drug preparation equipment, such as drug cookers and filtration cotton, seems to persist in IDUs. Furthermore, among heroin and cocaine noninjection drug users (NIDUs), there are other risk factors such as transmission through the sharing of equipment which could convey the viruses to denuded nasal mucosa or practices such as tattooing and perhaps also piercing; finally, sexual intercourse is generally inside the drug users group, a very closed group. High HCV incidence and rapidly increasing HCV prevalence were and are observed among young IDUs, and factors associated with HCV contagion include recent initiation to injecting, unstable housing, female gender, ethnicity, survival sex work, imprisonment, frequent injecting heroin or cocaine use, and having a partner who injects. The high risk of HCV infection among younger and recent IDUs indicates a narrow window of opportunity for prevention, with estimates of the median time to HCV infection of about 3 years.

102.2.9.1 Epidemiology

In 2007, it was estimated that there were 15.9 million IDUs worldwide and that inside them no less than ten million have been exposed to HCV with eight million

of chronic infection. The largest populations of HCV-positive IDUs lived in Eastern Europe (2.3 million) and eastern and southeastern Asia (2.6 million): The three countries with the largest populations of HCV-positive IDUs were China (1.6 million), Russia (1.3 million), and the USA (1.5 million). Some epidemiological studies revealed that in 2010, about 1.2 million of IDUs were HBsAg positive, with an IDUs global prevalence of 8.45 %. The largest populations by region are Asia and Southeast Asia.

The local epidemiology of HCV, HBV, and HDV infection among IDUs has been evaluated in several clinical studies. In 1991, Thomas and colleagues found a prevalence of HCV antibodies in 89 % of IDUs in Baltimore, Maryland, USA. Fortunately, a decline of this prevalence was observed by *Des Jarlais and colleagues* among IDUs in New York from 1990 to 2001: 90 % to 63 % during that period. A study conducted by Centers for Disease Control and Prevention showed that injection drug use was the first risk factor for HCV infection in the USA from 1984 to 2001. *Stroffolini et al*. determined in 2009 the prevalence and characteristics of HCV infection in a national sample of drug addicts in Italy. 543 drug addicts were enrolled: anti-HCV prevalence was 63.9 %; HCVRNA was detected in 68.3 % of patients positive for anti-HCV. They found a major prevalence of genotypes 1 (especially 1a) and 3 (49.3 % and 39.7 %, respectively). Prevalence of HBsAg was 2.8 %, while HDV markers were not determined. Probably, a growing concern of the risk of acquiring infectious diseases from blood, in particular HIV infection, contributed to the decline in HCV incidence.

Hepatitis B outbreaks among IDUs are occurring with an increasing incidence, and this in spite of the availability of effective vaccines for more than 20 years, especially in countries where vaccination is not mandatory. HBV infection among IDUs, in fact, depends on the population surveyed. In 1996, a study of *Garfein et al*. revealed that the seroprevalence of HBV positivity among a population of 716 IDUs with up to 6 years of drug use was 65.7 %. However, a recent study of *Baklan et al*. in 2004 showed that the prevalence of HBV infection in a group of IDUs in maintenance methadone program was only 17 % and only one among them exhibited signs of active infection. In any case, all studies demonstrated that methadone program is protective in terms of HBV infection.

HDV is a defective RNA-containing passenger virus requiring helper functions provided by HBV including provision of the hepatitis B surface antigen coat for virion assembly and penetration into hepatocytes. Transmission of HDV occurs through the same modalities of HBV transmission, and the most important factor influencing efficiency of transmission is whether the exposed individuals are or are not carriers of HBV. In a study of *Chen et al*., over 628 IDUs' antibodies against HDV were found in 68.1 % of individuals testing positive for HBsAg. However, in a study of *Huo et al*., over 494 IDUs in 2004 showed that 87 patients (18 %) were HBsAg carriers and only 12 (14 %) were anti-HDV positive; the prevalence rate of HDV was significantly lower than that in 1985. In a recently published work (2011), Paul Nelson and colleagues reviewed more than 5,000 abstracts, papers, and online resources reporting an estimate of global prevalence and population size for HCV and HBV infections in IDUs living in 77 countries in the world.

102.2.9.2 Management and Treatment of HCV Infection

The pharmacotherapeutic treatment of HCV in the general population has made great progress in recent years. The use of peginterferon and ribavirin plus boceprevir or telaprevir, new protease inhibitors against HCV, has significantly increased the rate of SVR (sustained virological response) in patients with genotype 1 without decompensated cirrhosis. Genotypes 1a and 3, as above reported, are more prevalent in IDUs and they affect treatment duration and response. A liver biopsy, when feasible, is indicated in order to identify the level of fibrosis and the causes of liver damage (viral, toxic, steatosis, or others). A very important problem in IDUs is represented by potential drug interactions between peginterferon and methadone or alcohol use. Interferon seems to increase serum levels of methadone especially in the presence of alcohol. Furthermore, alcohol dependence in IDUs decreases treatment response rates to interferon therapy. Interferon-based regimens for hepatitis care are often complicated by neuropsychiatric adverse effects (depression in particular). Patients should be screened for depression and other mental health problems before beginning treatment with interferon, treated if necessary and monitored for these problems during treatment for HCV. Nevertheless, past episodes of depression or other psychiatric disorders are not an absolute contraindication to treatment for HCV. For many years, in the past, illicit drug use has been considered a contraindication to antiviral therapy for chronic hepatitis C. Actually, several studies show that adherence and therapeutical success in IDUs are similar to other patients. A study of *Zanini et al*. in 2010 analyzed 16 prospective studies and data from a cohort of 953 IDUs treated for HCV infection. The estimated overall SVR and dropout rates were 52 % and 26 %, respectively. The rate of psychiatric severe adverse events that led to treatment discontinuation was 2 %. These prevalences were not significantly different from those reported in registration trials of treatment of the normal population. Since the population of IDUs is not a homogeneous group, it was very important that the different subgroups could be studied: active IDUs, IDUs in methadone maintenance program, IDUs in alternative detoxification program, and former IDUs since multiple years. *Guidelines for the management of chronic hepatitis C in patients infected after substance use* in 2005 established that active IDUs will not be eligible for antiviral treatment, but decisions about antiviral treatment should be made by a multidisciplinary treatment team together with the patient based on individualized risk-benefit assessments. *Bruggmann et al*. demonstrated that active intravenous drug use during chronic hepatitis C therapy does not reduce sustained virological response rates in adherent patients. *Belfiori et al*. in 2008 evaluated efficacy, safety, and tolerability of a standard peginterferon alfa-2a or alfa-2b plus ribavirin treatment in IDUs who were receiving methadone or buprenorphine. The results indicate that patients on maintenance treatment can be treated for HCV with a good success rate and tolerability. In conclusion, adherence is the most important factor for the success of therapy. The multidisciplinary team (infectivologist, psychiatrist, and others) is the key to obtain good adherence and compliance. This is a fundamental theme. In June 2009, in Bologna, FederSerD (Federation of Italian SerDs, public structures for the care of drug addiction) organized a conference on

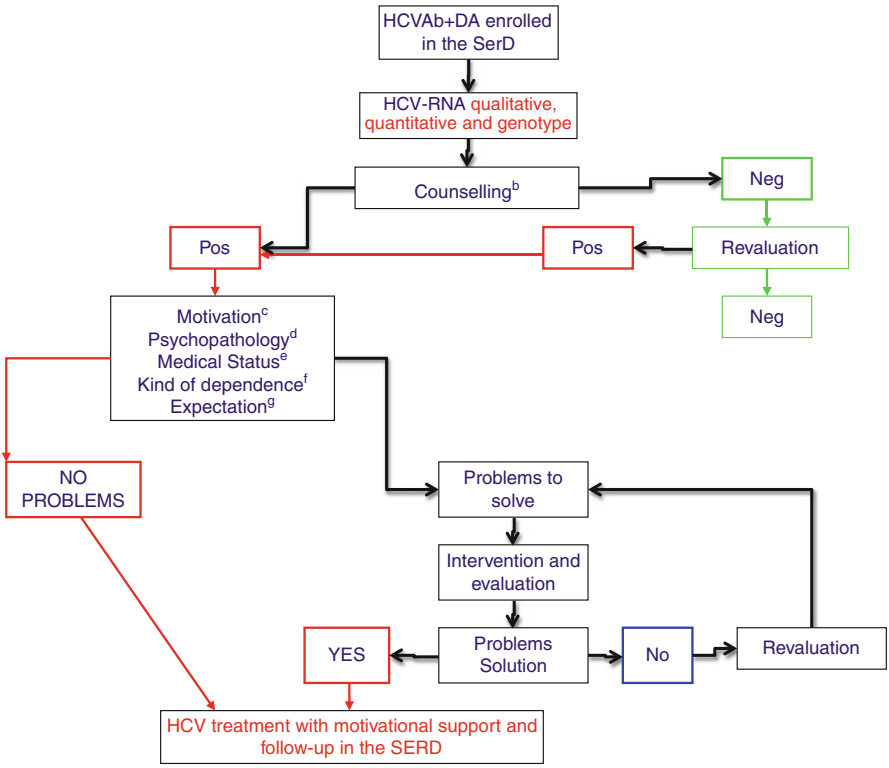

Fig. 102.1 Level of readiness for HCV treatment in IDUs

infectious diseases in IDUs. A working group (experts in addiction medicine, hepatologists, psychiatrists, psychologists, and nurses) presented a multidisciplinary model of care of HCV infection in IDUs. Because the major barriers to adherence to this therapy have been considered a lack of information about self-management, difficulty with motivation, and a lack of support for behavioral changes, we considered necessary that patients have to be informed, motivated, and skilled in the use of cognitive and behavioral self-regulation strategies to cope effectively with treatment-related demands. This model of intervention includes screening and treatment for HCV infection among IDUs; counselling pretreatment, during treatment, and posttreatment; psychiatric evaluation and enhanced cooperation with hepatologists/infectivologists, and following the steps represented in Fig. 102.1. Just after the Bologna Conference, an observational, multicenter study based on this model started under the surveillance of FederSerD; all enrolled patients are followed in the SerDs by addiction specialists together with infectivologists/hepatologists, psychiatrists, nurses, social workers, and counselors. About 40 % of patients are followed with a DOT (directly observed therapy), and the preliminary results have been presented at the 2011 and 2012 AASLD. We think

that our preliminary results emphasize either the epidemiological importance, for public health safeguard, to treat HCV-related CAH in IDU, or the feasibility and effectiveness of anti-HCV treatment in these subjects, if it may be adequately managed by a multidisciplinary team. SerDs represent the place where experts in addiction medicine, infectivologists, hepatologists, psychiatrists, psychologists, nurses, and social workers can work together caring for the "patient with his ill" in an atmosphere in which therapeutic means are explored, the regimen is explained, adherence is discussed, follow-up is planned, and DOT is often possible. So the adherence and the compliance to treatment regimens may be also better than in the general population because IDUs are monitored and supported during the treatment in the structure where they feel "a friendly care."

102.2.9.3 Management and Treatment of HBV/HDV Infection

Treatment indications of active HBV infection in IDUs are nearly the same of the common people. A liver biopsy, when feasible, is indicated in order to identify the level of fibrosis and to quantify cytoplasm and nuclear HBV markers. HBVDNA quantitative determination is very important to know the viral activity and decide the beginning of antiviral therapy. Peginterferon alfa-2a has been registered for the treatment of chronic hepatitis B at the dosage of 180 mcg for 48 weeks in both HBeAg-positive and HBeAg-negative patients. In IDUs, this therapy presents all the problems above reported and linked with peginterferon use. Entecavir and tenofovir, nucleos(t)ide analogs, inhibit HBV replication by competing with the natural nucleoside triphosphates for incorporation into viral DNA. They are generally well tolerated with few side effects. A monitoring of renal function during tenofovir use is requested. Interactions between tenofovir and entecavir with methadone or buprenorphine have not been pointed out.

Renal/Metabolic Consequences of Drug/Alcohol Use

103

Annemarie Hennessy

Contents

Abstract

This chapter outlines the indirect and direct effects of illicit *drug use* and alcohol on the kidneys and the renal tract. The classification of renal involvement as acute kidney injury or chronic kidney disease and the potential sites in the kidney for renal damage are outlined. These effects range from prerenal and hemodynamic effects which are rapidly reversible with appropriate treatment to intractable intrinsic renal disease directly related to drug or alcohol ingestion. The potential mechanisms of renal dysfunction are discussed. It also examines some of the chronic disease consequences of drug use such as blood-borne

infection which have complex renal involvement. Rhabdomyolysis is also explored here. Considerations of renal replacement therapy in the setting of drug use and end-stage renal disease are discussed. The metabolic effects of marijuana, alcohol, amphetamines, and MDMA are outlined.

103.1 Introduction

Renal disease is broadly defined by the effect it has on either immediate- or long-term renal function: acute kidney injury versus chronic kidney disease. Acute kidney injury (AKI) is defined as an acute decrease in urine flow and/or an acute rise in serum creatinine (a manifestation of a rapid decline in glomerular filtration rate). Chronic kidney disease is defined as a long-term alteration in renal function including abnormal urinary sediment, which may or may not be associated with a slow and progressive decline in glomerular filtration rate. It is these patients who are destined for renal replacement therapy, either dialysis or eventually, transplantation. It is common for indirect renal injury to arise from the hemodynamic and other systemic complications of drug taking including alcohol overdose.

Alternatively, direct renal injury and thus renal disease are defined by the part of the nephron that is most likely affected: glomerulus, tubules, renal interstitium, or blood vessels. It is more likely that tubular and vascular injury will result from drugs of addiction. It is much less common for glomerular injury to occur in this setting. The clinical terminology for glomerular disease is based on old-fashioned syndromal definitions, i.e., nephrotic and nephritic syndrome, or asymptomatic urinary abnormality such as proteinuria or hematuria. Any of these can be caused *directly* from drugs of addiction or alcohol but are more likely when they occur to be part of a complex chain of end-organ damage arising indirectly from the consequences of drug taking.

This chapter will review these indirect injury and direct injury pathways in the kidneys from alcohol and other drugs of addiction (Table 103.1).

103.2 Renal/Metabolic Consequences

103.2.1 Alcohol

103.2.1.1 Acute Alcohol-Related Injury

Cases of acute tubular injury have been associated with acute alcohol binging, but these reports are usually confounded by nonsteroidal anti-inflammatory use or rhabdomyolysis (Johnson and Wen 1995). The combination of an analgesic agent often used for alcohol-related symptoms such as headache (e.g., NSAID) which also diminishes glomerular filtration rate, in addition to the compromise of renal perfusion pressure (dehydration) seen as a result of alcohol-related inhibition of AVP (Coiro et al. 2009), is causative in this setting (Cecchin and De Marchi 1996).

103.2.1.2 Chronic Alcohol-Related Injury

Alcohol has profound renal effects as early as at the time of in utero renal development (3–6 weeks of embryonic life). There are now animal models which indicate a direct renal effect with decreased nephron number after in utero exposure to low-dose ethanol (Probyn et al. 2012). Renal injury has been associated with fetal alcohol syndrome (Qazi et al. 1979).

Alcohol is associated with a number of adult renal conditions. IgA disease (deposition of IgA in the mesangium of the glomerulus) can arise from hypergammaglobulinemia in the setting of alcoholic cirrhosis (Tissandie et al. 2011). The recent discovery of identifiable glycosylation properties of IgA in the setting of alcoholic cirrhosis indicates "unique biological properties" of circulating immune complexes which differentiate this type of secondary from primary IgA disease (Novak and Julian 2011). Rates as high as 64 % of autopsies from chronic alcoholics show evidence of renal IgA deposition (Smith and Hoy 1989).

Direct "alcohol nephrotoxicity" described in the 1960s was invariably associated with progressive and cirrhotic liver disease (Laube et al. 1967). It was more likely a manifestation of the association of advanced liver disease with renal failure (hepatorenal syndrome). It is now known that this injury is not specific to alcohol-related hepatic injury.

Hepatorenal syndrome is a well-described and often terminal complication of cirrhosis of all causes. This is diagnosed where there is a slow decline in renal function at the time of decline in hepatic function. Often the rise in serum bilirubin is a close marker of deterioration. It is almost invariable association with portal hypertension. The theories of cause link increased intra-abdominal pressure with the hypoperfusion of the kidneys, in a setting where blood volume is also reduced due to hypoalbuminemia. There is a concurrent increase in plasma renin activity. Hepatorenal syndrome is classified as type 1, an acute deterioration in GFR with a prognosis of 2 weeks, and type 2, slower onset and associated with ascites, with a prognosis of 6 months. Treatment of type 1 disease is with appropriate supportive care: hemodynamic restoration including active upper GIT bleeding, treatment of bacterial peritonitis, and albumin replacement; the addition of terlipressin, a vasopressin analogue, significantly improves survival and transplant-free time, with a relatively low complication rate and an 8 % recurrence rate for the hepatorenal syndrome (Sagi et al. 2010).

Alcohol has been associated with renal urothelial cancer (Probert et al. 1998), although this tracked with beer above other types of alcohol intake. The decreased risk of prostate cancer as conferred by folate intake (Roswall et al. 2013) is not altered by alcohol intake.

Alcohol has an indirect effect on renal function in the longer term by means of chronic hypertension (Klatsky et al. 1977) initially thought to be independent of age, sex, weight, smoking habit, and social class. Due to the contribution of alcohol to caloric intake, it also contributes to obesity and thus risk of diabetes mellitus. The relationship between alcohol and diabetes mellitus is complex as moderate consumption is associated with reduced incidence of diabetes (Mukamal et al. 2003). Less commonly chronic pancreatitis from alcohol intake can lead to diabetes

Table 103.1 Drug-specific effects on the kidney and renal tract

Pattern of injury	Substance use association
Indirect renal injury associated with drug use	
Prerenal failure/acute tubular necrosis in the setting of cardiogenic shock, hypovolemia, multiorgan failure, or septic shock	Any overdose leading to cardiogenic shock or hypovolemia
	Significant drug overdose including acute alcohol poisoning
	Hepatorenal syndrome associated with advanced cirrhosis from alcohol
	Significant (overwhelming) bacterial infection
Rhabdomyolysis	Significant drug use or overdose including acute alcohol poisoning, cocaine, MDMA and narcotic use, and overdose (prolonged immobilization)
Renal involvement in systemic infection including bacterial endocarditis and other intravascular infections	Intravenous drug use – any agent
Blood-borne virus infections with renal consequences	
Hepatitis C-related cryoglobulinemia	
Hepatitis B-related minimal change or	
Membranous nephropathy or	
Mesangiocapillary glomerulonephritis	
HIV-related nephropathy	
Hypertension and extrarenal vascular damage including accelerated atherosclerosis	Cocaine, methamphetamines, and heroin
Malignant hypertension	Chronic alcohol, MDMA
	Cocaine
Renal epithelial cell cancers (bladder and ureters)	Chronic alcohol
Obstructive uropathy	Rare cases with MDMA
Direct renal parenchymal injury from drug use	
Glomerular injury	Chronic alcohol
Secondary IgA disease from alcoholic liver disease	
Nephrotic syndrome/nephritic syndrome	
Acute glomerulonephritis (including post-infectious glomerulonephritis)	Cocaine and heroin – IV contamination with staph or strep and nasal disruption
Anti-glomerular basement disease (rare)	Cocaine
Amyloidosis	Skin-injected heroin
Tubular injury	
Acute tubular nephrotoxicity	Cocaine and heroin
Acute interstitial nephritis	Rare cases with MDMA
Vascular injury	Cocaine and amphetamines/MDMA
Renal arterial vasospasm, segmental infarction, drug-induced vasculitis	

mellitus (present in 50 % of chronic pancreatitis) and thus is a risk factor for diabetic nephropathy (Lowenfels et al. 1993); pancreatitis is not seen in acute alcohol binges (DiMagno and DiMagno 2012; see ▶ Chap. 101, "Gastrointestinal Disorders Related to Alcohol and Other Drug Use"). Healthy heart guidelines targeting weight and blood pressure will include a component recommending safe alcohol consumption parameters for men and women in order to decrease risk of pancreatitis-induced diabetes and alcohol-related hypertension (Bulpitt 2005) among other recognized alcohol-related complications.

103.2.2 Cocaine and Renal Injury

The commonest direct renal injury arising from cocaine use is renal infarction arising from intense renal arterial vasospasm and renal artery (or segmental artery) thrombosis (Zimmerman 2012). This is thought to be contributed to by the combination of vasoconstrictive sympathomimetic and prothrombotic mechanisms. The possible use of combinations of vasoactive and renal hemodynamic acting drugs (including NSAIDs) cannot be underestimated in this setting.

Other direct renal toxicity has recently been described in the form of antiglomerular basement membrane disease (Goodpasture's disease). This has been associated with intranasal and smoked "crack" cocaine use (Peces et al. 1999) and other modalities (Chan et al. 2011). Antiglomerular basement membrane disease presents as a rapidly rising creatinine, acute pulmonary hemorrhage, and pulmonary edema with an active urinary sediment (red cell casts). Rapid treatment with hemodialysis and immunosuppression or plasmapheresis is usually indicated for the specific treatment of uremia and for decreasing the circulating antibody. Other supportive measures including blood transfusion for pulmonary hemorrhage and treatment of hypertensive emergencies may be required.

As well as the indirect effect of hypertension on long-term renal function, cocaine contributes to glomerular damage and fibrosis due to effect on the RAAS (renin-angiotensin-aldosterone system) and endothelin-1. Nonspecific lesion has been identified in the glomerulus, tubules, and interstitium of animals and in human chronic exposure. These abnormalities contribute to progression to ESRD (end-stage renal disease) requiring chronic dialysis in some cases.

Indirect renal injury is most commonly due to rhabdomyolysis (Jaffe and Kimmel 2006). Other indirect effects are due to hypertension including malignant hypertension and accelerated atherosclerosis (Lange and Hillis 2001). Proteinuria is inevitably described in those scenarios and the patients are not often biopsied leaving open the possibility that there is coexistent glomerular injury (Jaffe and Kimmel 2006).

103.2.3 Amphetamines and Derivatives and Renal Effects

MDMA and other amphetamine derivatives are most commonly associated with AKI. When used in the setting of dance parties and other events associated with

extreme exertion and even seizures, the principal effect is a prerenal insult related to severe dehydration. AKI is further compounded by the presence of acute muscle injury and toxicity from muscle breakdown products in the form of rhabdomyolysis where pigmented toxins cause a direct tubular injury.

On rarer occasions and often with single-dose use, vascular injury in the form of acute segmental infarction has been described (Woodrow et al. 1995; Citron et al. 1970). Also, acute proximal tubular injury has been described (Kwon et al. 2003). It has also been noted that bladder outlet obstruction can be caused by some other unexpected cholinergic effect of these poorly controlled drugs (Bryden et al. 1995). Individual variation attributable to routine dose toxicity is thought to be related to cytochrome and metabolism genetic variations (de le Torre et al. 2004).

These insults are largely thought to be reversible when the acute intoxication has been treated with intravenous fluids and careful management of body temperature, dehydration with fluids, and urinary pH in the setting of rhabdomyolysis.

103.2.4 Heroin and Renal Injury

Historically, heroin-associated nephropathy was thought to be due to contaminants (bacterial or viral) or poor quality heroin or morphine as the incidence of these has declined in the era of proven blood-borne virus-related nephropathy. The data from the 1970 to 1980s suggested a range of nephrotic syndrome relating to minimal change lesions, mesangiocapillary lesions, but, more commonly, focal sclerosing glomerulosclerosis. This was most common in African-Americans of that era. This lead to end-stage renal failure, and the degree of tubule-interstitial scarring at the time of the initial diagnosis, as with most glomerular disease, is indicative of the prognosis.

Immune complex-mediated glomerular disease (presenting as nephrotic or nephritic syndrome) has been associated with chronic staphylococcal and streptococcal infections in the setting of either intravenous use or due to nasal disruption from intranasal administration (Koyama et al. 1995).

There are case reports of renal amyloidosis arising from chronic skin infection after subcutaneous use (Jacob et al. 1978).

Infective endocarditis is the most common direct intravascular infection still common in IV drug users. The renal complication of this is a manifestation of infectious vasculitis with mycotic involvement (bacterial microabscesses) as well as necrotizing segmental infarction from septic emboli. There are also immune complex-mediated inflammatory changes in the glomeruli including crescent formation and rapidly progressive renal injury. The presentation is most usually nephritic syndrome (hypertension and hematuria) but in 14 % of cases can be nephrotic with normal blood pressure. The severe forms of renal failure require support with dialysis, but the mainstay of treatment is the treatment of the underlying bacterial infection. In the case of large-sized valvular vegetations or mycotic aneurysm, cardiothoracic surgery or intravascular surgery may be required.

103.2.5 Intravenous Drug Use and Indirect Renal Effects

The commonest renal consequence of any IVDU is related to infections, either post-streptococcal acute glomerulonephritis or due to the renal effects of bacterial endocarditis or other intra-arterial vascular infection as outlined above. The mechanisms of renal injury here include acute glomerular injury, post-streptococcal glomerulonephritis and nephritic syndrome, and immune complex deposition disease from endocarditis. In the longer term, GN related to blood-borne virus (BBV) infection causes a significant burden of disease.

103.2.6 BBV in Drug Users and Renal Consequences

The viral consequences of IVDU and blood contamination include infection with hepatitis B and C and HIV.

Hepatitis B is associated with membranous nephropathy and mesangiocapillary pattern (membranoproliferative) glomerulonephritis, the former presenting as nephrotic syndrome (more commonly in infected children) and the latter as nephritic syndrome with progressive renal failure if left untreated. Males are more likely to be affected. This was described with case reports dating back to 1984 (Akinsola et al. 1984). The other rarer manifestations are minimal change nephropathy (nephrotic syndrome) and polyarteritis nodosa (an aggressive form of glomerular disease associated with progressive renal damage). These are widely thought to represent a spectrum of immune disease ranging from in situ immune reactions to hepatitis antigens present in various components of the glomerulus (membrane and subepithelial locations) to the deposition of immune complexes arising from the chronic antigenemia in the circulation (Venkataseshan et al. 1990; Adeyi 2009). Treatment strategies in hepatitis B-related GN have targeted reduction of proteinuria and maintenance or improvement of renal function (serum creatinine) with only marginally beneficial results from a combination of immunosuppressive therapy and antiviral treatment (Zheng et al. 2012). There are considerable implications for the management of hepatitis B in the setting of renal transplantation should that be required (Kalia et al. 2011) (Table 103.2).

Hepatitis C can be associated with cryoglobulinemic renal disease which can rapidly progress to AKI and irreversible renal injury. Specifics of treatment relate to viral control predominantly, but the need for aggressive renal management including plasma pheresis can be indicated in severe cases.

HIV-associated nephropathy has the following pathological presentations: immunotactoid deposition glomerular disease and HIV (viral) nephropathy. These are rare (Chen et al. 2011). There is considerable overlap in the literature with coinfection with hepatitis B and C and HIV, and therefore, the causal relationships with individual infections are still not entirely clear.

Other psychotropic drugs have not been associated with glomerular or other renal diseases. Kava has been associated with increased rates of nephropathy

Table 103.2 IVDU viral infections and their associated glomerular complications

Hepatitis B	Membranous glomerulonephritis
	Membranoproliferative glomerulonephritis (MPGN)
	Polyarteritis nodosa (PAN)
Hepatitis C	MCD ?coincidental
	Membranoproliferative glomerulonephritis (MPGN)
HIV	Immunotactoid GN (rare)
	HIV nephropathy (rare)

(proteinuria) and transitional epithelial cell hyperplasia and cancer potential renal tract cancers in animal studies (National Toxicology Program 2012).

103.2.7 Rhabdomyolysis and Its Management

Rhabdomyolysis is the commonest form of indirect renal injury, and this can arise from significant drug use or overdose including acute alcohol poisoning, cocaine, MDMA and narcotic use, and overdose (prolonged immobilization). It is of particular concern in the setting of dehydration, hyperthermia, and drug toxicity from MDMA used in dance settings. The specific pathophysiological abnormalities include direct tubular toxicity from myoglobin metabolites such as ferrihemate, vasoconstriction from these agents, and lipid peroxidation. There are myoglobin casts in tubules which cause obstruction.

The diagnosis of rhabdomyolysis is confirmed by the concentration of creatine kinase (CK) in the circulation. For acute kidney injury, generally high CK levels ($>$15,000 U/l) are required except when the rhabdomyolysis is accompanied by acidosis, dehydration, and/or sepsis. Cytokine release has also been described.

Treatment is mainly focused on fluid resuscitation and restoration of electrolyte disturbances. This is best performed with extremely close attention to the repeated measurement of urine electrolytes including urinary pH, normalizing serum potassium, sodium, and chloride and by establishing a reasonable urine output (0.5 ml/kg/h), although much high targets ($>$2.5 ml/kg/h) are desirable. There is limited level A evidence for urinary alkalinization (urine Ph $>$ 7.0) (Tolouian et al. 2005) which is often very difficult to achieve in clinical practice. In severe cases, dialysis may be required for 3–6 weeks.

103.2.8 Renal Replacement Therapy: Dialysis and Renal Transplantation in the Setting of Drug Use and End-Stage Renal Disease

Although end-stage renal disease rarely arises de novo from drug use, this has been described with prolonged MDMA and cocaine use and malignant hypertension.

Providing long-term dialysis to individuals with drug and addiction issues can be complex. Issues of vascular access, repeated intravascular infection, difficulties with pain management, and compliance with fluid restriction regimes are just a few of the complications.

Transplant in addicted individual poses particular challenges. These largely relate to the acute surgical issues, such as pain management, and longer-term issues, such as immunosuppression, and infection and cancer risk. Poor compliance issues are largely thought to be the main contributor to poor renal graft survival in ages 15–25 years (ANZ data); addictive drug behavior and poor adherence lead to the same poor outcomes from the point of view of the kidney function after transplantation but also for the patient overall (reduced patient survival). There is no evidence that substance abuse relapses after transplantation, but the presence of intercurrent either alcohol-related injury (especially hypertension and cardiomyopathy) or hepatitis C infection in IV drug users poses increased risks after transplantation.

103.2.9 Metabolic Consequences of Marijuana

There are no direct renal consequences of marijuana use, but recently a case report of metabolic disturbances in the setting of diabetes has arisen (Hennessy et al. 2011). It is postulated that the acid-base disturbance arising in diabetic ketoacidosis has a different acid-base profile and attention to ketosis is an essential component to safe management in this setting. The confounding comorbidity here is vomiting. There is another anecdotal evidence of hyperemesis with heavy cannabis use which will independently lead to mild hypokalemia and a low serum bicarbonate (Wild and Wilson 2012). The association of intractable vomiting with excessive hot water bathing has been noted (Nicolson et al. 2012). In general, the longer-term metabolic derangements from marijuana relate to liver and lipid dysfunction (Muniyappa et al. 2013).

103.2.10 Metabolic Consequences of Alcohol

The commonest metabolic abnormalities arise from chronic alcohol use and are indirect in that they are secondary to excessive vomiting/gastritis, chronic diarrhea, and pancreatitis.

Electrolyte disturbance from alcohol-induced diarrhea is well reported (Testino 2008). There are additional complications related to specific inhibition of magnesium absorption and phosphate malabsorption, but the major pathology is from rapid GIT transit time, mucosal damage, and a range of gastropathies (gastritis, ulceration, and paresis).

Acute and chronic effects of alcohol on arginine vasopressin (AVP) function are also important in electrolyte balance. Acute alcohol ingestion leads to

a demonstrable increase in urine flow as a direct result of inhibition of AVP. Alcohol further disrupts the AVP response to rising electrolyte concentrations and perpetrates the hemoconcentration (Rubini et al. 1955). This effect is seen in both acute and chronic ingestion but seems in part to be moderated by age. Despite this direct water balance effect mediated by hormones, the net effect of very large intakes of hypotonic fluids is a hyponatremic syndrome. This is usually a conflation of low-salt food intake at the same time. Alcohol also has a direct effect in acute doses on sodium, potassium, and chloride excretion. Hypophosphatemia is generally thought to be related to poor nutrition in a chronic setting. Direct muscle toxicity from alcohol can lead to a mild hyperphosphatemia. Chronic alcoholic intake has in the past been shown to be the commonest cause of hypomagnesemia (Epstein 1992). The mechanism of this deficiency is most likely due to increases in urine flow rate but can also effect tubular magnesium exchange (Romani 2008). Calcium excretion is similarly increased with alcohol use.

The hemodynamic response to alcohol has in part been shown to be related to changes in renin secretion (Puddey et al. 1985). This may account for some of the additional changes seen with alcohol use including hypokalemia and a systemic alkalosis.

103.2.11 Metabolic Consequences of Cocaine and Narcotic Use

As MDMA use, cocaine has been associated with malignant hyperthermia, excessive sweating, and fluid losses and with the development of rhabdomyolysis. These are the same mechanisms which contribute to the development of hyponatremia in some cases. Hypoglycemia has also been described.

103.2.12 Metabolic Consequences of Amphetamines and MDMA

The use of MDMA causes a direct increase in body temperature and ability to exercise excessively. This response has been associated with rhabdomyolysis as described above but has also been associated with hyponatremia related to excessive drinking with its use.

MDMA has a complex interaction with water balance leading to well-documented cases of water intoxication and hyponatremia; these cases have been described after a single use but will also occur with accumulated doses. The profound hyponatremia was largely thought to be due to water intoxication in the setting of dehydration and excessive sweat loses, but a high rate of this abnormality with MDMA would suggest that an additional effect is in play – the AVP effect of MDMA on decreasing water losses and decreasing aquaporin.

Abstract

Drugs of abuse can impinge upon an individual's brain function and produce myriad neurobiological consequences. Drugs of abuse can produce neurobiological complications during acute intoxication, after withdrawal, and/or as a consequence of long-term abuse/dependency. Whether a direct or indirect consequence, substance abuse can induce severe negative neurobiological complications acutely or chronically. Cellular pathologies may include microglial activation, neuronal cell loss, gliosis, and axonal damage.

104.1 Introduction

In 2012, an estimated 23.9 million Americans were current (past month) illicit drug users. This estimate represents 9.2 % of the population aged 12 years or older, an increase of over 8 % in just 10 years' time (NSDUH 2013). Drugs of abuse can impinge upon an individual's brain structure and function to produce myriad neurobiological consequences. Substances of abuse can induce severe negative neurobiological effects directly or indirectly, acutely or chronically. For example, consequences such as seizures or stroke can occur almost immediately upon intoxication, whereas encephalopathy is more likely to develop chronically. Continued abuse, in many instances, can lead to substance-use disorders that are frequently associated with comorbid functional deficits in working memory, attention, and decision-making. A diminution in executive functioning can result in aggressive, sexual, and/or other behavioral activities that lead to further destructive personal and social health.

In addition to medical complications, persons with substance-use disorders are at risk for potentially severe social and occupational adverse consequences. Individuals with substance-use disorders are more likely to be unemployed and less likely to find a job compared to people who are not dependent. Substance abuse increases the risk of domestic violence in families. Children of substance-abusing parents are at higher risk for poor social, educational, and health functioning and are more prone to abuse drugs themselves.

Neurobiological complications can be associated with intoxication, dependence, and/or withdrawal depending upon the type of drug abused. Drugs can initiate a cascade of intertwined direct (e.g., toxic) and indirect (e.g., vascular) within the central nervous system (CNS). Nearly all drugs of abuse affect adversely the frontal/prefrontal circuitry of the brain, areas that are important for controlling decision-making and mitigating impulsivity. In terms of direct actions, several aspects of drug intoxication may lead to cellular pathology and likely underlie medical consequences. These can be increased neuronal cell loss, neurodegenerative-related modifications, a reduction of astrocytes, widespread axonal damage, and/or microglial activation (Buttner 2011).

As a substance-use disorder develops, there is an increasing difficulty for an individual to prevent the compulsive abuse of drugs. The overlap of brain areas

involved in substance-use disorders indicates that brain changes stemming from abuse may interact to precipitate the other. For example, associated changes in schizophrenia may increase the vulnerability to substance abuse or vice versa. This added layer of complexity involving comorbid disorders may increase the likelihood for, or enhance the severity of, the neurobiological complications of substance abuse.

104.1.1 Substance Abuse as a Part of Substance-Use Disorders

Substance-use disorders develop along a clinical continuum. An individual develops a substance-use disorder at different rates depending on one's genetic makeup, environment, the substance or substances being abused, and the route by which a substance is introduced into the body (e.g., oral, inhalation, injection). The faster a substance with an addictive liability enters the body and reaches its active site(s) in the brain, the more likely that substance will be abused.

Intoxication is associated with recent substance abuse. It can involve either a drug or a chemical toxin and has the potential to develop into maladaptive substance-use disorder with repeated use or abuse.

Repeated abuse of drugs frequently results in homeostatic adaptations that buffer or diminish the effects of a drug. This is drug tolerance. Tolerance varies based upon the type and quantity of the drug taken and is associated need for markedly increased amounts of the substance to achieve the previously experienced level of intoxication.

Withdrawal is the group of symptoms that occurs upon the abrupt discontinuation or markedly reduced intake of a chronically abused substance. Withdrawal only develops after an individual has developed a physical dependence to a given substance. Withdrawal symptoms generally present as opposite of the drug's direct effects on the body. For example, withdrawal from a sedative such as alcohol or barbiturates can result in rebound hyperexcitability and an increased likelihood for the onset of generalized tonic-clonic seizures.

Substance abuse was previously considered to pertain to those individuals who did not yet meet the criteria for dependence; however, the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5), no longer separates abuse from dependence. Instead, the DSM-5 now combines abuse and dependence categories into a common "substance-use disorder." These are frequently associated with "substance-induced disorders," such as intoxication and withdrawal, depending on the drug of abuse (see Table 104.1) (American Psychiatric Publishing Group 2013).

Because neurobiological complications of substance abuse can occur during any of the aforementioned "phases" of substance abuse – acute intoxication, as a consequence of long-term abuse/dependency, or withdrawal – associated consequences of various classes of drugs of abuse are presented along this "continuum" below.

Table 104.1 DSM-5 diagnoses as they relate to various classes of drugs. The neurobiological complications associated with these various drug classes vary based upon the associated severity of drug abuse as presented within the context of these clinical diagnoses

Drug class	Drug examples	Clinical diagnoses
Cannabis	Marijuana	Cannabis intoxication
		Cannabis use disorder
		Cannabis withdrawal
Hallucinogens	Lysergic acid diethylamide	Phencyclidine intoxication
	Phencyclidine (angel dust)	Phencyclidine use disorder
	Psilocybin (mushrooms)	Other hallucinogen intoxication
	Mescaline (peyote)	Other hallucinogen use disorder
		Hallucinogen persisting perception disorder
Inhalants	Toluene	Inhalant intoxication
	Butane	Inhalant use disorder
Opioids	Hydrocodone	Opioid intoxication
	Hydromorphone	Opioid use disorder
	Oxycodone (oxycontin)	Opioid withdrawal
	Heroin (opiate)	
	Morphine (opiate)	
Stimulants	Cocaine	Stimulant intoxication
	Amphetamine	Stimulant-use disorder
	Methamphetamine	Stimulant withdrawal
	3,4-Methylenedioxy-N-methamphetamine (MDMA, ecstasy)	
Sedatives	Alcohol (ethanol)	Alcohol intoxication
	Benzodiazepines	Alcohol-use disorder
	Barbiturates	Alcohol withdrawal
		Sedative, hypnotic, or anxiolytic intoxication
		Sedative-, hypnotic-, or anxiolytic-use disorder
		Sedative, hypnotic, or anxiolytic withdrawal
Tobacco (nicotine)	Cigarettes	Tobacco-use disorder
	Smokeless tobacco	Tobacco withdrawal

104.2 Neurobiological Consequences

104.2.1 Neurobiological Complications of Substance Abuse

Neurobiological complications arising from six major classes of drugs of abuse are discussed including:

1. Cannabis (e.g., marijuana, synthetic cannabinoids)
2. Hallucinogens (e.g., LSD, PCP)

3. Inhalants (e.g., toluene, butane)
4. Opioids (e.g., oxycodone, heroin)
5. Stimulants (e.g., cocaine, amphetamines, bath salts, ecstasy, nicotine)
6. Sedatives (e.g., alcohol, benzodiazepines)

104.2.2 Cannabis

Cannabis (marijuana) is one of the most commonly used/abused drugs worldwide, behind caffeine, alcohol, and tobacco. In the United States, marijuana was the most commonly used illicit drug in 2012 with 18.9 million past-month users (NSDUH 2013). Marijuana use and abuse has increased dramatically among young people since 2007; there are now more adolescent marijuana smokers than there are cigarette smokers.

Marijuana consists of the dried flowers of cannabis plants which are selectively bred to produce high levels of THC and other psychoactive cannabinoids such as cannabidiol. The principal psychoactive ingredient responsible for the euphoria associated with marijuana abuse is delta-9-tetrahydrocannabinol (THC). Marijuana is typically smoked or consumed orally.

"Spice" refers to a wide variety of herbal mixtures containing synthetic cannabinoids that produce psychoactive experiences similar to marijuana. Spice products are sold under many names such as K2, fake weed, Yucatan Fire, Skunk, or even Moon Rocks. These products are marketed as "safe," legal alternatives to marijuana (National Institute on Drug Abuse 2012c).

104.2.2.1 Neurobiological Mechanisms of Action

THC is a partial agonist for CB1 and CB2 cannabinoid receptors. CB1 receptors are dispersed widely throughout the CNS including the basal ganglia, substantia nigra, hippocampus, and cerebellum. When activated, CB1 receptors inhibit presynaptically both glutaminergic and GABAergic interneuronal neurotransmission, whereas CB2 receptors are expressed mainly in the immune cells of the periphery. Because THC activates CB1 receptors in the CNS, it is considered to be responsible for mediating the addictive effects of marijuana.

104.2.2.2 Acute Intoxication

Marijuana abuse can result in increased appetite, heightened sensory perception, inattentiveness, cognitive dysfunction, motor incoordination, an altered perception of time, and talkativeness. It can also impair short-term memory. Effects can vary dramatically for individuals and, when smoked, typically persist for 1–3 h (National Institute on Drug Abuse 2012a).

With heavier marijuana smoking, toxic psychosis, hallucinations, paranoia, and a loss of the sense of personal identity can occur. Neurovascular complications have also been reported with heavy abuse, although these data are preliminary. As with other substances of abuse, the proposed mechanisms for marijuana-induced ischemic events include vasospasm, vasculitis, and/or orthostatic hypotension (Tamrazi

and Almast 2012). Because confiscated samples of marijuana have demonstrated that THC content has increased significantly over the past three decades, complications of heavy marijuana abuse may become increasingly more common (National Institute on Drug Abuse 2012a).

A variety of neurobiological complications have also been described for spice or K2 abusers who have been taken to Poison Control Centers. Some complications that have been reported include the following: elevated heart rate, nausea, agitation, confusion, and hallucinations. Spice can also raise blood pressure, can produce myocardial ischemia, and, in rare instances, has been linked to heart attacks (National Institute on Drug Abuse 2012c).

104.2.2.3 Complications of Dependence

Chronic marijuana smoking can result in dependence. Although the DSM-5 does not define a "cannabis-use disorder," neurobiological complications stemming from chronic marijuana abuse may increase anxiety and depression and/or contribute to an amotivational syndrome. Although research has not yet determined whether marijuana is causally linked, or is only correlated with, these mental health issues, there is some evidence to suggest that there may be a link between chronic marijuana abuse and schizophrenia (National Institute on Drug Abuse 2012a).

104.2.2.4 Withdrawal

Regular smokers of marijuana or abusers synthetic cannabinoids can experience withdrawal and addiction symptoms. With repeated abuse, CB1 receptors can homeostatically downregulate, which may contribute to cannabis-induced withdrawal symptoms when drug use is abruptly discontinued. Some of the neurobiological complications that regular marijuana smokers may experience during withdrawal may consist of restlessness, anorexia, irritability, and, perhaps most prominently, insomnia.

104.2.3 Hallucinogens

Hallucinogenic compounds are found in mushrooms and some plants. Common hallucinogens include substances such as lysergic acid diethylamide (LSD), phencyclidine (PCP) (angel dust), psilocin (psilocybin), mescaline (peyote), and ketamine (vitamin K). They can be classified into three main types: psychedelics, dissociatives, or deliriants based on purported mechanisms of action. Unlike other psychoactive drugs (e.g., opioids or stimulants), hallucinogens induce changes in perception, thought, emotion, and consciousness. The main difference between a psychedelic versus a dissociative hallucinogen is that acute intoxication with dissociatives results in a more intense detachment from the individual's self and his/her perceived reality. In 2012, there were over one million people aged 12 years or older who were current users of hallucinogens (0.4 %; NSUDH 2013).

104.2.3.1 Neurobiological Mechanisms of Action

Many hallucinogens have chemical structures similar to those of natural catecholamine neurotransmitters such as acetylcholine, serotonin, dopamine, or norepinephrine. Whereas the exact mechanisms remain unclear, psychedelic hallucinogens such as LSD, psilocin, and mescaline appear to exert their effects via agonism of 5-HT_{2A} serotonin receptors, perhaps in conjunction with mGluR2 receptors (González-Maeso et al. 2008) acting within the prefrontal cortex. By comparison, dissociative hallucinogens such as PCP or ketamine appear to exert their effects by temporarily antagonizing glutamatergic NMDA receptors, and deliriants are considered to be anticholinergics. LSD's effects typically begin within 30 min of ingestion and can last up to 12 h.

104.2.3.2 Acute Intoxication

Following acute intoxication, individuals who abuse low-to-moderate doses of LSD may physiologically experience an increase in breathing rate (yet more shallow), dilated pupils, elevated heart rate, hypertension, hyperthermia and diaphoresis, loss of appetite, sleeplessness, and dry mouth. A generalized numbness of the extremities and loss of muscular coordination may occur. At higher doses, blood pressure, pulse rate, and respirations may drop significantly. This may be accompanied by nausea, vomiting, blurred vision, nystagmus, drooling, and/or ataxia. However, the major neurobiological complications following LSD intoxication are psychological. Acute intoxication with LSD may result in neurobehavioral complications such as psychoses, anxiety, panic, and/or hallucinations, wherein transitions between various emotional states are frequent or even sensed simultaneously. LSD may also have dramatic effects on the senses. Acute LSD intoxication can lead to "mash-ups" of colors, smells, sounds, and/or other sensations, which may seem intensified. Sensations may also seem to "cross over." For example, an individual may "hear" colors, while "seeing" sounds. These changes can produce anxiety and ultimately result in panic and terrifying thoughts and feelings of despair or insanity (National Institute on Drug Abuse 2001).

In terms of PCP, intoxicated individuals are often brought to emergency rooms because of overdose or because of the drug's severe untoward psychological effects. Some of the neurobiological complications that PCP abusers may experience include suicidal and/or violent behavior. They can become extremely dangerous to themselves and to others. Acute intoxication with higher doses of PCP may lead to neurobiological severe neurobiological complications such as seizures, coma, and death. Cases of fatal status epilepticus have occasionally been reported (National Institute on Drug Abuse 2001). Because PCP can interact with other CNS depressants such as alcohol and benzodiazepines and enhance sedation, in some instances, acute intoxication with PCP may lead to coma or even death. It is important to note, however, that PCP-induced death is most likely to result from indirect consequences stemming from accidental injury or suicide than it is from a drug-induced physiological consequence.

Neurobiological complications arising from ketamine abuse are similar to those of PCP. Psychologically, acute intoxication with ketamine produces sensations of

detachment from an individual's perceived reality and one's self. There may be wild paranoid delusions, confusion, difficulty concentrating, agitation, alterations in mood, sleep disruptions/nightmares, catatonia, ataxia, and/or deficits in working memory.

104.2.3.3 Complications of Dependence

Repeated abuse of LSD may produce tolerance over time. Toward this, an individual must ingest progressively higher doses of LSD to reach a similar level of acute intoxication that she/he experienced previously. Although LSD does not typically induce addictive-like, compulsive drug-seeking behaviors, chronic abuse of PCP can.

104.2.3.4 Withdrawal

There is no evidence that LSD produces physical withdrawal symptoms when chronic use/abuse of the drug is stopped. However, former LSD users have reported "flashbacks," which have periodically been mistakenly diagnosed as brain tumors or other neurological disorders (National Institute on Drug Abuse 2001). Unlike LSD, the abrupt discontinuation of chronic PCP ingestion can be associated with withdrawal. Symptoms such as memory loss and depression may persist for up to a year after a chronic user stops taking this hallucinogen.

104.2.4 Inhalants

National surveys indicate that nearly 21.7 million Americans aged 12 years and older have used inhalants at least once in their lives. There are four general categories of inhalants: volatile organic solvents, aerosols, gases, and nitrites. Inhalants can be directly insufflated; fumes can be sprayed or deposited inside a plastic/paper sack and "bagged"; gases can be inhaled from balloons; or solvents can be "huffed" directly from an inhalant-soaked rag. Abuse of volatile organic solvents, such as gasoline, butane, glues, paint thinners (e.g., toluene), dry-cleaning fluids, or felt-tip markers, appears to be most prevalent. Volatile organic solvents are highly lipophilic and, therefore, can be neurotoxic.

104.2.4.1 Neurobiological Mechanisms of Action

Mechanisms of action for inhalants appear to be similar to those produced by CNS depressants such as alcohol or barbiturates – except on a shorter time frame. The onset of symptoms for inhalants occurs within seconds. Effects are also short lived and commonly disappear in 30 min or less. Some inhalants such as toluene have been shown to decrease neuronal excitability by acting as an NMDA receptor antagonist and a $GABA_A$-receptor positive allosteric modulator.

104.2.4.2 Acute Intoxication

Acute intoxication with organic solvents such as toluene can produce a variety of feelings including euphoria, exhilaration, or giddiness. Hallucinations, confusion,

nystagmus, drowsiness, ataxia, and temporary memory loss may also occur. This may be followed by nausea and vomiting.

Because intoxication lasts only a few minutes, abusers frequently seek to prolong the high by inhaling repeatedly over the course of several hours (Goforth et al. 2010). This is when the neurobiological complications from inhalant abuse become increasingly apparent. In the short term, many abusers may feel less inhibited and/or out of control. They may experience drowsiness and a lasting headache. Nystagmus, double vision, difficulty enunciating words, ataxia, and progressive cognitive dysfunction can become increasingly evident over time. In some instances, a protracted confusional state may last for several days (Enevoldson 2004).

Upon repeated exposure, inhalant-induced neurobiological complications become increasingly apparent and CNS recovery post abuse may be incomplete. For example, as a result of chronic toluene abuse, there may be cognitive changes, ocular motor abnormalities, and pyramidal features that are unlikely to resolve when drug use has been discontinued. As a result of damage to the myelin sheath, there may also be a loss of coordination and limb spasms. Deterioration may continue for 1–4 months post cessation (Enevoldson 2004). Solvent-induced encephalopathy may also result in cognitive dysfunction, psychiatric symptoms, and cortical and cerebellar brain atrophy (Neiman et al. 2000). Demyelination and gliosis in the cerebral and cerebellar white matter have been observed up to 7 years after chronic abuse and appear to be irreversible (Tamrazi and Almast 2012).

Successive inhalations may lead to death. Acting indirectly, inhalants may lead to death if the substance is inhaled from a bag or abused within a sealed-in area and respiratory depression reaches a point whereby the individual then loses consciousness and suffocates (Neiman et al. 2000). Acting directly, inhalants may lead to death if high concentrations of the substance are sniffed (e.g., using aerosol sprays). This syndrome, known as "sudden sniffing death," can directly lead to heart failure within minutes and result from a single session of inhalant use by an otherwise healthy young person.

It is also important to note that, in addition to the substance of abuse, other chemical ingredients found within the various types of inhalants may produce a variety of other neurobiological complications. Chemical toxicants may result in short-term nausea or vomiting as well as other, more serious long-term neurobiological consequences such as liver and kidney toxicity/damage, hearing loss, and/or bone marrow damage.

104.2.4.3 Complications of Dependence

Addictive-like behavior is not unlikely to develop upon repeated use/abuse of inhalants.

104.2.4.4 Withdrawal

Although rare, compulsive use and a mild withdrawal syndrome can occur with long-term inhalant abuse.

104.2.5 Opioids

Approximately 100 million individuals in the United States have chronic pain. Opioid narcotics are a first line treatment for pain. Prescription opioids include narcotics such as oxycodone (OxyContin), methadone, hydrocodone, and fentanyl. As sales of prescription opioids like these have increased, so too have the complications arising from their improper use and abuse. In 2010, 4.8 % of the US population aged 12 years or older had reported using an opioid pain reliever nonmedically (Paulozzi et al 2011).

Heroin (diacetylmorphine) and morphine differ from the opioids described above. Unlike the synthetic opioids above, heroin and morphine are alkaloid compounds derived from naturally occurring opium. Heroin is mainly used intravenously and, as such, has a greater potential for dependence. When compared to the synthetic opioids such as oxycodone or hydromorphone, former addicts showed a strong preference for heroin and morphine; this finding suggested that heroin and morphine are particularly susceptible to abuse and addiction. Indeed, approximately 23 % of individuals who use heroin once go on to become dependent on it. In 2011, 4.2 million Americans aged 12 years or older (or 1.6 %) had used heroin at least once in their lives.

104.2.5.1 Neurobiological Mechanisms

Opioids act by attaching to three main classes of opiate receptors including mu, delta, and kappa receptors. Heroin can act on all three receptor types. These receptors are found both pre- and postsynaptically on neurons. In general, mu receptors are thought to underlie analgesia by presynaptically enhancing the release of GABA via acute disinhibition. Opioid receptors are located in areas of the CNS such as the nucleus accumbens, amygdala, and cerebral cortex; the spinal cord; as well as the gastrointestinal tract.

104.2.5.2 Acute Intoxication

Euphoric effects of opioids are thought to arise chiefly via activation mu receptors, whereas analgesic effects are thought to arise via activation of the kappa and delta opioid receptors.

Opioids such as oxycodone can induce analgesia, sedation, pruritus, nausea, euphoria, decreased respiration, miosis, and constipation. Some of these effects, such as analgesia, sedation, euphoria, and decreased respiration, tend to diminish as tolerance develops.

At higher doses, opioids can manifest as drowsiness, depress consciousness, an acute change in mental acuity, and/or delirium. Other symptoms include seizures and muscle spasms. Heart rate and breathing can slow or stop resulting in hypoxia or coma. A person experiencing an opioid overdose usually will be nonresponsive. Death may occur. Additional CNS depressants such as alcohol and benzodiazepines are frequently detected in the majority of opioid overdose deaths (National Institute on Drug Abuse 2005; Buttner 2011). One of the only treatments available for opioid overdose is naloxone, an opioid receptor antagonist which can be either injected or intranasally administered in emergency situations.

Heroin does not elevate blood pressure as stimulants do. Accordingly, cerebral infarcts or hemorrhagic stroke is not as likely to result directly from drug-induced effects. However, heroin frequently contains toxic contaminants and is not injected as a pure substance. These impurities can result in an embolus that occludes blood vessels serving the lungs, liver, kidneys, and/or brain, which can result in irreversible necrosis. Indeed, postanoxic encephalopathy is one of the more frequent neurobiological complications of heroin abuse.

Intravenous drug use using nonsterile syringes/equipment increases dramatically the risk of pathogenic infection. Co-occurring infections such human immunodeficiency virus (HIV) and/or hepatitis C (HCV) can produce a set of complex neurobiological complications in and of themselves that can be exacerbated by substance abuse (see Sect. "104.2.8" below).

104.2.5.3 Complications of Dependence

Frequent and regular administration of opioids is associated with tolerance and physical dependence. In terms of heroin, toxic progressive spongiform leukoencephalopathy is evidenced by symmetric white matter degeneration, especially when heroin is smoked (i.e., "chasing the dragon"). Within this white matter, there is a noted activation of microglia (Buttner 2011). In the spinal cord, similar neurobiological complications involving the white matter have been noted. For example, heroin abuse may also produce acute transverse myelitis involving thoracic segments of the spinal cord.

Heroin abuse may sometimes result in permanent peripheral nerve damage. Deep intradermal injections of heroin have produced neuropathies and rhabdomyolysis. Direct trauma surrounding the injection site ("skin popping") is a manifestation of localized edema, which may compress a nerve and have an immediate adverse effect on action potential propagation. If the compression becomes increasingly severe over time, focal demyelination can occur which can be followed by axonal damage and permanent scarring. Compressive neuropathies can occur most commonly in the lateral popliteal and ulnar nerves but also the sciatic nerves. Neuropathies can produce numbness, tremor, or possibly an abnormal gait. Myopathies have similarly thought to arise from drug (or impurity)-induced toxicity and ischemia.

Finally, an increase in the number and distribution of hyperphosphorylated tau-positive neurofibrillary pretangles has been noted in populations of young, chronic heroin abusers. In conjunction with reports of occasional ubiquitin-positive inclusions in neurones of drug abusers, indicate that chronic opioid abuse also leads to drug-related neurodegeneration (Buttner 2011) and brain atrophy (Tamrazi and Almast 2012).

104.2.5.4 Withdrawal

Withdrawal symptoms can include restlessness, muscle and bone pain, insomnia, diarrhea, vomiting, cold flashes with goose bumps ("cold turkey"), and involuntary leg movements. Certain drugs, including heroin, cause strong physical reactions in the body when drug use stops. When a person addicted to heroin stops taking heroin, he or she can experience a variety of symptoms ranging from miosis to

agitation, anxiety, diaphoresis, abdominal cramps, nausea and vomiting, loss of appetite, diarrhea, shivering, sweating, a heightened sensitivity to pain, and/or insomnia.

Typically, opioids should not be used with other substances that depress the CNS. This would include sedatives such as alcohol or benzodiazepines, because these combinations of substances would increase greatly the risk of life-threatening respiratory depression.

104.2.6 Stimulants

Common stimulants include cocaine, amphetamine, methamphetamine, methylenedioxy-methylamphetamine (MDMA), and, increasingly, synthetic cathinones (or "bath salts"). In 2012, there were 1.2 million persons aged 12 or older who were current, nonmedical users of stimulants in 2012 (0.5 %; NSDUH 2013).

104.2.6.1 Cocaine

Cocaine is a water-soluble white salt derived from the leaves of the coca plant. In this form, it can be snorted or injected. Cocaine can also be chemically modified into a free alkaloid and smoked as "crack" cocaine. Cocaine comes in two main forms, a hydrochloride salt or base form. The hydrochloride salt (or powdered) form of cocaine can be either insufflated or dissolved in water and injected. The base form of cocaine is typically formed by adding a solution of baking soda and water into what is referred to "crack" cocaine. In its base form, because of its lower melting point (85–95 °C), crack cocaine is generally smoked. In 2012, there were 1.6 million current cocaine users aged 12 or older, comprising 0.6 % of the population (NSDUH 2013).

104.2.6.2 Amphetamines

Amphetamines are available as capsules, tablets, or fluids. They can be swallowed, crushed and "snorted," injected intravenously, or smoked.

104.2.6.3 Bath Salts

Synthetic cathinones, or "bath salts," are synthetic substances of abuse that chemically resemble cathinone. Cathinone is an amphetamine-like stimulant found naturally in the Khat plant (National Institute of Drug Abuse 2012b). Bath salts can be snorted, ingested orally, or, more rarely, injected (1–3 %) (EMCDDA 2011). Mephedrone and methylone are two of the most common bath salts. Self-reported user surveys in the United Kingdom suggest that approximately 41 % had used mephedrone and 10 % had used methylone in 2012 (Prosser and Nelson 2012). To date, no other known epidemiological prevalence data have been published.

104.2.6.4 MDMA

Also known as ecstasy or molly, MDMA/ecstasy can be ingested orally as a capsule or tablet. Molly (i.e., slang for "molecular") refers to the pure crystalline

encapsulated powder form of the drug. MDMA is commonly taken in combination with other substances of abuse including cocaine, gamma-hydroxybutyric acid, methamphetamine, or ketamine (National Institute on Drug Abuse 2006). NSDUH and MTF data showed generally consistent trends for past-month use of MDMA, with decreases in use from 2002 to the middle of the decade, then increases in use from 2007 to 2010, and declines between 2010 and 2012 (NSDUH 2013).

104.2.6.5 Nicotine

According to the 2010 National Survey on Drug Use and Health, an estimated 69.6 million Americans aged 12 or older reported current use of tobacco – 58.3 million (23.0% of the population) were current cigarette smokers, 13.2 million (5.2%) smoked cigars, 8.9 million (3.5%) used smokeless tobacco, and two million (0.8%) smoked pipes, confirming that tobacco is one of the most widely abused substances in the United States. There are more than 4,000 chemicals found in the smoke of tobacco products. Of these, nicotine, first identified in the early 1800s, is the primary reinforcing component of tobacco.

Neurobiological Mechanisms of Action

Cocaine

Cocaine binds tightly to the dopamine transporter to block its function. Dopamine subsequently accumulates within the synaptic cleft resulting in prolonged and enhanced dopaminergic signaling. Cocaine also reversibly blocks sodium channels. By doing this, it interferes with the propagation of action potentials and acts as a local anesthetic. It also acts as a vasoconstrictor via its inhibition of norepinephrine reuptake in the autonomic nervous system.

Amphetamines

Amphetamines not only inhibit monoamine transporters as does cocaine, but they also stimulate the release of norepinephrine via the inhibition of vesicular monoamine transport, which is responsible for monoamine reuptake into the vesicles for storage from the cytosol. Acting through a variety of mechanisms, amphetamines can also cause release of dopamine from the mesocorticolimbic system and the nigrostriatal dopamine neurons, inhibit metabolic enzymes such as CYP2A6 and MAO, as well as act as a direct agonist on 5-HT receptors.

Bath Salts

Presently, little is known about the pharmacokinetics and pharmacodynamics of bath salts, largely because these substances are frequently abused as a combination of substances and the true contents of these various substances remain obscure. Because of their structural similarity to amphetamines, these compounds are presumed to inhibit monoamine reuptake inhibitors presynaptically and promote the release of norepinephrine, as do amphetamines, and increase the concentration of dopamine, serotonin, and norepinephrine in synapses.

MDMA

MDMA induces the monoamine neurotransmitters to be released from their storage sites in neurons via an inhibition of the vesicular monoamine transporter, which results in increased concentrations of serotonin, norepinephrine, and dopamine in the cytoplasm, resulting in increased neurotransmitter activity. Compared to methamphetamine, however, MDMA causes a surge of serotonin release which is associated with its neurobiological actions/complications (National Institute on Drug Abuse 2013).

Nicotine

The mechanism of action for nicotine dependence includes the activation of ionotropic nicotinic-acetylcholine receptors. Like cocaine, heroin, and marijuana, nicotine increases levels of the neurotransmitter dopamine, which affects the brain pathways that control reward and pleasure by binding nicotinic receptors in the brain. For many tobacco users, long-term brain changes induced by repeated exposure to nicotine can result in addiction, a condition of compulsive drug seeking and use despite known negative consequences associated with its use (e.g., lung cancer). Studies suggest that additional compounds in tobacco smoke, such as acetaldehyde, or perhaps substances of abuse that may be co-ingested (e.g., alcohol) may enhance nicotine's effects on the brain. Upon entering the bloodstream, nicotine immediately stimulates the adrenal glands to release epinephrine (adrenaline) causing a sympathomimetic "fight or flight" response. Epinephrine stimulates the CNS to ultimately increase blood pressure, respiration, and heart rate.

Acute Intoxication

Cocaine

The intense euphoria from snorting cocaine typically lasts 5–10 min. Even though cocaine intoxication generally lasts less than 30 min, it is important to note that its major metabolites (e.g., benzoylecgonine) are broken down and eliminated from the body over a period of several days. Thus, in conjunction with other complicating events, these active metabolites post use may continue to build up and contribute to the manifestation of adverse neurobiological complications several days post use.

Several neurobiological complications may occur as a result of cocaine intoxication. Miosis, hyperthermia, increased heart rate, arrhythmia, hypertension, and vasoconstriction may all occur post use. Seizures may be induced as a result of any combination of cocaine-induced hyperexcitability, cardiovascular dysfunction (arrhythmia), intracranial hemorrhage (hypertension), and/or cerebral ischemia (vasoconstriction). Sudden death may also occur following initial misuse or after repeated abuse. Cocaine-related deaths are often a result of cardiac arrest or seizures followed by respiratory arrest.

Following high doses of cocaine, neurobiological complications may become more severe including bizarre, erratic, and violent behavior. Some cocaine users report feelings of restlessness, irritability, anxiety, panic, paranoia, and 3hallucinations.

Users may also experience involuntary dyskinesias or vertigo, gastrointestinal complications, abdominal pain, and/or nausea (National Institute of Drug Abuse 2010).

Cocaine is the most frequent drug of abuse associated with fatal and nonfatal cerebrovascular events. About 70 % of strokes arising with cocaine-abuse result are hemorrhagic rather than ischemic (Enevoldson 2004). Cocaine-induced hemorrhagic (or ischemic) neurovascular strokes can occur in any brain region. Arteriovenous malformations or aneurysms frequently underlie cocaine-induced hemorrhagic stroke (Buttner 2011). Hemorrhages may be intracerebral, intraventricular, or subarachnoid and generally occur within 1 h post use (Enevoldson 2004).

Cerebral infarction is less common than hemorrhagic stroke but is more commonly associated with smoking crack (Enevoldson 2004). Often these complications present over a more long-term time course such as a headache, encephalopathy, and bilateral clinical/radiological abnormalities.

As with heroin users (see also above), cocaine abusers are at increased risk for contracting such infectious diseases as HIV and/or HCV, not only from stemming shared contaminated needles/drug paraphernalia but also from engaging in risky sexual behaviors as a result of intoxication.

Amphetamines

At higher doses, amphetamines may result in hyperthermia, tachycardia, and/or arrhythmia. An acute agitated state of delirium, paranoia, and hallucinations may also be present. Neurobiological complications may include insomnia, hyperexcitability, aggressive behavior, and/or convulsions. Amphetamine-induced seizures have the potential to subsequently induce cardiovascular failure and death.

When taken nonmedically, amphetamine abuse can produce euphoria, decreased fatigue, heightened arousal, increased libido/fornication, involuntary dyskinesias, irritability, and/or aggressiveness. Appetite may diminish. Mydriasis, hypertension, vasoconstriction, and increased blood glucose may also occur.

Bath Salts

Individuals who abuse bath salts such as mephedrone commonly abuse at least one other substance as well. Recent survey data show that 89 % of mephedrone users reported drinking alcohol, 17 % used cocaine, 23 % used MDMA, 34 % used cannabis, and 24 % used ketamine (EMCDDA 2011). Polysubstance abuse like this is likely to exacerbate and/or increase the likelihood of neurobiological complications associated with bath salt intoxication.

Neurobiological complications commonly associated with mephedrone (poly) intoxication include agitation/aggression, fatigue, impaired attention/poor concentration, increased empathy, talkativeness, and/or an increased urge to move (EMCDDA 2011).

Physiologically, bruxism/teeth grinding (jaw soreness and headache), dizziness, lightheadedness, tremor, and seizures have all been associated with mephedrone intoxication (Prosser and Nelson 2012). Appetitive drive may be significantly

reduced or eliminated. Sweating, headaches, tachycardia, palpitations, nausea, chest pain, and/or increased sexual arousal may also occur (EMCDDA 2011). Adverse events are likely to last 1–2 h post use (Prosser and Nelson 2012).

In terms of medical management, patients with extreme agitation, psychosis, significant tachycardia, hypertension, or seizures following bath salt intoxication should be treated with benzodiazepines to mitigate hyperexcitability and help control convulsive activity (Prosser and Nelson 2012).

MDMA

Acute intoxication with MDMA may lead to a state of confusion, depression, sleep problems, and/or anxiety. The drug's effects last approximately 3–6 h. These neurobiological complications may occur within a few hours post use or present more gradually over a period of days. Heavy users of MDMA may experience long-lasting confusion, depression, sleep abnormalities, and/or problems with attention and memory, although it is possible that some of these effects may be due to the use of other drugs in combination with MDMA (especially marijuana) (National Institute on Drug Abuse 2013).

Physiologically, MDMA produces many of the same effects as other stimulants. These include, for example, increases in heart rate, hypertension, muscle tension, bruxism, nausea, blurred vision, faintness, and/or sweating (National Institute on Drug Abuse 2013).

Hyponatremia is also a commonly reported complication of MDMA use. This is thought to result from several factors including over hydration in the setting of drug-induced secretion of vasopressin (Prosser and Nelson 2012).

MDMA induces a large surge in the release of serotonin. In turn, serotonin triggers the release of the hormones oxytocin and vasopressin, which play important roles in love, trust, sexual arousal, and other social experiences and are likely associated with the characteristic feelings of heightened emotional closeness and increased empathy associated with MDMA abuse. These closeness-promoting effects of MDMA and its use in sexually charged contexts (and especially in combination with sildenafil) may encourage unsafe sex, which is a risk factor for contracting or spreading sexually transmitted infections such as HIV and/or HCV (National Institute on Drug Abuse 2013) (see also Sect. "104.2.8" section below).

Nicotine

Acute intoxication from cigarette smoking or nicotine exposure is rare. Exposure to high doses of nicotine over a short period of time, such as those found in some insecticide sprays, can be extremely toxic, causing vomiting, tremors, convulsions, and death. Nicotine poisoning has been reported from accidental ingestion of insecticides by adults and ingestion of tobacco products by children and pets. Death usually results in a few minutes from respiratory failure caused by paralysis.

Cigarette smoking produces a rapid distribution of nicotine to the brain, with drug levels peaking within 10 s of inhalation. However, the acute effects of nicotine dissipate quickly, as do the associated feelings of reward, which causes the smoker

to continue/increase dosing repeatedly over time to maintain the drug's pleasurable effects, overcome tolerance, and prevent withdrawal.

Complications of Dependence

Cocaine

Because cocaine is highly lipophilic and readily crosses the blood-brain barrier (BBB), it can induce its effects rapidly and has the high potential for dependence. Tolerance can develop. At the same time, abusers can also become more sensitive to cocaine's stimulant effects. The decreased dopaminergic signaling after sustained cocaine abuse may contribute to depressive mood disorders, sensitize the mesodopaminergic circuit toward cocaine's reinforcing effects, and contribute to dependency.

Through an induction of pro-inflammatory cytokines and enhanced leukocyte migration across the brain endothelium, cocaine opens the BBB for HIV invasion and the neurobiological consequences that follow. The presence of acute and chronic BBB breakdown in drug abusers suggests that the brain parenchyma is exposed to unusual quantities of serum proteins, including immunoglobulins, and HIV (Buttner 2011).

As with opioid abuse, imaging data show that chronic cocaine abuse can result in ischemic leukoencephalopathy (Tamrazi and Almast 2012).

Amphetamines

Tolerance can develop rapidly following repeated amphetamine abuse. This can lead to hostility, paranoia, or even psychosis. Amphetamines may also directly induce neurotoxicity. Some studies indicate that neuronal cell loss may be a consequence of excitotoxicity, mitochondrial dysfunction, and/or the subsequent generation of free radicals and nitric oxide (Buttner 2011). Indirect neurotoxicity may result as a consequence of drug-induced damage to astrocytes, axons, and/or the cerebral vasculature. Repeated stimulant abuse appears to decrease basal release of glutamate to stimulate further drug seeking (Goforth et al. 2010) and thereby increase the likelihood for additional stimulant-induced neurobiological complications.

After cocaine, amphetamines are the second leading cause of strokes in persons younger than 45 years (Buttner 2011). In a chronic user, amphetamine-induced strokes usually occur in the first few hours after ingestion. This usually manifests with a headache and progresses into a focal deficit and impaired level of consciousness.

Especially when used chronically and intravenously, amphetamine and methamphetamine are the drugs most commonly associated vasculitis histologically. This, along with a sudden elevation in blood pressure, may result in subarachnoid or intracerebral hemorrhage. Especially in smaller caliber vessels, ischemic infarction may also occur. This could result from the vasoconstrictive effects associated with stimulant use and/or may be an acute hypersensitivity reaction, perhaps, in the case of injectors, due to contaminants of the injection solution (Enevoldson 2004). These complications may result in decreased brain volume. Imaging studies show that there is cerebral atrophy with neuronal damage and glial proliferation following chronic amphetamine abuse (Tamrazi and Almast 2012).

Long-term methamphetamine abuse has many negative health consequences, including extreme weight loss, severe dental problems ("meth mouth"), anxiety, confusion, insomnia, mood disturbances, and violent behavior. Chronic methamphetamine abusers can also display a number of psychotic features, including paranoia, visual and auditory hallucinations, and delusions. Transmission of HIV and hepatitis B or C can also be a consequence of methamphetamine abuse. The intoxicating effects of methamphetamine can also alter judgment and inhibition and lead people to engage in impulsive, unsafe behaviors, including risky sexual behavior.

Bath Salts

A recent survey of 1,506 mephedrone users found that ~50 % consider mephedrone to be addictive (Carhart-Harris et al. 2011). Similar to other stimulants such as cocaine and MDMA, data suggest that mephedrone dependence is associated with psychological, rather than physical, dependency. There is the long-term potential for neurobiological complications as a direct result of acute mephedrone toxicity including status epilepticus-induced cerebral hypoxia (Prosser and Nelson 2012). Despite this, there are no investigations that directly assess chronic neurobiological complications of mephedrone abuse to date.

Preclinical data indicate that repeated administration of mephedrone did not lower striatal dopamine levels or modify the expression of the dopamine transporter. In addition, it was also reported that mephedrone did not cause microglial activation nor did it increase glial fibrillary acidic protein levels in the striatum (Angoa-Pérez et al. 2012).

MDMA

A propensity for MDMA dependence is not clear cut. Some users report symptoms of dependence, including continued use despite knowledge of physical or psychological harm, tolerance (or diminished response), and withdrawal effects. Upon repeated administration, there is evidence that MDMA reduces the concentration of serotonin reuptake transporters in the brain. There are some preclinical and clinical data to indicate that MDMA is associated with dopaminergic and especially serotonergic neurotoxicity, neurodegeneration, and axonal loss, perhaps as a result of increased oxidative stress, excitotoxicity, apoptosis, and/or mitochondrial dysfunction (Buttner 2011).

Nicotine

Cigarette smoking kills an estimated 440,000 US citizens each year – more than alcohol, illegal drug use, homicide, suicide, car accidents, and HIV/AIDS combined. Nicotine dependence linked with cigarette smoking is associated with the inhalation of myriad toxicants (either via primary or secondary smoke) and harms virtually every organ in the body in addition to the CNS. It has been conclusively linked to pneumonia and cataracts and accounts for about one-third of all cancer deaths. In addition to cancer, nicotine dependence linked with smoking also results in lung diseases such as chronic bronchitis and emphysema, and it has been found to

exacerbate asthma symptoms in adults and children. Smoking substantially increases the risk of coronary heart disease, heart attack, vascular disease, cerebrovascular infarction, and brain aneurysm.

Withdrawal

Cocaine

Similar to amphetamines, withdrawal symptoms associated with discontinuation of cocaine use may include lethargy, dysphoria, increased appetite, vivid dreams, disturbed sleep patterns, and/or anxiety.

Amphetamines

Withdrawal from amphetamines does not generally lead to strong physical reactions. Perhaps because associated reactions are not pronounced, symptoms can vary widely across individuals and may include lethargy, dysphoria, increased appetite, vivid dreams, hypersomnia or insomnia, increased or decreased movement, and/or anxiety.

Bath Salts

Reports suggest that there is no reported physical withdrawal syndrome, although psychological dependency is possible.

MDMA

Approximately 60 % of individuals who repeatedly abuse MDMA report withdrawal symptoms. These symptoms include fatigue, depression, diminished appetite, and trouble maintaining concentration (National Institute on Drug Abuse 2006).

Nicotine

Nicotine withdrawal (associated with cigarette smoking) symptoms include irritability, craving, depression, anxiety, cognitive and attention deficits, sleep disturbances, weight gain, and increased appetite. These symptoms onset rapidly within a few hours after the last cigarette, quickly driving people back to tobacco use. Withdrawal symptoms peak within the first few days of smoking cessation but do usually subside within a few weeks post use. For some people, however, symptoms may persist for months.

Although withdrawal is related to the pharmacological effects of nicotine, many cue-induced behavioral factors can also affect the severity of withdrawal symptoms. For some nicotine-dependent people, the feel, smell, and sight of a cigarette and the ritual of obtaining, handling, lighting, and smoking the cigarette are all thought to contribute to the pleasurable effects of smoking and can make withdrawal and/or craving worse. In terms of treatment, nicotine replacement therapies (NRT) such as gum, patches, and inhalers may help alleviate the pharmacological aspects of withdrawal; however, for the aforementioned reasons, cravings often persist making quitting more difficult. Thus, in combination with existing pharmacotherapeutics (e.g., varenicline, NRT, bupropion), behavioral therapies can act to help smokers mitigate environmental triggers of craving and possible relapse.

104.2.7 Sedatives

Sedatives are CNS depressants. Examples include alcohol (ethanol), benzodiazepines such as diazepam (Valium), non-benzodiazepine medications such as zolpidem (Ambien), and barbiturates, such as pentobarbital sodium (Nembutal). Alcohol-use disorders are medical conditions that doctors can diagnose when a patient's drinking causes distress or harm. In the United States, about 18 million people have an alcohol-use disorder, classified as either alcohol dependence – perhaps better known as alcoholism – or alcohol abuse.

104.2.7.1 Neurobiological Mechanisms of Action

Ethanol has multiple diverse actions in the brain. It is known to be positive allosteric modulator of $GABA_A$ receptors, a $5\text{-}HT_3$ receptor agonist, an NMDA receptor antagonist, an AMPA receptor antagonist, a glycine receptor agonist, and an inhibitor of potassium, sodium, and calcium ion channels.

Benzodiazepines bind to the gamma subunit of the postsynaptic $GABA_A$ receptor complex as full agonists to increase the frequency of inhibitory channel opening and to decrease neuronal function. Barbiturates similarly act on the $GABA_A$ receptor but bind to the beta subunit and enhance neuronal inhibition by increasing the mean open time of these ion channels. Barbiturates also inhibit glutamate (AMPA) receptors.

104.2.7.2 Acute Intoxication

Following acute intoxication, sedatives can produce a wide range of effects depending upon dosage consumed. These include induced euphoria, lethargy, ataxia, nystagmus, anxiolysis, confusion, stupor, depressed consciousness, respiratory depression, coma, or even death. Alcohol intoxication can impair significantly cognitive function and motor skills. In addition to hepatic encephalopathy, heavy alcohol ingestion can also affect heart rhythm, can slow respiration, and may even lead to death.

104.2.7.3 Complications of Dependence

Alcohol. Chronic alcohol abuse (i.e., >7 drinks per week for women; >14 drinks per week for men) may produce both structural and functional CNS abnormalities. The pathophysiology of alcohol abuse includes both direct effects on the brain as well as secondary complications arising from liver cirrhosis. In conjunction with nutritional thiamine (vitamin B1) deficiency, chronic alcohol abuse can result in a Wernicke's encephalopathy including ophthalmoplegia, gait disturbances, and a state of confusion; if left untreated, this can lead to Korsakoff psychosis and perhaps eventually death (Tamrazi and Almast 2012). Heavy or chronic use of alcohol may also result in cardiomyopathy, arrhythmias, stroke, high blood pressure, alcoholic hepatitis, fatty liver, fibrosis and cirrhosis, pancreatitis, and increase risk of developing certain cancers, such as cancer of the esophagus, liver, throat, and breast. Chronic consumption of alcohol also suppresses immune system, and chronic drinkers are more liable to infections.

In addition to the well-known tolerance that can develop following alcohol consumption, tolerance can also develop following repeated use or abuse of benzodiazepines and/or barbiturates. Taken orally, these preparations may lead to coma and similar complications to those described from heroin comas, including cardiorespiratory depression (especially after barbiturates), aspiration, anoxic encephalopathy, and peripheral nerve compression syndromes (Enevoldson 2004).

104.2.7.4 Withdrawal

Withdrawal from prolonged barbiturate or alcohol dependence can have life-threatening neurobiological complications. Withdrawal can produce excitotoxicity, irritability, increased tension, diaphoresis, anxiety, panic attack, restlessness, insomnia, tachycardia, delirium tremens, hallucinations, seizures, status epilepticus, or death. Seizures experienced during alcohol abstinence are thought to result from the homeostatic upregulation of NMDA glutamate receptors in the brain. Apoptosis may also occur due to excitotoxicity.

104.2.8 Co-occurring Infections

Injection drug use remains a major risk factor in the acquisition and transmission of viral infections such as HIV and HCV. For example, the hepatitis C virus may remain in the needles, syringes, and/or other drug-injection utensils such as filters, spoons, or even within rinsing liquids. Up to 90 % of HIV-infected injection drug users may also be infected with hepatitis C virus.

Co-occurring infections can each produce their own unique set of neurobiological consequences and may further exacerbate complications produced by substance abuse. HIV may induce mild/moderate motor abnormalities, severe HIV-associated dementia, or neuro-acquired immunodeficiency syndrome (AIDS). HCV infection may cause mild neurocognitive dysfunction or more severe consequences such as hepatic encephalopathy. Because drugs like cocaine and methamphetamine upregulate the chemokine receptors such as CCR5 and downregulate various chemokines that are involved in the viral entry into the immune cells such as microglia, drug abuse is reported to further intensify the neurobiological consequences of viruses like HIV and HCV. Although these complications can also be seen in patients injecting other substances of abuse such as amphetamines or cocaine, they are much more common in heroin abusers who form the vast majority of injection drug users.

Methamphetamine abuse may also worsen the progression of HIV/AIDS and its consequences. Studies of methamphetamine abusers who are HIV positive indicate that HIV causes greater neuronal injury and cognitive impairment for individuals in this group compared with HIV-positive people who do not use the drug.

Long-term infection with both viruses is associated with much more severe neurocognitive consequences. However, clinical management of HIV-associated neurological complications with HIV therapy can improve the

overall cognitive as well as motor performance mono- or dually infected patients, especially when combined with methadone or buprenorphine treatment for substance abuse.

For additional information on co-occurring infections in substance-abusing populations, the reader is directed to a chapter entitled, Chap. 106, "Substance Use and Co-occurring Infections: An Overview," by Khalsa et al. within this book.

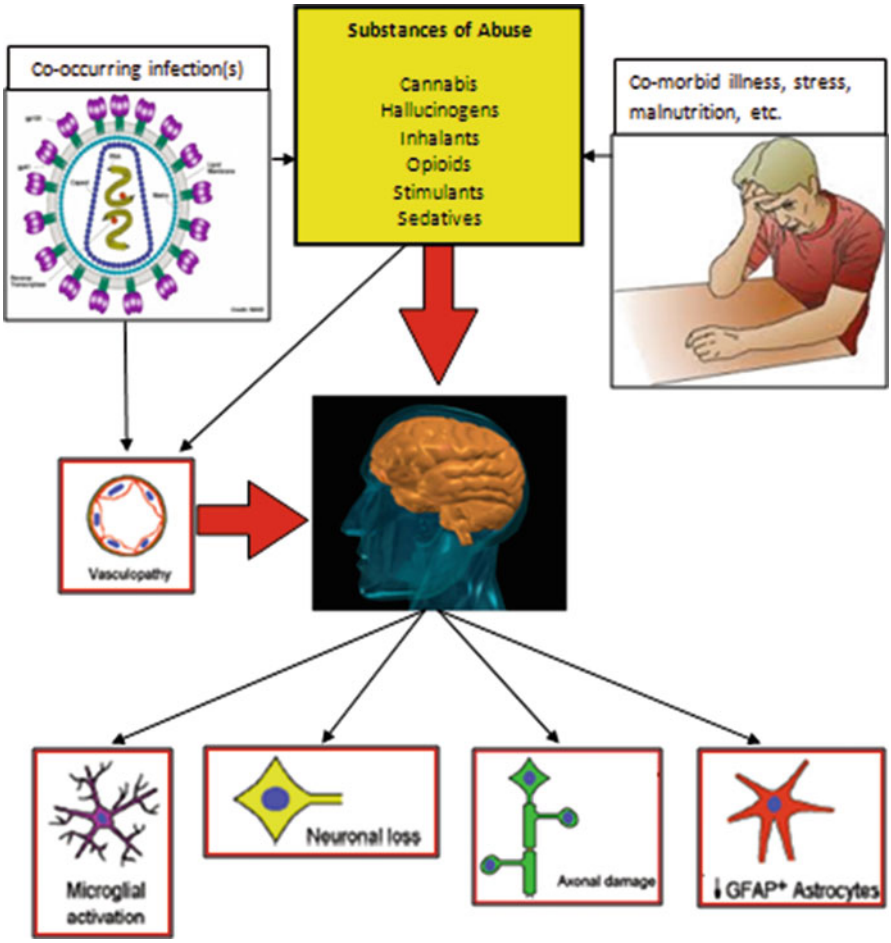

Fig. 104.1 Substance abuse and associated environmental stressors can produce severe negative neurobiological consequences. Whether via a direct or indirect adverse complication arising acutely or subacutely, neuropathological elements such as microglial activation, neuronal cell loss, axonal damage, and/or reduced astrocytes have been noted (see text for details; figure adapted from Buttner 2011)

104.3 Conclusion

Drug abuse is a substantial problem in society today. Substance abuse can result in a complex cascade of toxic, ischemic, and/or hemorrhagic events that directly and indirectly lead to diverse physiological and psychological neurobiological complications (Fig. 104.1). For example, systematic neuropathological studies of polydrug abusers revealed ischemia-independent widespread neuronal loss, a reduction of GFAP-positive astrocytes, an axonal damage with concomitant microglia activation, as well as reactive vasculitis (Buttner 2011). These changes can also influence significantly behavior. Drug abuse can also increase the chances for acquiring/transmitting co-occurring infections that further exacerbate complications arising from abuse.

In the future, imaging modalities such as MRI and computed tomography may aid in the diagnosis and optimal clinical management of drug-related neurobiological complications surrounding SUDs.

Abstract

Memory is a very complex function and it can be affected adversely by almost all substances that are liable to abuse. The totality of memory problems and other cognitive changes will influence profoundly a patient's ability to live and function independently. The effect of substances may be cumulative and can be caused by direct acute or chronic pharmacological action and withdrawal, through secondary mechanisms such as vascular or hepatic damage, and will be also be influenced by the patient's physical, psychiatric, and psychological state. In this chapter the known effects of commonly abused substances are summarized with reference to clinical features and recent brain imaging studies. Memory problems may have a major influence on the ability of patients to interact with treatment, and therefore evidence of memory and other cognitive impairments should be sought for always.

105.1 Introduction

Memory is an essential component of all but the most basic physiological human functions. Any disturbance, be it temporary or permanent, will affect everyday life in one way or another. Memory is also one of the most complex of neurological processes and can be influenced by both mental and physical health disorders, psychological state, and a range of environmental factors including substances. People may complain of a poor memory without there being any objective evidence by formal testing, while others, for example, those with dementia, may deny the existence of memory disorder when it is patently obvious that it is present. Those with memory problems may also demonstrate behavioral and functional dysfunction as well as having psychotic symptoms. Pharmaceutical products, both prescribed by physicians and obtained from other sources and substances used both legally and illegally, can all have potent effects on memory. Their influence can be direct (e.g., benzodiazepines), mediated through associated mechanisms (e.g., thiamine deficiency in alcohol dependence), or through comorbidity (e.g., encephalopathies associated with AIDS or liver disease) or vascular pathologies. As can be seen from Table 105.1, a single substance, e.g., alcohol,

Table 105.1 Factors associated with memory impairment and substance use

Direct intoxication, e.g., benzodiazepines
Chronic use
Withdrawal, e.g., delirium tremens
Associated biochemical abnormalities, e.g., thiamine deficiency
Associated physical illness, e.g., vascular dementia in chronic alcohol abuse
Psychological issues (preceding or consequential)
Comorbid mental illness

can cause memory impairments through a variety of causative and associated mechanisms (see Table 105.1). This chapter comprises a further description of memory and a review of memory problems associated with individual substances with reference to some recent literature.

105.2 Cognitive Aspects of Drug Misuse

The impact of cognitive deficits in drug misuse can have significant effects on both day-to-day function and response to treatment programs (Rogers and Robbins 2001). While memory disorders are most often seen as deficits in the function of memory systems, some theories of addictive behavior focus on the development of pathologically strong memories which influence subsequent drug-seeking behavior (Hyman 2005).

105.2.1 Memory

Memory may be considered under several different headings, for example, short-term (or working memory) as opposed to long-term memory. A classification of memory types is shown in (Table 105.2). An example of short-term memory would be the ability to retain a telephone number read from a directory and then dial that number without having recourse to having to reread that number. Telephone numbers usually have a maximum of seven digits which is the conventional maximum number that can be retained. This type of memory can be tested by digit span tests.

Longer-term memory can be considered as being divided into procedural memory (or implicit memory) and explicit memory. Examples of procedural memory

Table 105.2 Classification of memory disorders

1. Short-term memory/sensory memory
Auditory
Visual
2. Sensory (very short term)
3. Long-term memory
Declarative/explicit
Episodic: autobiographical facts
Semantic: knowledge of the world
Non-declarative/implicit
Procedural skills
Priming: the power of suggestion
Conditioning
Emotional responses
Skeletal musculature
Non associative learning: habituation and sensitization

would include riding a bicycle, driving a car, getting dressed, or using a knife and fork correctly. Of course having an intact memory of how to drive a car or ride a bicycle is only part of the requirements for safety which are integrated with other cognitive skills such as judgement. Explicit memory (memory about facts) can be further subdivided into episodic memory and semantic memory. Episodic memory refers to personal information – what one ate the day before and biographical information about one's family. Semantic memory refers to the meaning of words or, for example, knowing what the capital of France is.

Each of these aspects of memory can be tested separately, but the functional impact depends on the totality of disturbance combined with other cognitive impairments and is modulated by the environment in which the user is placed, e.g., living alone or with somebody else.

The various substances which are liable to misuse can be classified according to type and effect (Table 105.3), and the effects of these substances on memory will be discussed using the following general classification headings:

Table 105.3 Classification of substances

Sedative-hypnotics (central nervous system (CNS) depressants)
Barbiturates
Nonbarbiturate hypnotics
Ethyl alcohol
Benzodiazepines (anxiolytic or antianxiety)
GHB
Narcotic analgesics (opiates)
Opiates
Opiate derivatives
Synthetic opiates
CNS stimulants
Cocaine
Amphetamines
Nicotine
Caffeine
Ecstasy
Psychedelics and hallucinogens
Lysergic acid diethylamide (LSD)
Mescaline (peyote cactus)
Phencyclidine (PCP; "angel dust")
Cannabis
THC; delta-9-tetrahydrocannabinol
Inhalants
Analgesic and anesthetic gases
Glues, solvents, and aerosols

105.2.2 Sedative-Hypnotics (Central Nervous System (CNS) Depressants)

105.2.2.1 Benzodiazepines

Within the normal dose range of prescribed benzodiazepines, an impact on memory can be detected with anterograde amnesia being the most common deficit, elderly subjects being more frequently affected, and the effects being dose related (Curran 1992; Curran et al. 2003). In healthy volunteers who have had therapeutic doses of benzodiazepines, administered effects have been observed on both explicit and implicit measures of memory (Curran and Birch 1991).

The use of benzodiazepines in conjunction with opiate substitution treatments with methadone or buprenorphine has been shown to affect both objective and subjective measures of memory when compared with none drug-using controls (Rapeli et al. 2009).

A review of the effects of benzodiazepines on memory (Beracochea 2006) concluded that while these substances are normally seen as "memory acquisition impairing," most research has not shown evidence of impairment of memory retrieval (retrograde impairment). However, the review highlights the fact that benzodiazepines have been shown to impair other aspects of memory and that impairment of consolidation of memory may result in an apparent retrograde amnesia.

Studies of the impact of benzodiazepines on memory have the potential to be confounded by the underlying psychological and mental health problems for which they are prescribed. A study of the role of benzodiazepines in memory dysfunction in patients with panic disorder was designed to explore this issue and compared a group of patients with panic disorder who were benzodiazepine-free with a group of long-term benzodiazepine users also with panic disorder. The study indicated that panic disorder itself appears to impair nonverbal short-term memory, nonverbal episodic long-term memory and visuo-constructive memory; chronic treatment with benzodiazepines was found to be associated with increased impairment in some aspects of memory (Deckersbach et al. 2011).

105.2.2.2 Narcotic Analgesics (Opiates)

The administration of therapeutic doses of immediate-release opiates in patients receiving palliative care who are treated with sustained-release opiates over a period of time has been shown to produce impairment of both anterograde and retrograde memory (Kamboj et al. 2005). This is in contrast to the findings in healthy volunteers who are administered single oral doses of opiates where only marginal effects on working memory are found (Friswell et al. 2008).

The study of the impact of opiate addiction on memory is complicated by the common pattern of multiple substance misuse including alcohol dependence (Darke et al. 2000; Mintzer and Stitzer 2002), and differentiating the respective contribution of opiates and other substances used by subjects requires complex control measures. The effect on cognitive function of cocaine use in methadone maintenance patients has been studied, and the results indicate that in the absence of

cocaine intoxication, the use of cocaine does not produce any added impairment in cognitive function in methadone maintenance patients (Henry et al. 2012). Studies of neuropsychological function in current methadone patients compared with abstinent heroin users matched for age, education, IQ, employment status, and lifetime drug abuse patterns have shown that methadone consumption alone induces significant cognitive impairment with reduced accuracy of working memory and slower performance on a variety of measures including processing speed and attention (Verdejo et al. 2005).

The neuroanatomical basis of memory deficits in opiate users has been investigated using imaging techniques and demonstrates the key areas which appear to be affected. An fMRI study of opiate-dependent patients compared with healthy controls showed that in tasks which required a high working memory load, the opiate-dependent patients showed hyperactivity in the superior and inferior cerebellum and amygdala and possible hypoactivity in the left prefrontal and medial frontal areas compared with the controls (Marvel et al. 2012). An fMRI imaging study comparing patients treated with methadone or buprenorphine with controls showed altered neuronal activity in the brain areas associated with working memory in those treated with opiates when compared with the controls but found no impairment of visuospatial ability (Bach et al. 2012).

A review of the neuroanatomical basis of working memory found that a number of studies have shown decreased gray matter in the inferior lobes of the cerebellum of a drug- and alcohol-addicted subject (Marvel and Desmond 2010); specifically a study of young lifetime heroin users showed significant decreases in the density of gray matter in prefrontal, temporal, and cingulate areas of heroin-dependent subjects, and the degree of loss of density correlated with the length of time of heroin use (Yuan et al. 2009).

105.2.2.3 Alcohol

The effects of alcohol on memory can be considered within a framework of the nature of the alcohol intake. Conditions such as acute intoxication, hangovers, binge drinking, low to moderate intake, and heavy drinking have all been the subject of research into the cognitive effects of alcohol (Kim et al. 2012).

The acute intoxicant effect of alcohol has been shown to affect both encoding and recall of memories; as alcohol levels increase over a drinking session, encoding is often at a lower alcohol level than recall during the period of intoxication and at a higher level than recall once sober. The effect of state-specific learning is therefore believed to be one of the key factors in observed memory deficits in intoxication. The concept of "alcohol myopia" has been postulated whereby intoxicated subjects encode and recall peripheral information less efficiently than they recall immediate situational cues which are central and subject-centered information (Josephs and Steele 1990; Steele and Josephs 1990). A study of alcohol intoxication and free recall of information in a simulated "real world" situation has shown that the phenomenon of alcohol myopia can be demonstrated (Compo et al. 2011). The impact of alcohol myopia on behavior while intoxicated has been described in risky sexual behavior and may be a more cogent explanation for such

behaviors than disinhibition (MacDonald et al. 2000a, b). Similarly alcohol myopia has been suggested to be a suitable model to partly account for the occurrence of violent behaviors when intoxicated (Giancola et al. 2011). Further research on the concept will be aided by work which has devised a scale to measure alcohol myopia, the Alcohol Myopia Scale (Lac and Berger 2013).

Rapidly increasing levels of alcohol during intoxication are known to precipitate alcohol-induced "blackouts"; this state is characterized by periods of memory loss for events during the drinking period but with retention of consciousness and motor and psychomotor abilities such as conversation and driving during the drinking period (White 2003). This phenomenon does not appear to be state dependent and attempts to induce recall by increasing the alcohol levels to the same point at which the blackout occurred does not result in the retrieval of the lost information (Lisman 1974).

The effect of a hangover, defined as unpleasant symptoms occurring 8-16 h after drinking, on cognition has been explored and indicates that during a hangover state there is impairment of memory (Kim et al. 2003); in particular difficulties with memory retrieval have been identified (Verster et al. 2003). There are considerable methodological difficulties in studying cognitive function during the hangover period; the effects of sleep deprivation, residual alcohol levels, and level and frequency of drinking pattern may all have an independent effect, and research design needs to take account of this (Prat et al. 2008). However, a recent review of the literature on cognitive effects of hangover has concluded that there are four robust studies and four less rigorous but valid studies which indicate specific negative effects of hangover on attention and memory (Ling et al. 2010).

The effects of binge drinking on cognitive function has been the subject of both animal and human research; a review of the literature concluded that binge patterns of drinking can be shown to have effects on both the prefrontal cortex and amygdala resulting in impairment of associative learning. Studies of binge drinking in adolescent subjects using fMRI during memory tasks have shown gender-specific effects on memory tasks with female binge drinkers exhibiting less spatial working memory (SWM) activation than controls, while male binge drinkers showed more SWM activity than controls. The authors suggested that females may be more susceptible to the neurotoxic effects of binge drinking of alcohol during adolescence than males (Squeglia et al. 2011). These gender differences are reflected in the effects of binge drinking on brain morphology in adolescents.

A study using nondrinking controls showed female binge drinkers have greater disruption of cortical brain morphology than male binge drinkers (Squeglia et al. 2012); however, MRI of binge-drinking adolescents has shown reduced cerebellar volumes in male and female binge drinkers compared with controls, and the degree of effect is related to the intensity of the binge-drinking pattern (Lisdahl et al. 2013).

The impact of heavy drinking and alcohol dependence on memory function is well documented, with effects being seen in both short-term and long-term memory and general working memory (Selby and Azrin 1998).

Alcohol-related memory problems are seen with Wernicke-Korsakoff syndrome (WKS); the two clinical presentations of Wernicke's encephalopathy and

Korsakoff's psychosis were originally seen as separate entities but are now known to be a single progressive syndrome. Chronic excess alcohol intake combined with a poor diet will result in a depletion of body store of thiamine. Alcohol blocks the uptake of thiamine from the gut, and this combined with low thiamine content diets can deplete the body store of thiamine in a matter of weeks (Harper 2009). The acute stage of thiamine depletion, whether alcohol related or not, is termed Wernicke's encephalopathy and presents with the distinctive triad of ataxia, mental confusion, and ocular motor disturbance. This can then lead to the end stage of thiamine-deficient brain damage and Korsakoff's psychosis, with irreversible memory changes. If thiamine deficiency is untreated, then up to 20 % of cases will not survive, with the cause of death normally being cardiovascular collapse; aggressive treatment with high dose parenteral thiamine will decrease both the mortality and morbidity arising from thiamine depletion.

The characteristic memory deficits in WKS are related to inability to acquire and recall new information with long-term memory being resistant to thiamine deficiency; imaging studies of patients with acute thiamine deficiency have shown effects in the areas of the third ventricle, the periaqueductal area, the mamillary bodies, and the midbrain which would be consistent with the observed reductions in performance of memory formation (Jung et al. 2012). Some patients with WKS may show the phenomenon known as confabulation; this is seen where patients compensate for the lack of recent memory by filling the gaps in their memory with events which either did not occur or are displaced in time. The exact mechanism responsible for the memory problems seen in WKS is thought to be a complex interaction of alcohol-related damage and thiamine deficiency effects impacting on a variety of cognitive systems which are required for efficient memory storage (Hayes et al. 2012). It has been suggested that the resulting severe anterograde amnesia may not be related directly to alcohol-induced neuronal damage but rather to a disruption of neuronal connections and reduced levels of neurotrophic factors leading to atrophy of isolated and unstimulated neurons (Harper and Matsumoto 2005).

105.2.2.4 CNS Stimulants

Much research on the effects of stimulants on memory has focused on cocaine. Studies of cocaine users who have been abstinent for over 10 days have shown deficits in verbal learning efficiency resulting from poor memory storage, reduced visuospatial abilities, and reduced concentration (Manschreck et al. 1990; Berry et al. 1993; Mittenberg and Motta 1993). Imaging studies during cocaine abstinence using fMRI have shown hypoactivation in brain areas associated with arousal and attention; these areas are associated with dopamine neurotransmission and are located in the cortical and subcortical areas (Tomasi et al. 2007).

The frontoparietal areas of the brain are associated with attention and working memory and have been shown to have reduced activation in fMRI studies in cocaine-dependent subjects; in particular chronic cocaine use is thought to affect the right parietal lobe with reduced performance on verbal working memory tasks (Bustamante et al. 2011).

Other studies have linked fMRI findings with response to treatment in early abstinent cocaine-dependent subjects. When compared with controls, the subjects showed reduced activation in the prefrontal cortex, striatum, and thalamus; these areas are associated with working memory, attention, and vigilance. Low levels of activation in the thalamus pretreatment correlated with poor treatment response (Moeller et al. 2010).

Exposure to stimulants has been shown to affect cognition across age ranges. Prenatal cocaine exposure predicts poorer visual memory at 12 months (Singer et al. 2005); this deficit is not found in prenatal exposure to tobacco or cannabis. Testing of adolescents who were exposed in the prenatal period to cocaine has shown deficits on both incidental face memory and incidental word memory tasks, but no effect on working memory (Betancourt et al. 2011).

The effects of methylenedioxymethamphetamine (MDMA or ecstasy) on memory have been well documented for many years. An impairment of verbal and visual memory was found in studies of abstinent MMDA users when compared with matched controls with the degree of impairment correlating with the amounts and length of time of MMDA use (Bolla et al. 1998). Visuospatial working memory impairment was seen in both current and abstinent MMDA users when compared with controls who had never used the substance (Dafters et al. 2004). The long-term effects of use of MMDA have been studied; a prospective study comparing persistent users of MMDA with less frequent or MMDA naive subjects showed deficits in immediate and delayed verbal recall in the persistent users compared with the naïve and occasional users (Schilt et al. 2007). The use of nonrandomized methods and prospective studies in the study of memory effects of MMDA has been criticized as it may overlook confounding factors such as drug use history and anxiety levels on testing and retesting of memory (Krebs and Johansen 2008, 2012). However, these findings were replicated in a stratified study of MMDA polydrug users which strongly suggested a sustained negative effect of MMDA on verbal memory (Schilt et al. 2008). In addition, studies on middle-aged MMDA polydrug users have shown similar findings to those seen in younger users which were independent of any age-related decline in function (Schilt et al. 2010).

Systematic reviews of the effects of recreational ecstasy have indicated that despite the relatively low quality of some of the research, there is evidence that recreational use of ecstasy is associated with significant deficits in immediate and delayed verbal memory (Rogers et al. 2009) and that there are significant weighted mean effect sizes showing poor performance by ecstasy users on visuospatial memory tasks (Murphy et al. 2012).

105.2.2.5 Nicotine

Perhaps the most commonly used CNS stimulant is nicotine; according to the World Health Organization the global prevalence is 48 % of adult males and 12 % of adult females; this gives an estimated two billion smokers worldwide including child smokers.

The effects of nicotine on performance and memory were the subject of a meta-analysis of all studies published between 1994 and 2008; the authors concluded that there was evidence for positive effects of nicotine on six domains including short-term episodic memory and working memory which were not confounded by withdrawal relief (Heishman et al. 2010). The effect of nicotine on cognitive function has been investigated using fMRI techniques (Kumari et al. 2003). The results which showed activation of a network including frontal and parietal areas are consistent with previous studies which have shown improvements in cognitive function to be related to enhancement of attention and arousal.

Nicotine withdrawal has been shown to produce a decrease in cognitive function including functions such as attention, working memory, and episodic memory (Ashare et al. 2013; Wesnes et al. 2013). Studies of nicotine withdrawal using fMRI techniques have shown significantly reduced activation of the prefrontal cortex and temporal lobes during working memory tasks when treated with a placebo nicotine patch rather than an active patch (Sweet et al. 2010). These effects were more pronounced in subjects aged 50 years and over than in the under 50s suggesting age-related effects may be operating in the magnitude of abstinence effects on cognitive function (Falcone et al. 2013). Treatment of nicotine withdrawal using bupropion has been shown to reduce the level of cognitive impairment on the first day of a quit smoking attempt with improved response times for working memory being seen with bupropion compared with placebo (Perkins et al. 2013). Other studies have shown less clear results with bupropion producing an improvement in working memory during nicotine withdrawal in female subjects but not in males (Ashare and McKee 2012).

105.2.3 Psychedelics and Hallucinogens

The use of so-called psychedelic or hallucinogenic substances such as lysergic acid diethylamine (LSD) and MMDA (see previous section) is not normally associated with the experience of hallucinations except in very high doses. However, the experience of disturbance of perception and cognitive processing is common at low and moderate levels of use (Nichols 2004). Reports of the effects of hallucinogens on memory are mainly confined to those described in the previous section of this chapter regarding the use of MMDA.

With regard to LSD the experience of "flash backs" or reexperiencing of the effects of the use of the drug appears to be a common experience and is classified as hallucinogen persisting perception disorder.

In a review of studies of such experiences (Halpern and Pope 2003), the authors concluded that there were three possible etiological explanations:

(a) They are the result of "heightened awareness of normal visual phenomena."
(b) The result of normal memory with an associated emotional distress.
(c) The result of "lasting memories": resulting from the strong emotional content of the drug experience.

105.2.3.1 Cannabis

Self-reports of the effects of long-term heavy users of cannabis indicate that negative effects of cannabis use on memory are reported in significant numbers of both current (90.5 %, $n = 63$) and former users (88.9 %, $n = 45$) (Gruber et al. 2003) with similar proportions reporting more general effects on cognition.

These self-reported effects on short-term memory have also been documented in web-based studies (Rodgers et al. 2001). A review of the effect of cannabis use on attention, memory, and executive functioning concluded that there is evidence of deficits in all three of these areas from both imaging and neuropsychological studies. Acute effects are seen within 12–24 h of use and are related to cannabis intoxication; longer-term heavier use produces changes which increase in severity over years of use with a good body of evidence showing impairment of recall of word lists and divided attention tasks (Lundqvist 2005). The reversibility of such deficits has been studied using long-term heavy users of cannabis before and after a 28-day washout period and a control group of light users. Heavy users of cannabis showed poorer recall of word lists when compared with light users, but the deficits appeared reversible with no difference between the two groups on retest after the washout period (Pope et al. 2001).

Reviews of studies of the effects of cannabis on neurocognitive functioning covering the period 2001–2007 (Solowij and Battisti 2008) and 2007–2012 (Crane et al. 2013) conclude that acute cannabis effects cover a range of cognitive functions including working memory, attention, and concentration.

There is also sufficient evidence to conclude that cannabis use is associated with impairment of memory beyond the period of the acute intoxicated state.

There are however a number of factors such as age and gender of users, interaction of cannabis with other substances, differences in strength and composition of cannabis used, and length of abstinence from cannabis which may affect the validity of many of the studies with regard to precise conclusions on the effects of longer-term use.

Overall however it would appear that longer-term cannabis use results in impaired attention and concentration, but there is mixed evidence on the effects on working memory.

105.2.3.2 Inhalants

The use of inhalants such as glues, petrol, and other solvents has been shown to have effects on cognition, but many studies have used poly-substance users with resulting lack of clarity as to the exact effect of inhalants (Takagi et al. 2011a, b). Focusing on exposure to specific volatiles has produced clear evidence of impairment of cognitive function and structural brain abnormalities in volatiles such as toluene. A systematic review of both neuropsychology and imaging literature on toluene misuse concluded that there is strong evidence to support an association between this misuse and impairment in a range of cognitive functions including attention, learning and memory, and working memory (Yucel et al. 2008).

Poly-substance users who also use inhalants have been shown to have greater impairment in verbal and nonverbal processing and show more memory problems than those who have not used inhalants (Scott and Scott 2012).

A study of 55 long-term solvent abusers using neuropsychological testing and MRI techniques showed evidence of impairment in working memory and executive functions in the solvent-using group when compared with a control group of users of other drugs. The solvent-using group also showed a higher rate of MRI abnormalities than the other drug users (Rosenberg et al. 2002).

The findings in adolescent inhalant misusers are consistent with studies of occupational exposure both in adolescents and adults (Saddik et al. 2005; Akila et al. 2006) with impairment of working memory and motor dexterity.

105.2.3.3 Cognition Enhancers

The development of a range of substances for treatment of memory problems associated with dementia has produced the potential for misuse of such substances (Lanni et al. 2008), and a black market is reported to already be in existence for purchase of some cognitive-enhancing medications (Jones et al. 2007). The range of putative cognition enhancers is large, and the evidence base for efficacy is poor for many of the substances; there are however trials of the use of some medications in treating substance misusers with memory deficits.

The increasing use of cognitive enhancers by a healthy population for performance improvement is a concern, and their use by students was the subject of a recent review which called for more research on the impact of such drugs in society (Ragan et al. 2013).

A role for cognitive enhancers in the treatment of memory impairment secondary to drug use has been suggested; the aims of such treatment would be to improve function but also to address the circularity of cause and effect in the influence of memory impairment on ability to learn new coping strategies and decrease drug use.

Modafinil is a cognitive enhancer with clinical applications in the treatment of dementia but has also been used to treat long-term, high dose, cocaine users with memory problems. In a clinical trial it was shown to significantly improve two measures of working memory span, but there was no improvement in episodic memory (Kalechstein et al. 2013). Other trials of modafinil using fMRI techniques in cocaine-dependent patients have shown that it modifies the enhanced cue-reactivity to cocaine-related visual stimuli seen in cocaine dependence. The study using a randomized placebo crossover design showed reductions in activity of reward centers and cognitive control areas following dose of modafinil (Goudriaan et al. 2013).

105.2.4 Memory Loss and Engagement with Treatment

The presence of memory loss is an additional factor that is likely to make engagement with treatment more problematic particularly so in those whose lives are already chaotic. Failing to attend for medical appointments and not following instructions about medication are obvious examples. However, differentiating those who do not

want to engage with treatment from those whose memory problems genuinely cause difficulties is often problematic. Some of the strategies to overcome these difficulties in both groups of patients are essentially part of the routine consultation. These include checking with patients that they understand important advice (getting them to repeat it back), providing written information in a form that the patient can understand, and where appropriate, enlisting support from the family. Telephone and SMS reminders are now becoming common practice. Simplifying information to a patient may help people to remember the essentials. The evidence base on improving adherence to treatment in those with memory impairment is limited with most studies being rather small scale. NICE guidance suggests a range of interventions that might be helpful for individuals whose memory problems are such that adherence to treatment is problematic (Nunes et al. 2009).

105.3 Conclusion

The relationship between memory problems and substances is complex. From a clinical perspective, what is required is that clinicians ask patients presenting with substance issues about their memory problems. Informant information is also important. Neuropsychological testing might be helpful. A suggestion of memory loss should lead to the investigation for other cognitive deficits and functional impairments.

Similarly, patients presenting with memory loss should be asked about substance use and again informant information may be useful.

There are few specific pharmacological treatments for memory loss, and the management plan should be focused on treatment of the underlying substance problem and treatment of physical and psychiatric comorbidities and psychosocial support.

105.4 Case Vignettes

105.4.1 Patient 1. Female Aged 63

Presentation: Referred to a memory clinic by family physician. History of 6 months of declining memory. She forgets appointments and dates. Her husband has to supervise medication and assist with cooking. Her husband has taken over domestic finance. One episode of not recognizing daughter. Four blackouts but none for past year. Alcohol history: Drinks 8 UK units a day for several years. Medication includes thiamine and vitamin B complex. Mini-mental state score 28/30.

Assessment: Typical history of Alzheimer's disease but MMSE score higher than would be expected for the degree of impairment. Drinking above safe limits.

Progress: No change in drinking habits. Admission to hospital because of gastritis/hematemesis. Abnormal liver function tests. Acknowledges risk of alcohol but declines referral to alcohol treatment service.

Issues: In view of the clinical history which suggests Alzheimer's disease, should this patient be prescribed cholinesterase inhibitors? Is it desirable in patients such as this to differentiate between alcohol-related dementia and Alzheimer's disease? Should memory clinics, primarily designed for older people with degenerative dementia, also provide alcohol treatment services?

105.4.2 Patient 2. Female Aged 75

Presentation: Progressive memory loss over 12 years, worse over the previous year. Sometimes disorientated in time but not in place. Tendency to be repetitive in speech. She mixes up her children's names. She performs most basic activities of daily living well but needs occasional help from her family. She drinks two glasses of wine each evening with her meal (5 UK units). Her mini-mental state examination score was 16/30.

Past medical history: Delirium with urinary tract infection, minor strokes.

Assessment: Thought to have a mixed dementia. No recognized clinical features of vascular dementia but CT scan showed vascular disease. Drinking above safe limits of alcohol but not excessively so.

Issues: On initial assessment: What advice should be given about alcohol consumption in view of suggested protective effect on vascular disease?

Progress: Her condition deteriorated and 6 months later she was drinking two bottles of wine a day. She completely denies any issues with alcohol or memory. She is supported by her son at home who visits three times a day.

Issues at this time: Is any therapeutic intervention likely to be of benefit? In retrospect should a more aggressive approach to trying to reduce alcohol consumption at initial presentation been made?

105.4.3 Patient 3. Female Aged 63

Presentation: A 63-year-old woman taken on for treatment after she presented with distressing tactile and auditory hallucinations. She was a regular cannabis user, and a week prior to the sudden onset of her psychotic symptoms, a new GP had significantly and suddenly reduced the woman's longstanding diazepam prescription from 30 to 5 mg daily. On admission her husband reported that he noticed that her memory was deteriorating and that she had been using cannabis more heavily than previously.

Assessment: A full assessment of her mental and physical state following withdrawal from cannabis and benzodiazepines is needed so as to differentiate the possibilities of her condition at presentation, i.e., diazepam withdrawal, or cannabis-induced psychosis or other possibilities for a new presentation at this time of life was a new onset organic cause and nothing to do with her substance use.

Progress: The patient was detoxified from diazepam but refused to stop cannabis completely.

Her psychotic symptoms subsided and although her memory improved considerably she still had some cognitive dysfunction.

Issues: Continued counseling for cannabis use, and assessment for depression and anxiety, for which she had been treated initially, and keeping an eye on the development of an organic cause for memory dysfunction, would be a way forward.

105.4.4 Patient 4. Male Aged 60

Presentation: A 60-year-old man presented to the drug service with positive urine test for opiates.

He was shocked as were the staff. He had been stable on a dose of 50 mls methadone for 10 years. He had begun a prescription when he had become dependent on heroin following the need for pain relief for back ache. His partner had recently died and he felt low and lost. He also complained of difficulty in concentration. When probed as to whether he had taken any new medications for any reason, he volunteered that he had taken what he thought was some aspirin which he had found in the house.

Assessment: The urine sample was sent for toxicological analysis where codeine and benzodiazepines were found. He brought in some of the tablets which were analyzed and were indeed a combination of codeine and aspirin. He stopped using these and he was advised to take them to a pharmacy for disposal.

Issues: Comprehensive assessment of the mental and physical state as well as more detail about other prescription or over the counter substances is essential.

The possibility of drug interaction and unsuspected drug interaction due to patient ignorance.

Progress: Following some bereavement counseling and abstinence from all other medications, the patient improved and wanted to start a methadone reduction program.

105.4.5 Patient 5. Male Aged 62

Presentation: A 62-year-old man presented to the emergency clinic requesting detoxification. He said that he had forgotten to collect his grandchildren from school one day and that he now wanted to be drug-free so that he could continue his role in their care.

At the time of presentation he was drinking alcohol, using benzodiazepines, taking cocaine occasionally, and topping up his methadone prescription with street opiates. He lived with his partner and had a central role in the care of his two grandchildren.

He had a longstanding history of substance misuse.

He had first tasted alcohol at the age of 5 years and started drinking regularly at 12 years. He had tried almost every substance, including solvents, amphetamines, ecstasy, magic mushrooms, and heroin. He had been in custody for three periods because of theft, burglary, and shoplifting offences, committed to fund drugs or to maintain basic living needs.

During this initial presentation he appeared not to be able to give a coherent history about his drug-taking career.

Assessment: Further detailed assessment of cognition is required in relation to corroboration of his substance use at the present time and in the past.

He is on numerous drugs which might have an impact on his cognition, e.g., benzodiazepines, cocaine, and methadone.

This has to be separated if possible from other mental and physical health problems which might interfere with attention and concentration.

Issues: This is clearly complex so ideally admission for detoxification and regular reassessment is needed following stabilization of substitution therapy and detoxification from alcohol and benzodiazepines. The patient needs to be informed about the effects on memory of all the drugs he is taking as he may not realize what the impact may be. The care of his grandchildren needs to be reconsidered and reviewed since the episode may simply have been a "one off" or have more serious implications. This may help him resolve to reduce or stop drug use.

Progress: The patient was admitted and detoxified. He was reassessed regularly but continued to use a range of substances albeit erratically.

Abstract

Substance use and co-occurring infections are two of the major health issues in the world today. Both cause serious health complications involving almost every physiological system. Most notably, in substance users, human immunodeficiency virus (HIV) and/or hepatitis C virus (HCV) are common co-occurring infections. These infections result in immunological impairment and a related enhancement in the acquisition/transmission of other opportunistic infections ([OIs] such as tuberculosis [TB], streptococcus, staphylococcus). There are also neuropsychiatric complications and consequential liver damage frequently associated with chronic HCV infection. Research suggests that clinical management of substance users with co-occurring infections is feasible. In addition to preventative measures to reduce substance use or infective complications such as education, prodromal diagnosis, medical therapy, and close monitoring for medication adherence to treatment regimens in substance users is likely to be significantly effective at reducing the global health care burden in this highly vulnerable population.

106.1 Introduction

Substance use and co-occurring infections and associated morbidity and mortality are among the most significant health problems that the world faces today. Although numerous viral and bacterial infections occur in substance-using individuals, in this chapter, we review in depth current research on health consequences associated with viral infections such as human immunodeficiency virus (HIV) and hepatitis C virus (HCV), as well as briefly review sexually transmitted infections (STIs), TB, and fungal and parasitic infections. We also summarize currently available therapeutic modalities for the treatment of viral infections in the substance-using population. Due to space constraints, the reader is also directed to the websites of www.who.org, www.unaids.org, www.cdc.gov, and www.drugabuse.gov for additional current information on statistics for substance use and infections.

It is estimated that 153–300 million people abuse illegal drugs regularly worldwide (World Drug Report 2012). In the USA alone, it is estimated that 22.5 million Americans 12 years of age and older (8.7 % of the population) have used at least one illegal drug (e.g., cocaine, heroin, cannabis) (SAMHSA 2013) during the month prior to the survey interview. In addition to substance use, more than half of the world population is currently infected with one or more infections. There are an estimated two billion people infected with the hepatitis B virus, of whom more than 350 million are chronically infected; and of these subjects chronically infected with HBV, an estimated 500,000–700,000 people die each year. There are nearly 2.3 billion people infected with *Mycobacterium tuberculosis* (TB), of which nine million people go on to develop TB disease each year. This ultimately results in about 1.4–2 million TB-induced deaths annually. There are an estimated 170–200 million people chronically infected with the hepatitis C virus (HCV), of which more than 350,000 people die each year from HCV-related liver disease. And since 1981, when acquired immune deficiency syndrome (AIDS) was first described, an estimated 60 million people have contracted the

human immunodeficiency virus (HIV), nearly 30 million have died of HIV-related causes, and approximately 34 million people currently live with the infection. An estimated 23.5 million (69 % of all people living with HIV) live in sub-Saharan Africa including 91 % of the world's HIV-positive children. About 2.5 million new cases of HIV infection are reported each year (United Nations AIDS 2012).

Globally around 16 million people inject drugs, and three million of them are living with HIV. On average 10 % of new HIV infections are caused by injection drug use. In parts of Eastern Europe and Central Asia, over 80 % of all HIV infections are related to drug use (WHO 2010). Indeed, according to the Centers for Disease Control and Prevention (CDC), drug use remains the third most frequently reported risk factor for HIV infection in the USA after male-to-male sexual contact or high-risk heterosexual contact. Men who have sex with men (MSMs) around the world have higher HIV prevalence rates than the general population of reproductive-aged adults, with highest rates in sub-Saharan Africa and the Caribbean regions. Pooled HIV prevalence ranges from 3 % in the Middle East and southeast North Africa region to 15.4 % in North America and 25.4 % in the Caribbean. It is important to note that young MSM in the USA and elsewhere have the highest rates of HIV infections. But they are also the least likely to be in HIV care. Further, the high prevalence of HIV among MSMs also drives new infections and increases the lifetime likelihood of HIV acquisition among its members (Beyrer et al. 2012). Although a significant portion of HIV-infected MSMs do not enter into HIV care and better intervention programs are needed to engage them into HIV care, MSMs can be successfully treated with the currently available behavioral and antiretroviral therapeutic modalities combined with addiction therapy for HIV-infected drug-using MSMs (The Lancet 2012: http://www.amfar.org/uploadedFiles/_amfarorg/On_the_Hill/SummaryPtsLancet2012.pdf).

Other than injection drug use as a risk factor for exposure to HIV, ongoing substance use, correlates of the lifestyles associated with substance use, and issues of access and adherence to treatments for substance use and its associated medical consequences represent just some of the ways in which drug-related factors interact to affect the onset and progression of HIV/AIDS.

In terms of HCV infection, of the estimated 170–200 million people infected with HCV worldwide, nearly 1 % of the US population is currently infected with HCV. An estimated 80–90 % of HIV-infected injection drug users (IDUs) are also coinfected with HCV that may result in liver cancer and death. Approximately one million people worldwide die each year from liver disease/cancer. Injection drug use accounts for 60 % and 25 % of new HCV and HIV cases, respectively (Sullivan and Fiellin 2004). Injection drug use is also a major risk factor for HCV/HIV coinfection that can significantly impact the transmission and progression of either disease. Although both HCV and HIV infections share common routes of transmission and risk factors, sexual transmission of HCV is low among non-IDUs (Hammer et al. 2003). An estimated 80–90 % of HIV-infected IDUs are also coinfected with HCV that may result in liver cancer and death. Approximately one million people worldwide die each year from liver disease/cancer. Among IDUs worldwide, the incidence and prevalence of HCV infection are

50–90 % and 10–30 % per year, respectively (Hagan and Des Jarlais 2000). More recently, in an emerging epidemic in the USA, injection drug use has played a major role in the transmission of HCV infection among 18–25-year-old young adults who switched from prescription drug use to injecting drugs (Valdiserri et al. 2014; CDC 2013).

106.2 Substance Use and Co-occurring Infections

106.2.1 Human Immunodeficiency Virus (HIV)

HIV is a blood-borne retrovirus and infects CD4 T-cell lymphocytes and macrophages causing profound immunosuppression. In some cases, it eventually may develop into full-blown AIDS (CDC 2013). The course of HIV infection and development of AIDS can be complicated by a variety of metabolic and endocrine abnormalities secondary to the direct toxic effects. These result in viral infection, opportunistic infections (OIs), neoplasms, and complications of antiretroviral therapy. In acute infection, 40–90 % of patients exhibit transient symptoms. In general, the time from initial exposure to symptoms, such as flu-like syndrome consisting of fever, fatigue, and pharyngitis, is about 2–6 weeks; and the mean duration of symptoms lasts 1–2 weeks (Quinn 1997). Almost all patients seroconvert in less than 6 months. There are several factors that can speed up this process. Seroconversion may be accelerated by the individual's genotype, risky sexual behaviors, illicit drug use, and/or the presence of other OIs. Other clinical features of acute infection can include decreased CD4 T-cell lymphocytes and increased viral load and progression to AIDS. In chronic HIV infection, the rate of progression to AIDS is variable and dependent on several factors such as the use of illicit drugs, OIs, and adherence to antiretroviral therapy (ART). Without access and adherence to treatment, the median time from initial infection to AIDS is about 8–10 years (Vergis and Mellors 2000). In terms of diagnosis, the viral load and CD4 cell count are used to assess the stage of disease progression and evaluate the treatment efficacy. HIV infection does not progress to AIDS in about 5 % of individuals. Known as the long-term nonprogressors, these individuals present with a low viral load burden, strong virus-specific immune response, and moderate viral attenuation (Cao et al. 1995).

106.2.1.1 HIV and Substance Use

The combination of substance use and co-occurring infections is associated with more serious adverse health consequences than either drug abuse or an infection alone. These consequences may include increased risk of immune dysfunction, cardiometabolic diseases, persistent dysregulated chronic inflammation, tissue fibrosis, increased vulnerability to infections, and premature aging. Thus, prevention and clinical management of dually infected drug-addicted patients also need to be innovative and effective. Treatment of infectious diseases in substance-using patients requires a multipronged therapeutic approach that addresses the type of infection and psychiatric, medical, legal, and social consequences of addiction (Volkow and Li 2005).

A good example of this is methadone. Since the 1960s, methadone has been effectively used for the treatment of opiate addiction and among HIV-infected heroin-using populations following the emergence of the HIV pandemic in the 1980s. Methadone treatment decreases opiate use as well as needle sharing among opiate addicts and reduces the number of multiple sex partners and the practice of exchanging sex for drugs or money (Meandzija et al. 1994). In addition, there is also evidence that methadone therapy lowers the incidence and prevalence of HIV infection among opiate injectors (Metzger et al. 1993).

106.2.1.2 Treatment of HIV/AIDS in Substance Users

Interventions for HIV/AIDS among substance users consist of preventive measures, lifestyle and behavioral changes, and the use of pharmacotherapies. Firstly, prevention must be targeted to slow the spread of infection by the use of sterile injection equipment and safer sexual practices (e.g., use of condoms), as well as discouraging the use of illegal drugs. Treatment of HIV/AIDS, consisting of postexposure prophylaxis of acute infection, has been proven safe and effective for IDUs in methadone treatment programs and to further prevent the spread of infection (O'Connor 2000). Treatment for substance use disorders, for example, with methadone or buprenorphine, further improves adherence to antiretroviral therapy and prevention of development of antiretroviral (ARV) drug resistance. Treatment of HIV during its acute phase produces a strong HIV-specific response of CD4 cells and undetectable virus. These patients have fewer OIs and mitigated disease progression to AIDS (Berrey et al. 2001). Since the approval of the first ARV medication, zidovudine [AZT] in 1987, several new, pharmacologic agents have been approved for the treatment of HIV/AIDS. In general, these ARVs fall into six broad categories with disparate mechanisms of action (De Clercq 2009): nucleoside reverse transcriptase inhibitors (NRTIs), nucleotide reverse transcriptase inhibitors (NtRTIs), non-nucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), cell entry inhibitor (fusion inhibitor [FI] that binds selectively and inhibits fusion of the virus to the CD4 cell, Lalezari et al. 2003), co-receptor inhibitor (CRI), and integrase inhibitor (INI) (See Table 106.1).

The best virologic response is seen when three or more drugs, known as highly active antiretroviral therapy (HAART), are used to treat HIV/AIDS (Baxter et al. 2000). Briefly, HAART consists of two NRTIs combined with either an NNRTI or a PI (USPHS Kaiser Guidelines 2003) or any of the new inhibitors. Most recently, a 5-drug combination has been reported to cut down even the viral reservoir (Wolf et al. 2013). The goals of HAART include long-standing viral suppression, restoration and preservation of immunological function, improved quality of life, and decreased HIV-related morbidity and mortality. The risk for OIs such as *Pneumocystis carinii*, *Toxoplasmosis gondii*, or *Mycobacterium avium complex* increases as the CD4 count declines below 200/mm^3, 100/mm^3, or 50/mm^3, respectively, and that is when the primary and secondary prophylaxis should be instituted. HAART has significantly reduced the morbidity, including the AIDS-defining illnesses and mortality of HIV/AIDS (Pallela et al. 1998). The effectiveness of therapy is impacted by adherence, safe sexual practices, injection of psychoactive drugs, and any of the many side

Table 106.1 Drugs used in the treatment of HIV infection

Brand name	Generic names(s)	Manufacturer name
Multi-class combination products		
Atripla	Efavirenz, emtricitabine, and tenofovir disoproxil fumarate	Bristol-Myers Squibb and Gilead Sciences
Nucleoside reverse transcriptase inhibitors (NRTIs)		
Combivir	Lamivudine and zidovudine	GlaxoSmithKline
Emtriva	Emtricitabine, FTC	Gilead Sciences
Epivir	Lamivudine, 3TC	GlaxoSmithKline
Epzicom	Abacavir and lamivudine	GlaxoSmithKline
Hivid	Zalcitabine, dideoxycytidine, ddC	Hoffmann-La Roche
Retrovir	Zidovudine, azidothymidine, AZT, ZDV	GlaxoSmithKline
Trizivir	Abacavir, zidovudine, and lamivudine	GlaxoSmithKline
Truvada	Tenofovir disoproxil fumarate and emtricitabine	Gilead Sciences, Inc.
Videx EC	Enteric-coated didanosine, ddI EC	Bristol-Myers Squibb
Videx	Didanosine, dideoxyinosine, ddI	Bristol-Myers Squibb
Viread	Tenofovir disoproxil fumarate, TDF	Gilead
Zerit	Stavudine, d4T	Bristol-Myers Squibb
Ziagen	Abacavir sulfate, ABC	GlaxoSmithKline
Nonnucleoside reverse transcriptase inhibitors (NNRTIs)		
Rescriptor	Delavirdine, DLV	Pfizer
Sustiva	Efavirenz, EFV	Bristol-Myers Squibb
Viramune	Nevirapine, NVP	Boehringer Ingelheim
Protease inhibitors (PIs)		
Agenerase	Amprenavir, APV	GlaxoSmithKline
Aptivus	Tipranavir, TPV	Boehringer Ingelheim
Crixivan	Indinavir, IDV	Merck
Fortovase	Saquinavir (no longer marketed)	Hoffmann-La Roche
Invirase	Saquinavir mesylate, SQV	Hoffmann-La Roche
Kaletra	Lopinavir and ritonavir, LPV/RTV	Abbott Laboratories
Lexiva	Fosamprenavir Calcium, FOS-APV	GlaxoSmithKline
Norvir	Ritonavir, RTV	Abbott Laboratories
Prezista	Darunavir	Tibotec, Inc.
Reyataz	Atazanavir sulfate, ATV	Bristol-Myers Squibb
Viracept	Nelfinavir mesylate, NFV	Agouron Pharmaceuticals
Fusion inhibitors		
Fuzeon	Enfuvirtide, T-20	Hoffmann-La Roche & Trimeris
Co-receptor inhibitors		
Selzentry	Maraviroc	Pfizer
Integrase inhibitors		
Isentress	Raltegravir	Merck

Table 106.2 Antiretroviral agents in development

Therapeutic class	Mechanism of action
Maturation inhibitors	Prevent the development of HIV's internal structures
Assembly and budding inhibitors	Interfere with the final stage of the HIV life cycle
Zinc finger inhibitors	Break apart structures holding HIV's inner core together
Antisense drugs	Lock onto the virus to prevent it from functioning
Cellular metabolism modulators	Interfere with HIV's ability to self-replicate
Immune therapies	Help the body defend against HIV
Gene therapies	Block HIV replication by producing immune cells that are genetically resistant to HIV infection
Variety of Immune modulators (e.g., cytokines)	Increase the host immune system's response to HIV

effects. These may include ART hypersensitivity, mitochondrial toxicity (hepatic steatosis, lactic acidosis), neuropsychiatric symptoms, metabolic (lipid) abnormalities, cardiovascular complications, and drug-drug interactions. Still to overcome some of the adverse drug effects associated with the current HAART, newer agents continue to be developed (see Table 106.2).

Treatment of HIV infection in IDUs generally poses a significant challenge to clinicians since patients adhere poorly due to reported poor adherence to treatment regimens, engage in risky and unsafe sexual behaviors, and continue injection drug use. However, studies show that HAART therapy is effective among drug abusers who are successfully enrolled into drug treatment programs, and thus substance use treatment must become an integral part of HIV management (O'Connor et al. 1994) where the compliance to treatment is also significant. One of the complications that can occur in this population is pharmacokinetic drug-drug interactions between antiretroviral medications and opioid agonists, such as methadone. Methadone increases the blood levels of oral and intravenous zidovudine [AZT] as well as decreasing its clearance but decreases the blood levels of other NRTIs – didanosine and stavudine – suggesting that higher doses of these medications might be necessary in patients in methadone treatment. NRTIs themselves do not alter the levels of methadone, while NNRTIs that induce cytochrome P450 enzymes significantly decrease blood methadone levels, requiring the administration of supplemental doses to prevent opiate withdrawal. The coadministration of methadone, PI, and two other NRTIs leads to increased metabolism of methadone requiring methadone dose adjustment, whereas the coadministration of buprenorphine and AZT has no significant effect on any medication, viral load, or CD4 count in HIV/AIDS patients. Pharmacokinetic/pharmacodynamic drug interactions between medications for the treatment of addiction and HIV have been recently covered by McCance-Katz and colleagues in a special supplement of American Journal of Addiction (McCance-Katz et al. 2010; Khalsa and Elkashef 2010).

106.2.2 Hepatitis C Virus

Hepatitis C infection is the most common chronic blood-borne infection. As mentioned above, it affects an estimated 170–200 million people worldwide. An estimated 3.2 million persons are chronically infected in the USA (CDC 2013. Sixty to 70 % of persons newly infected with HCV typically are usually asymptomatic or have a mild clinical illness (acute infection phase). HCV RNA can be detected in blood within 1–3 weeks after exposure. The average time from exposure to antibody to HCV (anti-HCV) seroconversion is 8–9 weeks, whereas antibodies to HCV can be detected in >97 % of persons within 6 months after exposure. Mild clinical illness symptoms may include malaise, nausea, right upper quadrant pain, and jaundice. During the chronic phase of HCV infection that may last several decades, symptoms may include nausea, anorexia, myalgia, and arthralgia, with fatigue being the most common complaint. Alcohol use and advanced age accelerate the disease progression, especially among men. Approximately 20 % of these chronic patients will develop liver cirrhosis within 20 years, and 1–5 % of them will die from HCV-related liver cancer. Chronic HCV infection develops in 70–85 % of HCV-infected persons; 60–70 % of chronically infected persons have evidence of active liver disease. The majority of infected persons might not be aware of their infection because they are not clinically ill. However, infected persons serve as a source of transmission to others and are at risk for chronic liver disease or other HCV-related chronic diseases decades after infection. Chronic HCV infection is also associated with the development of diabetes mellitus among IDUs as well as non-substance-using populations. Further, gender (being male), poor immune system (i.e., lowest level of CD4+ lymphocytes), and highest viral load are all significantly correlated with liver disease progression (Rubio Caballero et al. 2004). Sexual and mother-to-child transmission of HCV, although rare, may occur during the pre- or postpartum period up to the age of 1 year via breast feeding or nosocomial transmission (Serfaty 1999). In Australia, HCV infection through prenatal transmission has been reported in children. Although HCV infection was largely asymptomatic, more than half the children had biochemical evidence of ongoing liver damage. Due to the chronicity of HCV infection and the long-term risks of liver cirrhosis and hepatocellular carcinoma, children with HCV infection represent a high-risk group worthy of routine follow-up (Karim et al. 2000).

HCV infection may resolve spontaneously in about 15–25 % of the infected people (although different studies report viral clearance rates of 10–50 %); it may persist without complications or become chronic in 75–85 % causing end-stage liver disease (ESLD), hepatic cancer, and death. Viral clearance occurs more often in Caucasians and those not infected with HIV than among people of African descent. The latter population clears the virus slowly and responds less favorably to treatment due to the absence of an IL28B cc allele as compared to the people of Caucasian descent (Duggal et al. 2013). The risk of ESLD is also higher for older persons and who consume more than 260 g of alcohol per week. Marijuana use is also associated with rapid progression of liver disease in HCV-infected subjects.

Although HCV infection could be self-limiting or associated with ESLD, the majority of adults have persistent viremia without clinically demonstrable liver disease. HCV viremia and inflammation are temporarily suppressed by interferon, but the relevance of these surrogate endpoints to progression of liver disease, and survival still needs to be assessed (Prestileo et al. 2000).

There are no prophylactic treatments (e.g., a vaccine) available for preventing HCV infection. Therefore, the medical management of HCV infection to date has focused upon primary prevention and pharmacotherapy. Primary prevention efforts include (a) improving the safety standards surrounding blood supply, (b) safe injection practices in health care, (c) fostering safe injection practices in other settings (e.g., needle distribution programs), (d) decreasing the number of people who initiate injection drug use (Shepard et al. 2005), (e) promoting lifestyle/behavioral changes (e.g., avoiding/minimizing alcohol use, eliminating hepatotoxic medications, avoiding high-risk sexual practices), (f) aggressive pretreatment of opportunistic co-occurring infections (e.g., TB) that are known to accelerate the progression of HCV disease, and (g) treatment with pharmacological agents during acute and chronic stages of infection. The issues of HCV prevention, care, and treatment have been addressed by Ward et al. (2012). The factors predictive of HCV seroconversion among IDUs are the exchange of syringes and cotton sharing (Lucidarme et al. 2004).

Rapid progress in the treatment of HCV infection has led to highly successful therapies that lead to viral eradication and sustained viral response in more than 50 % of patients. Nevertheless, subpopulations like HCV-/HIV-coinfected subjects, alcohol abusers, and HCV-infected African-Americans have reduced rates of treatment response. The use of peginterferon in conjunction with ribavirin improves response rates, but does not fully ameliorate the response deficit relative to patients enrolled in typical drug registration clinical trials (Sherman 2003). Incidentally, high viral load (HCV RNA levels) is associated with a poor response to treatment of chronic HCV and vice versa, and factors such as older age, alcohol use, and coinfection with HIV are predictors of higher viral load among drug users. More recently, two antiviral protease inhibitors – boceprevir and telaprevir – have been approved for treating HCV infection. Although both agents induce a high sustained virologic response (SVR), these must be administered in combination with peginterferon, which is associated with serious side effects. New antivirals that need NOT be coadministered with peginterferon are currently in various stages of development and should be available within the next few years for treating acute or chronic HCV infection.

106.2.2.1 HCV and Substance Use

In the USA, the prevalence of HCV infection in substance users has been reported to approximate 35 % (Hwang et al. 2000). In Japan, it is around 54 % among methamphetamine users, probably because of a high rate of needle and/or syringe sharing (Wada et al. 1999). The incidence or prevalence of marijuana abuse among HIV patients is not known, but the overall prevalence of smoked marijuana either for anxiety and/or depression, improving appetite, or relief of pain among HIV

patients is 23 %. Among the HIV-infected IDUs, the prevalence of HCV may be as high as 90 % (Hagan and Des Jarlais 2000). In general, 15–30 % of HCV— with the following: As above, although 15-30 % of HCV-infected people clear the virus spontaneously, other individuals become chronically infected. For example, in an Irish cohort of 496 HCV-infected patients in treatment clinics, HCV viral clearance was seen in 38 % of IDUs (47 % females, 34.5 % males), was independent of age and duration of intravenous drug use, and was sustained in 82 % of the subjects for 2 years giving an overall clearance rate of 31.1 % (Keating et al. 2005). HCV genotype distribution may vary among IDUs, with 48 % with subtype 1a and 16 % with subtype 1b (Garcia et al. 1998). In Spain, the genotype 3a was prevalent in 65 % of IDUs, whereas the genotype 1b was predominant among patients who had received blood transfusions (Cilla et al. 1996).

106.2.2.2 Treatment of HCV Infection in Substance Users

During the acute phase of HCV infection, the stage of infection which is most often missed, patients may be treated successfully with a combination of peginterferon and ribavirin, the goal being to achieve undetectable RNA levels at the end of 24 weeks of treatment (Grebely et al. 2011). During the chronic phase, when the patient has displayed persistently detectable RNA and elevated ALT levels for more than 6 months with moderate inflammation, fibrosis, or necrosis on biopsy, the gold standard for staging liver disease, therapeutic regimens can consist of peginterferon alone or in combination with ribavirin as is done most frequently. Newly approved antivirals (e.g., boceprevir, telaprevir) are currently being investigated in substance-using patients with acute HCV infection but not yet among substance-using patients with chronic infection.

To complicate further the development of new antiviral agents for treating HCV infection across populations, there are at least six genotypes and more than 50 subtypes of the hepatitis C virus, each of which is likely to respond differently to therapy. For example, in the USA, approximately 70 % of the HCV patients are infected with genotype 1 and the remainder with genotypes 2, 3, and 4; however, genotype 1 has a less favorable prognosis and response to treatment than do other genotypes for currently unknown reasons. The SVR rates range between 42 % and 33 % with peginterferon and ribavirin against genotype 1, whereas the SVR rates against genotype 2 and 3 range between 79 % and 82 %. The viral load of >2 million copies/ml is not responsive to treatment with peginterferon and ribavirin. Incidentally, serious side effects of therapy such as depression and suicidal ideation remain a concern. Multiple HCV genotype infections are associated with rapid immunological and clinical progression. HIV disease progression differs by HCV genotype and is faster in individuals whose HCV infection involves more than one HCV genotype. Although it has been postulated that failure to interferon therapy in IDUs may be related to different genotypes, Soriano et al. (2005) did not find such a case among former IDUs coinfected with HIV and HCV genotypes. Other factors such as frequent injection drug use, the prevalence of other OIs, and engaging in risky

behaviors could have further negative impact on the disease progression and thus the effectiveness of treatment modality. Side effects of treatment may include fatigue, headache, fever and myalgia, bone marrow suppression with pancytopenia, hemolytic anemia, depression, suicidal ideation, and suicide. In sum, about 10–40 % of patients on interferon develop significant adverse neuropsychiatric complications serious enough to discontinue therapy. Neuropsychiatric complications are further exacerbated by injection drug use, and as such, patients on interferon alone or in combination with ribavirin should be monitored closely for serious adverse events.

106.2.3 HIV/HCV Coinfection

It has been estimated that there are an estimated ten million HIV-/HCV-coinfected persons worldwide and an estimated 250,000 people live in the USA (Thomas 2008). HIV coinfection worsens the outcome of chronic HCV infection, increasing both serum HCV RNA level and liver damage and decreasing sustained response to interferon therapy. Age and alcohol appear to be the cofactors associated with cirrhosis and mortality. Alcohol consumption in amounts greater than 50 g per day (i.e., 4–5 drinks) is also a risk factor for liver disease progression among patients with HIV/HCV coinfection. Alcohol-induced cirrhosis can result in dramatic changes in drug metabolism via compromised liver function (Kresina et al. 2002). Chronic HCV infection also accelerates the course of liver disease in HIV-infected *IDUs*, leading to cirrhosis and liver failure in a short period of time. Medical complications of chronic HCV infection may include decompensated liver disease (e.g., encephalopathy, ascites, and jaundice), gastrointestinal bleeding, hepatorenal syndrome, and peritonitis (Soriano et al. 2011). HCV-positive subjects also remain at an increased risk for death and hospitalization post-HAART even after adjustment for antiretroviral use and time-updated CD4 cell and viral load measures. Deaths and hospitalizations in HCV+ patients are primarily for non-AIDS-defining infections and complications of IDU (Klein et al. 2003). Although HIV infection accelerates the natural history of HCV infection, conversely the impact of HCV infection on the natural history of HIV infection remains unclear. It is possible that HCV infection may negatively impact on the CD4 T-cell count and thereby act as a direct cofactor for HIV disease progression. Thus, treatment of chronic hepatitis C might indirectly benefit HIV disease and should be considered in future treatment strategies (Carlos Martin et al. 2004).

Chronic HCV infection also accelerates the course of liver disease in HIV-infected IDUs, leading to cirrhosis and liver failure in a short period of time. Medical complications such as decompensated liver disease (e.g., encephalopathy, ascites, jaundice, gastrointestinal bleeding, hepatorenal syndrome, peritonitis) have been reported (Soriano et al. 2011). HCV-positive subjects also remain at an increased risk for death and hospitalization post-HAART even after adjustment for antiretroviral use and time-updated CD4 cell and viral load measures (Anderson et al. 2004).

106.2.3.1 HIV/HCV and Substance Use

Coinfection of HCV and HIV is an important and frequent scenario, especially among IDUs. The prevalence of both HIV and HCV infections ranges from 30 % to 90 %, with incidence rates between 10 % and 30 % per year. Higher levels of infections may be associated with longer duration and higher frequency of injection drug use, incarceration, and/or lack of access to needle exchange programs. Both injection-related risk factors (i.e., years of injecting drugs, type of drug injected, sharing of injection paraphernalia) and sex-related risk factors (e.g., lack of condom use, multiple sexual partners) are conducive to the spread of multiple infections such as HIV and HCV (Estrada 2002). Since both viruses share common transmission pathways, HIV-HCV coinfection prevalence may be as high as 90 % of HIV-infected IDUs in less developed regions of the world such as Central, South, and Southeast Asia and Eastern Europe (Garfein et al. 1998; Quaglio et al. 2003; MacDonald et al. 2000). In Southeast Asia, HCV prevalence has been reported to reach between 50 % and 75 % (Thomas et al. 1995), 33 % in St. Petersburg, Russia (Law 1999), and 50–55 % in Australia (Dore et al. 2003). In India, there are an estimated ten million people living with HCV infection (Abraham 2012). Between January 1992 and May 1997, the prevalence of HCV infection among 350 HIV-infected veteran patients in the USA was 33 %.

The clinical course of HIV and HCV infections may include a number of adverse health effects including rapid progression of liver disease and death (Mayor et al. 2006). The prevalence of HIV and HCV infections among mentally ill patients may also be as high as eight times that estimated for the US population (Rosenberg et al. 2001). In a large cohort of 18,349 American veterans, Backus et al. (2005) found high rates of comorbid conditions that complicated both the pharmacotherapy and clinical course of both infections. Thirty-seven percent patients were HIV positive. The HIV-/HCV-coinfected patients tended to be older men, were either African-Americans or Hispanic, reported IV drug use as a risk factor for HIV acquisition, and/or were diagnosed with depression. Some subjects described alcohol abuse, substance use, or hard drug abuse compared with HIV-mono-infected patients. The authors suggested that optimal models of integrated care should be developed for populations with HIV, HCV, and HIV/HCV coinfection and who need substance use treatment and/or mental healthcare. Neuropsychiatric consequences of dual infections among the IDUs may also include emotional stress, psychological and coping problems (obsessive compulsive, phobic anxiety, paranoid ideation, psychoticism) and less fighting spirit, and hopelessness and anxious preoccupation towards illness. Routine assessment of psychosocial variables and coping mechanisms should be integrated into all HCV and HIV services, especially those dedicated to treatment of patients with substance use, as a vulnerable segment of the population at risk for life-threatening physical illness such as HCV and HIV infections (Grassi et al. 2002). HIV-/HCV-coinfected patients are also significantly more likely to have had past opiate, cocaine, or stimulant use disorders; have significantly greater incidence rates of past substance-induced major depression; and exhibited neurocognitive impairments (e.g., diminished executive functioning) and higher rates of perseveration. HCV+ patients also frequently have higher

degree of HIV-associated dementia. Interestingly, these noted impairments in cognitive function appear to be more closely associated with serology rather than liver disease severity. Overall, the neuropsychiatric impact of HCV is significant among patients with advanced HIV/AIDS disease (Ryan et al. 2005). In a study of 185 French hospital departments involved in HIV/AIDS management, of the 822 HIV-infected patients, 29 % were infected with HCV, 8 % with HBV, and 4 % with both HCV and HBV. The most frequent causes of death among HIV-/HCV-coinfected patients were liver disease (31 %) and AIDS (29 %). The risk of death from liver disease was the highest in patients coinfected by HCV and HBV. Fifteen percent of the patients who died from liver cancer were coinfected with HBV infection (Salmon-Ceron et al. 2005).

106.2.3.2 Treatment of HIV/HCV Coinfection infection in Substance Users

There are very few treatments available for patients who have a history of substance use and are also coinfected with HIV and or HCV. Compared to HIV-infected patients, patients coinfected with HCV are less likely to be on HAART and are frequently hospitalized with higher CD4 counts for non-HIV-related medical problems including complications of liver disease (Falusi et al. 2003). On the other hand, HAART reduces the incidence of death in HIV-infected patients but with variable rates of survival due to hepatitis C viral infection and drug use. Thus, management of HCV-coinfected IDUs must be optimized to achieve a similar benefit as has been observed among other individuals on HAART (Voirin et al. 2004). Early untreated HIV infection is associated with higher HCV viremia and more severe liver injury in IDUs with chronic hepatitis C infection (Serfaty et al. 2001). However, HIV coinfection does not compromise response to interferon therapy in patients with chronic HCV infection. The rate of response between HIV+ and HIV− patients remains in the range of 36–40 %, whereas it remains at 25 % among the interferon nonresponders regardless of HIV status. In HIV+ patients, the CD4 cell count did not influence the histological response. In HIV-/HCV-coinfected patients treated with interferon, liver histological improvement is frequently similar to that observed in HIV-negative patients, thereby supporting the early treatment of chronic hepatitis C in HIV-infected patients (Di Martino et al. 2002).

On the other hand, liver transplantation (LT) is being evaluated as a safe and effective therapeutic option for HIV-infected patients with end-stage liver disease (ESLD). Longer follow-up in a larger series is needed before any conclusive directive could be provided for HCV-/HIV-coinfected patients requiring LT (Norris et al. 2004).

In substance use treatment programs such as methadone maintenance treatment (MMT), the overall HCV prevalence may be as high as 67 %, 29 % for HIV, and 26 % for HCV/HIV coinfection. The high prevalence of HCV and HIV coinfections in MMT patients varies both by current age and age at admission to MMT. The prevalence of HCV may run as high as 45 % in 35–39-year-olds, all the way up to 92 % in 45–49-year-old patients, with a linear relationship between infection

seroprevalence and age at admission into MMT programs (Piccolo et al. 2002). Collectively, these data indicate that this population would benefit greatly from risk reduction education and pharmacologic treatment for HCV and HIV.

Despite drug abusers being at high risk for HCV infection, 45–85 % may be unaware of their infection status and associated health consequences. Methadone maintenance treatment programs cover a significantly greater number of HCV-related topics and other specific topics (e.g., how to avoid transmitting HCV, the importance of testing for HCV, treatment options if HCV positive) compared to drug-free programs. However, the vast majority of drug-free programs fail to address what needs to be done if an individual is coinfected with HIV and HCV and how to maintain health if found to be HCV positive. Drug treatment programs need to (1) better educate patients much more adequately about the proactive steps an individual should take to deal with HCV, (2) provide critically needed HCV services such as screening and referral to care, and (3) encourage patients to make full use of these services (Strauss et al. 2004). However, there are programs that are about 4.5 times as likely to provide HCV education and dispense methadone to patients, almost four times as likely to provide this service if they educate most of their staff about HCV, two times as likely if they are residential, and almost two times as likely if they conduct HIV testing on-site. Collectively, this suggests there is a major need to increase HCV educational services in drug treatment programs. Walley et al. (2005) report that although one-third of opiate-dependent patients in an MMT program knew about HCV treatment, more than half became "definitely interested" in HCV treatment after hearing the risks and benefits. Whites were seven times, and Latinos were about six times more likely than African-Americans to know about HCV treatment. In general, MMT programs could play a key role in increasing access to HCV treatment and educating patients about treatment options. Education programs need to be established to disseminate: (1) patients about the dangers of substance use and co-occurring infections, (2) primary health care providers, (3) infectious disease specialists, as well as (4) hepatologists available treatment/best practices knowledge about drug addiction. Conversely, it is equally important that psychiatrists and other health care providers be trained adequately about the problems of co-occurring infections in substance users.

106.2.3.3 Treatment of IDUs Coinfected with HCV

To date, clinical management of a single infection has been relatively simple. There exist a multitude of anti-infective agents (antibiotics against bacterial infections) or antiviral agents against viral infections available in the drug armamentarium that a physician could prescribe to a patient. However, clinical management of multiple infections such as HIV, HCV, and others poses a major problem when a patient is also addicted to multiple drugs of abuse, is homeless, and possibly has other comorbid psychiatric complication and, perhaps most importantly, is not likely to adhere to a treatment protocol.

Regarding the medical management of HCV infection in IDUs, although in 1997, the NIH consensus panel (1997) recommended that IDUs should abstain

from illicit drug use for 6–12 months prior to the initiation of HCV treatment, in 2002 the NIH consensus panel recommended that individuals with active injection drug use *could be considered* for HCV treatment (Seeff and Hoofnagle 2003). These recommendations were further reinforced by the American Association for the Study of Liver Disease (AASLD) practice guidelines for diagnosis, management, and treatment of HCV (Strader et al. 2004). Accordingly, treatment of HCV infection should not be withheld from IDUs or those who are on MMT, provided they wish to take HCV treatment, and are able to maintain close monitoring and practice contraception. In addition, several investigators (Edlin et al. 2005; Sylvestre 2005; Dore and Thomas 2005) have shown that drug addicts infected with dual infections can be successfully treated. Better response to therapy is seen if patients with multiple comorbidities are treated by a multidisciplinary team in an integrated treatment facility (Taylor et al. 2005). HCV treatment is rare in the HIV-/HCV-coinfected patients, especially the nonwhite urban poor who are less likely to receive HCV testing and subspecialty referral than their white or more affluent counterparts. The US Preventive Services Task Force (USPSTF 2013; Moyer 2013) recommended screening for HCV infection in persons at high risk for infection and those born between 1945 and 1965. http://www.uspreventiveservicestaskforce.org/uspstf/uspshepc.htm. More comprehensive recommendations for the management of hepatitis C infection among people who inject drugs also have been published by Robaeys et al. (2013).

In general, drug abusers face many challenges in gaining access to health care: (1) distrust of health care system, (2) cost of therapy, (3) poor adherence to therapy, (4) physicians' prejudice, and (5) potential for reinfection from injection use. IDUs or HIV-infected patients are less likely to receive pre-therapeutic evaluation as well as appropriate antiviral therapy even after evaluation as compared to others (Cacoub et al. 2005). Adherence is important but drug use itself does not necessarily predict lack of adherence. HCV-infected IDUs can be stabilized with methadone (or buprenorphine) and treated successfully with peginterferon alone or in combination with ribavirin and adjunct drug addiction services such as psychiatric and behavioral therapy (Litwin et al. 2009).

Substance abuse treatment programs represent a vital venue for curtailing epidemics of HIV and HCV among substance-abusing populations. Currently, substance abuse treatment programs vary in corporate structure, source of revenue, patient census, and medical and non-medical staffing; medical services, counseling services, and staff education targeted HIV/AIDS more often than HCV or STIs. HCV-infected drug addicts in a treatment program can be successfully treated with methadone or naltrexone (Brown et al. 2006, 2009).

Despite expedited referrals for HCV care, only a few participants receive an evaluation, and even far fewer are treated. Because increasingly effective treatment is available, better methods must be developed to improve evaluation and treatment of HCV-infected drug users including those coinfected with HIV (Fishbein et al. 2006). Strategies to improve access to HCV treatment for current and recovering IDUs include the following: (a) drug dependency treatment; (b) education and training for hepatologists, addiction medicine physicians, and other HCV treatment

physicians; (c) development of multidisciplinary clinics; and (d) peer-based education and support for individuals considering and receiving HCV treatment (Dore and Thomas 2005). Further, treatment of HIV infection with a combination of two nucleoside analogues alone, or with an additional protease inhibitor, significantly increases CD4+ cell counts and decreases the HIV viral load with no impact on HCV viremia and ALT or AST levels (Gavazzi et al. 1998). High viral load (HCV RNA levels) is associated with a poor response to treatment of chronic HCV and vice versa; and factors such as older age, marijuana use, alcohol use, and coinfection with HIV are predictors of higher viral load among drug users.

106.2.3.4 Costs and Burden to the Society

It is difficult to estimate the global economic burden of substance use and co-occurring infectious diseases. This is because data on direct expenses associated with inpatient and outpatient health care and economic damage associated with lost productivity, etc., are needed, both of which vary within each country. As an example, the annual substance use alone cost to the US society may be as high as $559 billion (www.drugabuse.gov). Hepatitis C infection-related costs to the society in terms of treatment duration, medication costs, and medication side effects can be enormous. El Khoury et al. (2012) reported that in the USA, the cost per patient per year for of liver transplants was at $201, 110 ($178,760–$223, 460), hepatocellular carcinoma (HCC) at $23, 755–$44, 200, variceal hemorrhage at $25, 595, compensated cirrhosis at $585–$1,110, refractory ascites at $24,755, hepatic encephalopathy at $16, 430, sensitive ascites at $2,450, moderate chronic hepatitis C at $155, and mild chronic hepatitis C at $145 per year per person. In general, in the USA, the 24-week cost of treatment regimen of boceprevir is approximately $22,000; the 12-week treatment regimen cost of telaprevir is approximately $49,200. What is more, this is in *addition to* the corequisite cost of about $38,000 for peginterferon. Depending on the response to the drug, the treatment regimen is either 24 or 48 weeks. But **it must be noted that there is a pressing need to halt or slow the *current* epidemic of curable HCV infection among substance-abusing populations**. The cost of new HIV infections in the USA in 2002 was estimated at $36.4 billion, including $6.7 billion in direct medical costs and $29.7 billion in productivity losses. Direct medical costs per case were highest for whites ($180,900) and lowest for blacks ($160,400). Productivity losses per case were lowest for whites ($661,100) and highest for Hispanics ($838,000). The use of ART and more effective ART regimens decreases the overall cost of illness (Hutchinson et al. 2006).

106.2.4 Other Opportunistic Infections in Substance-Using Populations

Illicit drug use is also associated with a wide variety of bacterial infections such as tuberculosis (TB) streptococcal and staphylococcal infections (Kaushik et al. 2011).

TB is a major public health problem among IDUs, especially in HIV-infected patients. Many IDUs are uninformed about TB and their personal TB status. The threat of TB-related involuntary detainment may lead IDUs to avoid TB diagnostic procedures, TB treatment, or drug abuse treatment (Grenfell et al. 2013). Tobacco smokers of 20 years or greater duration had 2.6 times the risk of nonsmokers for TB. Opiate drug users are also at much higher risk of acquiring mycobacterial infection than the general population. Based on a survey that showed the prevalence of smear-positive pulmonary TB in opiate drug users in Iran at more than 100 times than in the general population, the investigators recommended that active screening to detect pulmonary TB should be integrated into routine testing at all harm reduction facilities for drug users, irrespective of their route of drug use or HIV status (Honarvar et al. 2013). TB represents a major public health problem in Eastern Europe. There are worsening epidemics of TB, multidrug-resistant tuberculosis (MDR-TB), and HIV in Ukraine, against a background of epidemics of STI and IDUs (Atun and Olynik 2008).

Among drug users, prevalence of various infections including STIs has been reported as HCV, 35.1 %; HBV, 29.5 %; HIV, 2.7 %; HSV-2, 44.4 %; syphilis, 3.4 %; chlamydia, 3.7 %; and gonorrhea, 1.7 %. Of the 407 subjects, 62 % had markers for one of the STDs. HIV and STIs were seen in crack cocaine-using African-Americans; HCV infection was seen in 30-year-old or older IDUs sharing needles, and HSV-2 infection was observed in 30-year-old or older African-American women (Hwang et al. 2000). The sexually transmitted infections among IDUs may include syphilis, gonorrhea, chlamydia, trichomonas vaginalis, bacterial vaginosis, herpes simplex virus (HSV) infection, and human papillomavirus (HPV) infection (Kanno and Zenilman 2002), for which excellent diagnostic tests and antibacterial or antiviral medications are available. Staphylococcus *aureus* and streptococcus species, the most common pathogens, cause the most bacterial infections among drug users. Carriage rates of *S. aureus* and methicillin-resistant S. *aureus* are higher among IDUs than they are in the general population (Atkinson et al. 2009). Drug users have a higher rate of nasal or skin colonization with *S. aureus* than among non-drug users, perhaps because their nasal epithelium has been damaged by drug inhalation, their skin has been damaged by drug injection (Gordon and Lowy 2005), and/or they do not maintain a high standard of personal hygiene. Drug users may also transmit staph or strep bacteria by sharing contaminated drug paraphernalia. Transmission drug paraphernalia and/or drug adulterants may directly affect the risk of infection with particular organisms. IDUs may develop infections of the skin and soft tissue, musculoskeletal system, endovascular system, respiratory tract, and other miscellaneous tissues/organs. The medical management of bacterial infections in drug users begins with the recognition of substance use and its associated coexisting conditions. The specific issues of the management of drug withdrawal, adherence to therapy, and difficulties of intravenous access must be a part of a comprehensive therapeutic strategy. Although conventional treatment is suggested, short courses of parenteral and oral regimens have been investigated for right-sided infective endocarditis associated with injection drug use.

106.3 Conclusion

Millions of people who abuse drugs are also coinfected with one or more infections. The consequences of both substance use and co-occurring infections are serious and can result in death if left untreated. The adverse health consequences range from immunological, neuropsychiatric, cardiovascular, and/or hepatic complications to death. An early perception among infectious disease clinicians and/or hepatologists was that substance users who presented with co-occurring infections (e.g., HIV, HCV, or other OIs) were too difficult to treat; however, research shows that substance-abusing patients enrolled in drug treatment programs (e.g., MMT) with effective and safe antiretroviral or antiviral therapies (e.g., HAART) can have very positive clinical outcome, especially if closely monitored for adherence to therapeutic regimens and managed by a multidisciplinary clinical team. In sum, there is a pressing need to halt or slow the current epidemic of co-occurring infections among IDUs on fiscal grounds alone. An improved medical management of this highly vulnerable population will have a tremendous public health benefit.

Sleep Disorders in Addiction: An Overview

107

Michael Varenbut, Jeff Daiter, and Luke Rowsell

Contents

Abstract

The overall concept and aim of this chapter is to provide a basic sleep medicine "crash course," with a specific goal of describing a practical approach to treating the patient population afflicted with substance dependence and concomitant sleep complaints.

A sleep medicine overview will be provided, with specific emphasis on sleep physiology, nosology, and psychiatric and addictive disorders causing sleep concerns. As well, an overview of a diagnostic approach in addition to treatment

options will be presented. The treatment of sleep disorders with both pharmacotherapy and cognitive behavioral therapy approaches will be offered.

The often-heard complaint from our patients of "Doctor, I can't sleep" is not a simple problem, but requires a simple yet comprehensive approach. The addicted population is unique and a unique "skill set" is required from clinicians treating this population.

Treatment settings vary, and the question of "who is going to do what" is important and needs to be clarified prior to approaching optimal treatment strategies. Some treatment settings include physicians from various specialties, psychologists, therapists, program workers, and other health professionals. Invoking a multidisciplinary team approach to the diagnosis and treatment of sleep disorders, and "insomnia" in particular, is crucial.

An evidence-based approach is of paramount importance as we move to superior clinical paradigms and one that should be kept in mind throughout this process.

One can utilize a "sleep assessment package" which should include intake questionnaires, sleep diaries, and other structured assessments. Avoid medications for "insomnia" whenever possible, but when pharmacotherapy is deemed necessary, this chapter offers practical guidelines and describes other available resources.

It is advisable to screen all patients for obstructive sleep apnea, first clinically, and then with sleep studies if available. And lastly, it is important to link with local sleep clinics or specialists when possible to avail yourself and your patients of a specialist opinion when needed.

107.1 Introduction

People who abuse alcohol and other substances are at high risk for sleep disturbances due to the direct effect of the substance and/or its withdrawal on their sleep architecture and their sleep-wake cycle or its effect on their behavior and daily functioning, which in turn impacts their daily need for sleep.

Sleep problems in alcoholics, for example, increase rates of relapse as evidenced by subjective and polysomnographic sleep predictors (Brower et al. 1998). Higher levels of REM predicted relapse within 3 months after hospital discharge in 80 % of patients. In other studies, those who eventually relapsed exhibited a higher proportion of REM and a lower proportion of SWS at baseline. If sleep problems lead to relapse, then treatment of those problems should improve relapse rates.

107.2 Sleep Disorders

107.2.1 Many Suffer, but Few Are Treated Properly

It is estimated that up to one third of the adult population have occasional sleep problems. Of these, one third has chronic "insomnia" as a presenting complaint. For example, between midnight and 3 a.m., it has been estimated that on any night,

two million Canadians from the total population of 35 million are awake watching television. One of every two people has taken sedatives or tranquilizers at some time, and one in five uses them frequently. Many professionals in our current society (including doctors, nurses, EMS workers, and police) work irregular sleep-wake schedules or shift work, often leading to sleep deprivation. Compared with the population at the turn of the century, we are now sleeping 1.5 h less per 24-h period. Epidemiological studies show that the EDS (excessive daytime sleepiness) in Westerners is between 5 % and 36 %. The number one cause of excessive daytime fatigue is sleep deprivation. In any given year, 20–40 % of adults complain of difficulty sleeping and 17 % consider it serious. The majority remain unrecognized and untreated. It has been estimated that the average family MD asks two questions before offering a prescription medication to deal with "insomnia." In addition, it is well known that many medical school curricula do not spend adequate time in educating young doctors in the area of sleep medicine.

107.2.2 Implications and Consequences of Sleep Problems

There are multiple very-well-publicized examples of the implications of sleep deprivation, and fatigue secondary to excessive daytime sedation has been implicated in the following world catastrophes: Exxon Valdez oil spill, Three Mile Island nuclear accident, Chernobyl nuclear plant disaster, Bhopal chemical explosion in India, and the US Space Shuttle Challenger explosion.

Sleep deprivation studies in animals have clearly shown that "sleep is necessary for survival." In 1965, a 17-year-old college student tried to set a new world record for staying awake. The resulting clinical scenario was one of frequent micro sleeps, visual and auditory hallucinations, tachycardia, hypotension, psychosis, thermoregulatory abnormalities, profound weakness, and eventual collapse at 264 h and 12 min (11 days, 12 min). Interestingly, he fully recovered after sleeping 14 h and 40 min.

Sleep-deprived people have nearly as many car accidents as drunk drivers and double the rate of car accidents as the general population. Sleep-deprived people have a higher incidence of infection and other illnesses, as sleep acts as a "host defense" against infection and facilitates the healing process.

Specific consequences of OSA (obstructive sleep apnea), one of the most common sleep disorders, include high blood pressure, cardiac arrhythmias, cerebrovascular accidents (stroke), myocardial infarction, erectile dysfunction, and fatalities from driving while fatigued. Psychological manifestations of sleep apnea include depression and anxiety.

Sleep disorders medicine, from a historical and international perspective, is a relatively new field and one which many countries have little access to. The field largely began at Stanford University in 1970 and, as an example, is only approximately 25 years old in Canada. In 1981 with the introduction of CPAP (continuous positive airway pressure – used to treat obstructive sleep apnea), the field grew exponentially. There are currently available fellowship programs and board certification via the American Board of Sleep Medicine.

107.2.3 Sleep Laboratory and Sleep Disorders Centers

Most sleep laboratories deal with respiratory sleep disorders, such as obstructive sleep apnea (OSA), with a significant few providing the full range of sleep disorders diagnosis and treatment. The goal is to produce a technically pure polysomnogram (PSG or "sleep study"), which is the mainstay of sleep diagnostics and akin to the ECG for a cardiologist. Sleep specialists' backgrounds also differ widely and range from those whose primary training is, for example, in respirology, neurology, and psychiatry, and some who are board certified in sleep disorders medicine as well.

The PSG (polysomnogram, sleep study) is complex and labor intensive, often generating volumes of information which would be equal to 1,000 pages of data. A typical overnight sleep study monitors EEG (electroencephalogram), EOG (electroocculogram), chin EMG, EKG, respiratory effort (chest and abdominal movements), oxygen saturation, and leg movements (EMG), all using noninvasive leads. Some centers also perform MSLTs (multiple sleep latency tests) for narcolepsy and MWT (maintenance of wakefulness tests) for excessive daytime sedation differentiation.

107.2.4 Sleep Physiology

107.2.4.1 Normal Human Sleep

The exact function of sleep is still not precisely known. There is no "normal" amount of sleep that an individual needs, but the amount that one person needs is typically constant. It is estimated that 20 % of the population sleeps less than 6 h (short sleepers) and 10 % sleeps 9 h or more (long sleepers).

Sleep produces different EEG signals that range from wake patterns of beta waves to relaxed states with eyes closed producing alpha waves. Deeper sleep produces slower and bigger theta and delta waves.

There are two broad types of sleep: REM (rapid eye movement) and NREM (non-REM).

107.2.4.2 Normal NREM Sleep

NREM sleep is divided into three stages: stage N1 with low-amplitude mixed-frequency waves (predominantly in the 4–7Hz theta frequency) and slow rolling eye movements, stage N2 typified by theta frequency waves and the presence of physiological features known as "sleep spindles" and "K-complexes," and stage N3 featuring the emergence of slow (0.5–2 Hz) delta frequency waves.

107.2.4.3 Normal REM Sleep

Even without any instruments, we can tell if someone is in REM sleep by looking at the movements in their eyes, even when closed. In REM, we are usually dreaming, but not always. Alpha motor neuron activity is suppressed through a number of inhibitory pathways, and our skeletal muscles are typically paralyzed. REM periods typically occur every 90 min, with each successive REM phase getting longer in

duration: 1st, 5 min; 2nd, 10 min; and 3rd, 15 min. Blood flow is directed to the brain (active), and the EEG pattern is that of low-amplitude, mixed-frequency waves, often with the presence of distinct waves with a sawtooth appearance.

REM deprivation is associated with anxiety and agitation, and our primary drives (eating) are less controlled. In addition, most dreams are forgotten, unless we wake from them.

Historically, it was thought that sleep was simply the absence of wakefulness, resembling death. It is now well known that this is not the case, and on the contrary, sleep is an active process.

Sleep is not a homogeneous state, but rather a combination of two separate and distinct states: non-rapid eye movement (NREM) and rapid eye movement (REM) sleep. This characterization is based on behavioral and physiologic changes that occur during these phases of sleep. NREM sleep accounts for 75–80 % in adult humans and is further divided into three stages, based on EEG criteria.

- Stage N1 Sleep → 3–8 % of total sleep time
- Stage N2 Sleep → 45–55 %
- Stage N3 Sleep → 15–20 %

Sleep normally cycles through the various stages as follows: generally stage N1 → stage N2 → stage N3 → stage N2 → REM → stage N1, N2, or N3. A full sleep cycle consists of a sequence of NREM and REM sleep, typically lasting approximately 90–110 min, and there are generally 4–6 cycles per night. The first two cycles are dominated by SWS (slow-wave sleep), and REM sleep increases as the night progresses.

Sleep patterns also change throughout our lifespan, with sleep occupying two thirds of a human newborn's time and REM sleep occupying one half of total sleep time. The percentage of REM declines rapidly in early childhood, and by the age of 10, the adult percentage of REM sleep is achieved. SWS is minimally present in the newborn but rapidly increases to reach maximum by the age of 10 and then declines.

107.2.5 Classification of Sleep Disorders

107.2.5.1 International Classification of Sleep Disorders

The **International Classification of Sleep Disorders** (ICSD) is "a primary diagnostic, epidemiological and coding resource for clinicians and researchers in the field of sleep and sleep medicine" (American Academy of Sleep Medicine 2005).

The ICSD is produced by the American Academy of Sleep Medicine, in association with the European Sleep Research Society, the Japanese Society of Sleep Research, and the Latin American Sleep Society. The ICSD was first published in 1990. In 1997 it was revised; the title was changed to *The International Classification of Sleep Disorders, Revised* (*ICSD-R*), and the authorship was changed from "Diagnostic Classification Steering Committee, Thorpy MJ, Chairman" to "American Academy of Sleep Medicine". A second edition, called ICSD-2, was published in 2005.

The ICSD-2 was published with the goal of standardizing definitions of sleep disorders and creating a systematic approach to diagnosis. It is widely used by

clinicians and researchers worldwide, improving research efforts throughout the international community by adhering to a recognized set of standards. The ICSD-2 outlines the following goals:

1. To describe all currently recognized sleep and arousal disorders and to base the description on scientific and clinical evidence
2. To present the sleep and arousal disorders in an overall structure that is rational and scientifically valid
3. To render the sleep and arousal disorders as compatible with ICD-9 and ICD-10 as possible

As a result, the ICSD-2 organizes sleep disorders into the following eight categories:

1. Insomnias
2. Sleep-related breathing disorders
3. Hypersomnias of central origin not due to a circadian rhythm sleep disorder, a sleep-related breathing disorder, or other causes of disturbed nocturnal sleep
4. Circadian rhythm sleep disorders
5. Parasomnias
6. Sleep-related movement disorders
7. Isolated symptoms, apparent normal variants, and unresolved issues
8. Other sleep disorders

107.2.5.2 Psychiatric Disorders and Sleep

Troubled minds have troubled sleep – Shakespeare

Almost all mental disorders can have an associated sleep disturbance. Insomnia often sets the stage and is a major risk factor in the development of a psychiatric disorder. If we can treat insomnia, it may protect against significant mental illness.

The brief overview of the selected disorders below has also been found to be very commonly associated with substance use disorders of all types. Being aware of the specific sleep parameters and common presentations of these conditions can assist tremendously in the overall approach to sleep disorders in the substance use population.

The ICSD lists psychoses, mood disorders, anxiety disorders, panic disorders, and alcoholism.

The following section will aim to provide a brief description of the most commonly seen sleep architecture problems seen in the major mental disorders.

Sleep architecture and parameters characteristic of schizophrenia-associated sleep disorders: Sleep continuity disturbance, reduced SWS (slow-wave sleep/deep sleep), decreased REM latency (time to first REM episode), increased REM sleep (total percent of REM), and REM sleep "hallucinatory activity".

Sleep architecture changes typical of depression: Long sleep latency (from time to bed, to first sleep episode), shortened REM sleep latency (time to first REM episode), increased REM density, reduced TST (total sleep time), reduced sleep efficiency (total sleep time, divided by time in bed), increased awakenings, decreased SWS (slow-wave sleep, deep sleep).

It has been estimated that 90 % of cases of major depression have associated symptoms of insomnia. Sleep architecture and parameters can also be used to enhance pharmacotherapy. For example, clinical response to antidepressant medications is improved if the following can be achieved: persistent prolongation of REM latency, persistent reduction of total REM sleep time, and persistent reduction in REM density.

107.2.5.3 Sleep Consequences Associated with Anxiety Disorders

GAD (**Generalized Anxiety Disorder**): Prolonged sleep-onset latency, increased stages 1 and 2 sleep, less SWS (slow-wave/deep sleep), decreased REM sleep percentage, and increased or normal REM latency.

Approximately 70 % with panic disorder have initiation and or maintenance insomnia. Nocturnal panic is most common in NREM sleep and just before the onset of SWS. Nocturnal panic occurs in ~70 % of those with panic disorder. Nocturnal panic attacks result in worse daytime panic attacks and more somatic symptoms.

OCD (**Obsessive Compulsive Disorder**) **Sleep Characteristics**: Decreased total sleep time, increased number of awakenings, shortened REM sleep latency, reduced sleep efficiency, and reduced stage 4 sleep.

PTSD (**Post-traumatic Stress Disorder**) **Sleep Characteristics**: Frequent nightmares are a "hallmark," increased WASO (wake after sleep onset), increased sleep-onset latency, reduced SE (sleep efficiency), and increase in RBD (REM behavior disorder).

Personality Disorders: Personality disorders have been commonly associated with insomnia symptoms. These disorders are lifelong personality traits, which can be categorized as eccentric, schizotypal forms of behavior or erratic, labile, and aggressive characteristics typical of narcissistic or borderline personality disorders.

Patients with borderline personality disorder have been found to have a sleep architecture remarkably similar to those with major depression.

107.2.5.4 Comorbid Conditions and Disorders Causing Sleep Concerns

It is well recognized that primary sleep disorders, psychiatric conditions, substance use disorders, and psychiatric medications can all affect sleep quality and architecture. There are also many primary medical disorders and conditions which can cause sleep difficulties. These would include a myriad of neurologic, cardiovascular, pulmonary, gastrointestinal, genitourinary, endocrine, musculoskeletal, and reproductive conditions.

107.2.6 Contributing Medications and Substances Causing Sleep Problems

The majority of people with substance abuse or dependence experience some form of sleep disorder. While the effects of alcohol have been most studied, there is sufficient evidence on the direct effect on sleep architecture and parameters by a great variety of substances (see Table 107.1 below).

Table 107.1 Common medications and substances contributing to sleep concerns

Category	
Antidepressants	SSRI (fluoxetine, paroxetine, sertraline, citalopram, escitalopram, fluvoxamine), venlafaxine, duloxetine, MAO inhibitors
Stimulants	Caffeine, methylphenidate, amphetamine derivatives, ephedrine and derivatives, cocaine
Decongestants	Pseudoephedrine, phenylephrine, phenylpropanolamine
Narcotic analgesics	Oxycodone, codeine, morphine, propoxyphene, methadone
Cardiovascular	Beta-blockers, alpha agonists and antagonists, diuretics, lipid-lowering agents
Pulmonary	Theophylline, albuterol

107.2.6.1 Stimulants

Nicotine, caffeine, amphetamines, and cocaine can all cause increased arousal acutely and then subsequently cause hypersomnia and fatigue or sedation upon withdrawal.

Cocaine has been shown to increase awakenings and cause poor sleep quality by directly affecting dopamine levels.

107.2.6.2 CNS Depressants

Benzodiazepines, alcohol, and opioids can all cause excessive sedation and fatigue acutely while causing insomnia upon withdrawal. The effects of prescribed benzodiazepines for other indications, such as anxiety, require close monitoring and caution in patients with a history of substance dependence (Ciraulo and Nace 2000).

Heroin causes a decrease in stage 3 and 4 sleep and a decrease in REM sleep with frequent awakenings. Heroin withdrawal typically has been shown to cause REM rebound effect and more frequent nightmares.

107.2.6.3 Alcohol

Acute effects of alcohol intake include increased sleepiness approximately 30 min after ingestion, decrease in awakenings for the first 4 h but increase for the last 3 h, and an increase in dreams (often anxious dreams) (Aldrich 1998).

Chronic effects of alcohol use include increased sleep fragmentation and shorter SWS (slow-wave sleep) interrupted by brief arousals, and an increase in alcohol intake improves the above symptoms, which typically leads to a worsening problem (Landolt et al. 1996).

107.2.6.4 Alcohol Abuse and Dependence

Insomnia is a common feature for alcoholism with prevalence rates of 36–72 %. Alcohol is an REM suppressant but improves slow-wave sleep in the first half of the night.

The initial effect is relaxation and sedation but it also causes increased "WASO" (wake after sleep onset) and increased fragmentation during the second half of the night. Withdrawal from alcohol causes an increase in REM (nightmares), increased

WASO, and decrease in stage 3 or 4 sleep. Insomnia may also be a risk factor for relapse (Brower 2001, Brower et al. 2003).

107.2.7 Diagnosis of Sleep Disorders

The goal of this section is to provide a brief overview of a diagnostic approach to diagnosis of a variety of sleep disorders, with specific emphasis to substance use disorder patients. This section will cover initial sleep intake history and physical examination, sleep diary or log, and sleep questionnaires.

107.2.7.1 Intake History and Physical Examination

Much like with any other medical conditions, it is of paramount importance to obtain a full medical and psychiatric history. Specific to sleep disorders, it is important to include a bed partner or caregiver interview. Discussion about the patient's sleep habits and daytime functioning should be undertaken. Specific and detailed analysis of substance use or abuse is crucial. This should include both licit (e.g., tobacco, caffeine, alcohol) and illicit substances, as these can all have an effect on sleep.

The physical examination should be targeted at ruling out specific diagnosis but should typically include a mental status examination (e.g., mini mental status), as well as a cardiovascular, respiratory, and neurologic examination.

Specific details on a "typical" night's sleep should be obtained and should include the following:

- Time to bed
- Delay to onset of sleep
- Specific symptoms or behaviors delaying sleep onset
- Awakenings – number, duration, and cause if known
- Time of final awakening
- Time out of bed
- Total estimated duration of sleep (TST – total sleep time)
- Nocturnal behaviors – e.g., eating, smoking, and nocturia
- Napping behavior during daytime

The details above can be tabulated in detailed notes or by the use of a sleep "diary" or "log."

A variety of standardized sleep questionnaires exist that can be used to provide an objective characterization of specific sleep parameters, depending on the clinical situation at hand. The table below includes the most commonly used questionnaires and a brief description of same (Table 107.2).

107.2.7.2 Sleep Questionnaires

The Epworth Sleepiness Scale is a widely used and accepted questionnaire that a patient can complete in a few minutes and can help assess the patient's subjective level of sleepiness (excessive daytime sedation). This is of particular importance to assess daytime effects of sleep disorders. The scale is copyright protected but is

Table 107.2 Examples of insomnia questionnaires used in baseline and treatment outcome assessment

Questionnaire	Description
Epworth sleepiness scale	ESS is an 8-item self-report questionnaire used to assess subjective sleepiness (score range: 0–24; normal <10)
Insomnia severity index	ISI is a 7-item rating used to assess the patient's perception of insomnia
Pittsburgh sleep quality index	PSQI is a 24-item self-report measure of sleep quality (poor sleep: global score >5)
Beck depression inventory	BDI (or BDI-II) is a 21-item self-report inventory used to measure depression (minimal or no depression: BDI <10; moderate to severe: BDI >18)
State-trait anxiety inventory-form Y trait scale	STAI is a 20-item self-report inventory used to measure anxiety (score range: 20–80; minimum anxiety: T score <50; significant anxiety: T score >70)
Fatigue severity scale	FSS is a 9-item patient rating of daytime fatigue
Short form health survey (SF-36)	SF-36 is a 36-item self-report inventory that generically measures quality of life for any disorder (range from 0 (poorest) to 100 (well-being))
Dysfunctional beliefs and attitudes about sleep questionnaire	DBAS is a self-rating of 28 statements that is used to assess negative cognitions about sleep

available for private clinical use free of charge and can be accessed at the following web address: http://epworthsleepinessscale.com.

107.2.8 Treatment of "Insomnia"

The aim of this section is to provide a brief overview to an approach to deal with insomnia complaints in the substance use population. This is by no means an exhaustive account of each technique used, but rather a "primer" to introduce each modality.

The overall approach is that of identifying and treating the underlying condition, as well as perpetuating factors. One can then utilize a combination of behavioral, psychological, and pharmacological modalities, depending on the specific clinical presentation and patient needs.

Predisposing factors to insomnia typically include varying tendencies toward psychological, emotional, or cognitive arousal that promotes insomnia but insufficient to cause insomnia without the presence of other factors.

Precipitating factors are often identifiable events that initiate insomnia and can be major (e.g., bereavement) or minor (e.g., sleeping in unfamiliar bed). These also often depend on the predisposing arousal level of the individual.

Perpetuating factors include poor sleep habits that develop during episodes of insomnia such as erratic sleep-wake schedules, nocturnal eating, and excessive worry about sleep.

Table 107.3 Sleep hygiene rules: the dos and don'ts of a good night's sleep

1. Keep a regular schedule. Go to sleep and wake up roughly at the same time each day, even on the weekends
2. Exercise regularly, in the morning or afternoon. Don't exercise in the late evening
3. Have a comfortable bed in a quiet, dark room. Don't have your bedroom too hot or too cold
4. If hungry before bed, eat a light snack or have a glass of milk. Don't eat a heavy meal before retiring
5. Schedule a relaxing period before retiring
6. Keep the bedroom just for sleeping, sickness, and sex (3-S's), not as an all-purpose activity area
7. Don't use alcoholic beverages or recreational drugs as sedatives
8. Don't try too hard to fall asleep. Get out of bed and return to bed only when you feel sleepy (30 min rule)
9. Don't nap during the day
10. Don't smoke or drink caffeinated beverages or eat foods for several hours before bedtime
11. Use an alarm clock to wake you at your regular time, but position it away from you so you don't "clock watch" which can cause unnecessary tension
12. If worrying keeps you awake, set aside a 15-min "worry" period to occur at the same time, perhaps after dinner, and in the same place every day. Writing down a "problem" list may help to relieve stress associated with worrying about forgetting certain things

107.2.8.1 Treatment of Chronic Insomnia: An Overview

The overall approach is to identify and treat underlying condition(s) and to identify and treat perpetuating factor(s). This is best achieved with a combined approach which includes behavioral, psychological, and pharmacological strategies.

107.2.8.2 Sleep Hygiene Therapy

Sleep hygiene therapy typically makes an attempt to educate the patient about healthy sleep habits, exercise, caffeine consumption, eating behaviors, and sleep environment.

These suggestions may be ineffective alone in yielding results; they are usually a part of most behavioral treatments for insomnia. Above is an example of a list of sleep hygiene "rules" that can be utilized for this approach (Table 107.3).

You may choose to focus on two or three of the above recommendations at a time and reevaluate your sleep habits every few weeks. And remember, a consistent sleep schedule works best.

107.2.8.3 Behavioral Therapy

Behavioral therapies for insomnia that are empirically supported include stimulus control, progressive muscle relaxation, and paradoxical intention, with sleep restriction, biofeedback, and multifaceted cognitive behavioral therapy, also probably efficacious treatments (Benca 2005).

107.2.8.4 Stimulus Control Therapy

Based on the theory that cues in the bedroom precipitate and perpetuate arousal. The therapy involves instructions such as the following: "Go to bed only when sleepy," "Establish standard wake up time," "Avoid using the bedroom as

an all-purpose activity area, restricting behaviors to the 3 S's (sleep, sickness, sex)," and "Refrain from napping during the day."

107.2.8.5 Sleep Restriction Therapy

The therapy restricts time allotted for sleep each night. First, a "sleep log or diary" is maintained for 2 weeks and then initial TIB (time in bed) prescription is set at a minimum of 5 h of total bed time. This is followed by an expansion of a 15–30-min sleep at the end of the sleep phase (i.e., desired wake time), every few days. This is carried out over a few visits, with fine-tuning as needed.

107.2.8.6 Progressive Muscle Relaxation

Based on the theory that mental relaxation will be a natural outcome of physical relaxation, leading to sleep.

The patient is instructed to tense or tighten one muscle group, then release tension; muscle groups are tightened and relaxed one at a time in a specific order. A greater degree of muscle tension is attempted subsequently as familiarity increases.

107.2.8.7 Paradoxical Intention

Performance anxiety contributes to preventing proper sleep. The patient is encouraged to stay awake (the feared behavior). As the patient stops trying to fall asleep, the performance anxiety related to attempting to fall asleep is reduced.

107.2.8.8 Biofeedback

Teaches patients to facilitate increased slow brain wave activity (and thus facilitate falling asleep) by using electroencephalographic (EEG) monitoring of brain waves. Eventually this skill can be applied without the EEG.

107.2.8.9 Multifaceted Cognitive Behavioral Therapy

The goal is to identify dysfunctional beliefs and attitudes about sleep and replace them with more adaptive substitutes.

The treatment targets the following: Unrealistic sleep expectations ("I must get eight hours of sleep per night"), misconceptions regarding causes of insomnia ("My insomnia is due to a chemical imbalance"), amplification of consequences of insomnia ("I can do nothing after a bad night's sleep"), and performance anxiety due to excessive attempts at controlling the sleep process.

This is also referred to as CBT-I (cognitive behavioral therapy for insomnia) and involves a combination of cognitive and behavioral modalities.

Topics commonly addressed are an array of cognitive, circadian, and sleep-inhibitory factors that affect primary insomnia.

The combination of SCT (stimulus control therapy) and SRT (sleep restriction therapy) has proven most efficacious (Smith et al. 2002).

Cognitive behavioral therapy enhances sleep-related self-efficacy and reduces depressive and anxiety symptoms. It has also been shown to correct dysfunctional

beliefs about sleep and to reduce the use of sleep medications, with an overall improvement in insomnia-related sleep-wake symptoms.

CBT-I should be the standard treatment regimen for all insomnia patients, as comparative data suggest that CBT-I is associated with a greater and more durable benefit than pharmacologic therapy and may have an indirect effect of preventing drug dependence and relapse (Kupfer and Reynolds 1997).

107.2.9 Pharmacotherapy of Insomnia in the "Addiction Population"

107.2.9.1 Introduction

People who abuse alcohol and other substances are at a high risk for sleep disturbances due to the direct effect of the substance or its withdrawal on their sleep architecture and their sleep-wake cycle. The drug effect on their behavior and daily functioning, which in turn impacts their daily need for sleep, is also paramount (Eder 2002).

Benzodiazepines are the most commonly used prescription medication with good evidence of their effectiveness both objectively and subjectively. However, in those with a history of substance abuse, the potential for abuse of these substances is likely. In this population, alternative indicated medications such as melatonin receptor agonists (for sleep-onset insomnia) and histamine-1 antagonists (for sleep maintenance insomnia) may be preferential due to their low risk of abuse. Over-the-counter medications and off-label uses of antidepressant medications may also be considered, although limited evidence on efficacy, dosage, and safety is of concern.

107.2.9.2 OTC (Over-the-Counter) Preparations

The most commonly used medications in this class are diphenhydramine and dimenhydrinate.

107.2.9.3 Diphenhydramine

Some of the more commonly available brand names are sold as Excedrine® PM, Benadryl®, Tylenol® Allergy Sinus, Tylenol® Flu Nighttime Max Strength Powder, and Tylenol® PM.

This drug works as an antihistaminic agent, to decrease sleep latency (sleep onset), and also disrupts sleep architecture by decreasing REM sleep and increasing slow-wave sleep. The anticholinergic effect in the morning leads to drowsiness, especially in higher doses (Marzanatti et al. 1989). The potential for diphenhydramine-related toxicity and drug-drug interactions is substantial (Lessard et al. 2001), and tolerance to its sleep-inducing effects occurs within a few days (Richardson et al. 2002), suggesting that diphenhydramine and related compounds such as dimenhydrinate should not represent a viable treatment strategy for long-term sleep maintenance in chronic insomnia.

Table 107.4 Drugs with an FDA indication for insomnia

Generic name	Trade name	Dose (mg)	Mechanism of action	T max(h)	T ½ (h)
Flurazepam	Dalmane	15, 30	BzRA	0.5–1.0	47–100
Triazolam	Halcion	0.125, 0.25	BzRA	2	1.5–5.5
Temazepam	Restoril	7.5, 15, 30	BzRA	1.2–1.6	3.5–18.4
Estazolam	ProSom	1, 2	BzRA	0.5–6	Oct-24
Quazepam	Doral	7.5, 30	BzRA	2	39–73[a]
Zolpidem	Ambien	5, 10	BzRA	1.6	1.4–4.5
Zaleplon	Sonata	5, 10, 20	BzRA	1	1
Eszopiclone	Lunesta	1, 2, 3	BzRA	1	6
Zolpidem CR	Ambien CR	6.25, 12.5	BzRA	1.5	2.8
Zolpidem (sublingual)	Intermezzo	1.75, 3.5	BzRA	0.5–0.75	1.4–3.6
Ramelteon	Rozerem	8	MtRA	0.75	1.0–2.6
Doxepin	Silenor	3, 6	H1Ant	3.5	15.3–31[b]

BzRA benzodiazepine receptor agonist, *FDA* Food and Drug Administration, *H1Ant* histamine 1 receptor antagonist, *MtRA* melatonin receptor agonist
[a]Half-life for active metabolites
[b]Half-life for parent drug and active metabolite

107.2.9.4 Valerian

This older compound had been used for many years, in a variety of preparations and forms depending on country of origin. While there is some subjective improvement in the quality of sleep, there is little scientific evidence documented in clinical trials (Hadley and Petry 2003).

107.2.9.5 Prescription Medications

Benzodiazepine Receptor Agonists

These are the most commonly prescribed class of medications used for sleep. They are nonselective GABA-ergic (similar to Etoh) with effects on w1 receptors (causing sedation) and w2 receptors (with effects on memory and concentration). Commonly available and prescribed medications are zolpidem (Ambien), zaleplon (Sonata), zopiclone (Imovane), and eszopiclone (Lunesta). Eszopiclone (Lunesta) is the only hypnotic that is FDA approved without a specified time limit on the duration of prescription (Table 107.4).

The hypnotic efficacy of BzRAs has been well documented using objective and subjective measures of sleep induction, maintenance, and duration in clinical trials, as well as in meta-analyses (Holbrook et al. 2000). Thus, it can be concluded that they are effective.

Adverse reactions to BzRA hypnotics include residual effects, which can be related to the half-life of the specific hypnotic, falls in the elderly, amnesia, rebound insomnia, amnesic parasomnia episodes, and potential for abuse.

Behavioral dependence has been noted in daily and long-term use of anxiolytic BzRAs, as opposed to short-term (8/24 h) use as with hypnotics. Short-term studies (<2 weeks) (Roehrs et al. 1996) and a long-term study (12 months) (Roehrs et al. 2011) of hypnotic BzRA use did not indicate dose escalation.

However, the FDA has designated BzRA hypnotics as controlled substances, giving them a schedule IV designation, which indicates these drugs have a known abuse liability, and this must be a particular concern when prescribing these hypnotics to a patient with a history of substance abuse.

107.2.9.6 Melatonin Receptor Agonist (Ramelteon)

Ramelteon has an FDA indication for sleep-onset insomnia, supported by subjective and objective studies showing that sleep onset is hastened along in a dosage range of 4–32 mg (Erman et al. 2006; DeMicco 2006).

Adverse events report included somnolence, fatigue, dizziness, and nausea, all occurring at rates <5 %, and based on behavioral assessments of abuse liability, no liability was seen (Griffiths 2005).

107.2.9.7 Histamine-1 Antagonist (Low-Dose Doxepin)

Doxepin is a tricyclic antidepressant that is frequently used off-label as a hypnotic in antidepressant doses (25–150 mg). At the doses approved for insomnia (3–6 mg), doxepin is thought to be a relatively pure H1 histaminic receptor antagonist, which, when antagonized, produces sedating effects, without anticholinergic, antiserotonergic, and antiadrenergic activity. Doxepin has been shown in both adults and the elderly to maintain sleep, particularly in the last 2 h of the night, unlike the BzRAs, without producing residual effects. Doxepin is not a scheduled drug and is considered not to have an abuse liability; however, more evidence on this is required due to behavioral dependence of H1 antihistamines. As the clinical trials have all been short and intermediate term (≤3 months), the issue of dependence must be more fully studied before caution of low-dose doxepin is raised.

107.2.9.8 Other Off-Label Drugs Used to Treat Insomnia

Antidepressants

The most commonly used off-label drugs for insomnia are antidepressants used at "lower doses" for insomnia than their standard antidepressant doses (Walsh 2004). Trazodone, amitriptyline, and mirtazapine are three of the most widely used antidepressants. There is limited information regarding the dose range along which these drugs improve sleep and their safety at those doses. No studies of amitriptyline and mirtazapine on primary insomnia were found in literature, and two studies of trazodone gave mixed results with improvements at lower doses giving reduced sleep latency and increased total sleep time; however, these effects lasted for only 1 week.

The dosage generally recommended for sedation is lower than the antidepressant dosage, and it is not known where potential serious side effects documented at

higher doses – suicidality, residual effects, anticholinergic effects (i.e., dry mouth, urinary retention, and hallucinations) to orthostatic hypotension, priapism, cardiac arrhythmias, and conduction abnormalities – would occur at these low doses. Given that there is no clear understanding in regard to the dose range for the hypnotic efficacy and safety of these drugs, it is recommended they not be used as hypnotics.

There is currently no data available on antidepressants for use in sleep disorders among patients with substance use disorders.

Proper diagnosis of comorbid mood disorder may indicate that a single medication can be helpful to treat both conditions.

Atypical Antipsychotics

This class of medication includes "off-label use" of such drugs as olanzapine (Zyprexa) and quetiapine (Seroquel) for their effect on sleep parameters.

These agents have shown improvement in self-reported sleep measures (Roehrs and Roth 2012); however, the concern for the use of these drugs, as with the other off-label drugs, is that there is limited information regarding efficacious and safe doses, and their use as hypnotics is not recommended (National Institutes of Health 2005). There is currently no data available on olanzapine or quetiapine among patients with substance use disorders.

Off-Label BzRAs

Anxiolytic BzRAs are also often used as hypnotics, with clonazepam, alprazolam, and lorazepam the most commonly used off-label BzRAs. These share the same hypnotic mechanism of action of the indicated BzRAs and were used previously due to no limitations on long-term use; however, their hypnotic dose is unknown, and due to the above, there is no advantage to their use.

Guidelines for Prescribing Sedative/Hypnotics

- Initiate hypnotic use with identifying and addressing specific behaviors, circumstances, and underlying disorders contributing to insomnia
- Prescribe the lowest effective dose of the hypnotic
- Avoid hypnotic use or exercise caution if the patient has a history of substance abuse, myasthenia gravis, respiratory impairment, or acute cerebrovascular accident
- Prescribe hypnotics for short durations (2–4 weeks) and intermittently (duration based on the patient's return to an acceptable sleep cycle)
- Watch for requests for escalating doses or resistance to tapering or discontinuing hypnotic
- Hypnotics should be discontinued gradually (i.e., tapered); the physician should be alert for adverse effects (especially rebound insomnia) and withdrawal phenomena

General Comments About Sedatives/Hypnotics

- Administration on an empty stomach is advised to maximize effectiveness
- Not recommended during pregnancy or when nursing
- Caution is advised if signs/symptoms of depression, compromised respiratory function (e.g., asthma, COPD, sleep apnea), or hepatic heart failure are present
- Caution and downward dosage adjustment is advised in the elderly
- Safety/effectiveness in patients <18 years not established
- Additive effect on psychomotor performance with concomitant CNS depressants and/or alcohol use
- Rapid dose decrease or abrupt discontinuance of benzodiazepines can produce withdrawal symptoms, including rebound insomnia, similar to that of barbiturates and alcohol

Certain antidepressants (amitriptyline, doxepin, mirtazapine, paroxetine, trazodone) are employed in lower than antidepressant therapeutic dosages for the treatment of insomnia. These medications are not FDA approved for insomnia and their efficacy for this indication is not well established

107.2.9.9 Medications and Potential for Abuse

Abuse Liability Signs

There is abuse liability associated with the BzRA hypnotics. The non-BzRAs that are not scheduled have limitations in regard to their indications, ramelteon being only for sleep-onset and doxepin only for sleep maintenance insomnia. Therefore, a BzRA may be prescribed. The following important signs have been identified of physical/behavioral dependence on BzRAs (Kan et al. 2004):

1. Dose escalation beyond the indicated clinical hypnotic dose within the first week of treatment.
2. Use during daytime with multiple daytime doses being taken.

These patterns suggest nonhypnotic drug effects that were being sought and guidance to closely monitor the patient during the first week of use, and not allowing patient-initiated dose adjustments is recommended.

Precautions and Contraindications

Patients who have histories of drug or alcohol abuse with difficulty sleeping, particularly sleep maintenance, which is a chief complaint among abstinent alcohol and drug abuse patients, require precautions; these disturbances can continue for a year or more. The non-BzRA, low-dose doxepin may be an option, though further studies may uncover suspected dependence potential. If the physician considers the use of a BzRA hypnotic in an outpatient setting, the patient must be monitored closely beyond the initial week of use. Within the alcohol and drug abuse treatment community, stress-induced relapse is a well-recognized phenomenon that can occur

after months of successful abstinence. In such cases, the experience of new life stresses can induce a relapse to drug and alcohol abuse.

107.3 Conclusion

Insomnia is a prevalent symptom in those with chemical dependency, and it may be a predictor of relapse. The key is proper assessment and diagnosis of the underlying cause. Treatment with pharmacotherapy and behavioral therapy is likely the best option. As of this writing, there is still significant need for further research.

It is crucial to remember that not all "insomnias" are the same. The complaint of insomnia is extremely common, with significant implications and with a high rate for concurrent disorders: medical, psychiatric, and addiction. There is a need for a simple yet comprehensive approach for the diagnosis and treatment of sleep disorders in the substance-abusing population, which should involve a multidisciplinary team approach to care.

Sleep disorders medicine is a fascinating and rapidly growing field. Think about sleep disorders when patients complain of fatigue or EDS (excessive daytime sedation). Think about the possibility of OSA (obstructive sleep apnea) if the patient presents with snoring with fatigue, and they are also overweight or have hypertension or diabetes. It is prudent to stay away from benzodiazepines for insomnia as the first attempt at "treatment."

It is important to think of the ICSD classification system (as discussed earlier) and a differential diagnosis of the sleep complaint. "Insomnia" is not a diagnosis, but rather a presenting symptom.

The use of a sleep diary or log for a clear objective picture is very helpful clinically, and CBT-I accompanied by sleep hygiene modifications is the first-line "treatment" for most patients.

Endocrine Manifestations of Addictive Diseases

108

Richard Hallinan

Contents

Abstract

Endocrine manifestations of addictive diseases range from overt clinical syndromes, such as alcoholic Cushingoid syndrome, alcoholic hypoglycemia or ketoacidosis, and opioid-related hypogonadism, to subclinical disturbances, such as blunted adrenal or thyroid stress responsiveness. They include acute and chronic toxicological processes (such as alcoholic cirrhosis or pancreatitis) or predictable side effects (such as opioid-associated hypogonadism) that are incidental to the addiction process but also disturbances of endocrine and neuroendocrine function that are intrinsic to the pathophysiology of addiction.

Increasing evidence points to effects of prenatal drug exposure and early life stress in disturbed hypothalamic-pituitary-adrenal axis regulation later in life, of

sexually dimorphism in responses to addictive substances, and of involvement of sex hormones, oxytocin, and appetitive hormones to modulate the effects of drugs in humans.

In the addiction medicine settings, hypo- and hyperthyroidism are standard differential diagnoses for mood or anxiety disorders. Hypogonadism and/or hyperprolactinemia may cause sexual dysfunction, infertility, or gynecomastia. Psychoactive substances can contribute directly or indirectly to disturbances of glucose metabolism. Comprehensive assessment and management of people with substance use disorders may require attention to issues of metabolic and bone health.

The aim of this chapter is to foster the recognition and appropriate management of clinically important endocrine disturbances when they occur, also the appreciation of subtle endocrine and neuroendocrine effects contributing to withdrawal, craving, and relapse, better to inform counseling of patients, the understanding of laboratory tests, and making the reader aware of potential therapies arising out of the increasing body of knowledge in this area.

108.1 Introduction

Endocrine manifestations of addictive diseases range from overt *clinical* syndromes, such as alcoholic Cushingoid syndrome, to more subtle disturbances, such as blunted adrenal stress responsiveness, which are generally *subclinical*. They include not only acute or chronic toxicological processes (such as alcoholic pancreatitis) or side effects (such as opioid-associated hypogonadism) that are *incidental* to the addiction process but also perturbations of endocrine and neuroendocrine function, inherited or acquired, that are *intrinsic* to the pathophysiology of addiction. Not only are endocrine systems affected by psychoactive drugs, but they respond in ways that can contribute to the development and maintenance of addiction.

Addiction has famously been said to "hijack" limbic-hypothalamic hedonic motivational pathways that normally subserve basic biological functions including feeding and sexual behaviors (Olsen 2011). Disturbances of appetitive and metabolic regulation are emerging as an area of commonality or overlap between addiction to psychoactive drugs and "food addiction." Sexual dysfunction (dealt within the ▶ Chap. 109, "Sexual Function and Alcohol and Other Drug Use") is common in people with substance use disorders, and while the etiology is often complex and multifactorial, endocrine dysfunction may play a role, especially with opioids and alcohol.

In this chapter, we present both *clinical* endocrine disorders associated with the use of alcohol and other drugs and *subclinical* endocrine disturbances, taking endocrine systems in turn to support a broad conceptual understanding. While preclinical studies are considered, the main focus is on human studies.

The aim is to foster the recognition and appropriate management of clinical endocrine disorders and also appreciation of subtle endocrine effects that underpin acute and chronic withdrawal and relapse, better to inform counseling of patients

and the understanding of laboratory tests, and making the reader aware of potential therapies arising out of the rapidly increasing body of knowledge in this area.

108.2 Hormones and Addiction

108.2.1 The HPA Axis

Clinically manifest disorders of the hypothalamic-pituitary-adrenal (HPA) axis related to alcohol and other drug use are uncommon. By contrast, abnormalities in stress responsiveness, including but not limited to the HPA axis, are increasingly recognized as central to the pathophysiology of addiction syndromes. For heroin and as was later shown other drugs including cocaine and alcohol, cycles of intoxication and withdrawal were found to be associated acutely with stimulation of the HPA axis and chronically to dampened or blunted HPA reactivity to various experimentally testable physical and emotional stressors. By the 1970s, evidence of the improvement of these disturbances in opiate addicts receiving methadone maintenance treatment (MMT) led to two hypotheses: that it was the cycle of short-acting drug-induced changes rather than the action of opioids per se that led to changes in stress responsiveness and that the fluctuating conditions of repeated intoxication with opioids had endocrine effects that were more pronounced than under the relatively state of opioid receptor occupancy in MMT, during which a large proportion of opioid receptors remain unoccupied and hence available to perform their normal physiological functions (Kreek et al. 2002; Zhou et al. 2010).

Although the earliest evidence of HPA axis perturbations accrued in relation to opioids, and much information is available from animal studies of stimulants, overall the greatest body of information is available in relation to alcohol, albeit mainly in men. While there is evidence that HPA axis disturbance may precede problematic alcohol use in some people, alcohol intoxication and cycles of withdrawal both acutely stimulate the HPA axis, and chronic exposure leads to blunted HPA reactivity (Richardson et al. 2008).

The effects of addictive substances on stress response systems are seen at the level of the hypothalamus (corticotrophin-releasing factor, CRH), the anterior pituitary (adrenocorticotropic hormone, ACTH), and the adrenal gland (glucocorticoids – cortisol in humans). They are modulated by signaling molecules in the brain including the endogenous opioids β-endorphin and dynorphin (Bruchas et al. 2010; Sarkar 2012), which exert a tonic inhibition of ACTH reversible by naloxone, neuropeptide Y (Gilpin 2012), leptin, and orexin/hypocretin (Shalev et al. 2010). In response to stress, CRH not only regulates the HPA axis via the pituitary but acts in extrahypothalamic (limbic) areas of the extended amygdala to modulate its emotional consequences.

It has been postulated that activation of the HPA axis by stressful emotional states is a homeostatic process in which diurnal and metabolic signals are "superseded by signals from the limbic system and prefrontal cortex" (Lovallo 2006).

A chronically activated and response-blunted stress response system is postulated to contribute to vulnerability to stress-related and cue-related relapse, to the negative reinforcement which marks the shift from impulsive to compulsive behavior in the development of alcohol dependence (Koob 2013). However, dysregulation of the HPA axis may be related to the current level of alcohol consumption rather than dependence per se (Boschloo et al. 2011). Abnormalities in HPA stress responsiveness persist into, but eventually improve with, alcohol abstinence (Coiro et al. 2007). Elevation of brain glucocorticoids persisting after alcohol withdrawal may contribute to chronic cognitive impairment seen in recovering alcoholics (Rose et al. 2010), and stress-related craving has been associated with poorer alcohol treatment outcomes (Higley et al. 2011).

Similar HPA axis disturbances have been documented with cocaine (Zhou et al. 2010), cannabis (Somaini et al. 2012), benzodiazepines (Heberlein et al. 2008), MDMA (Wolff et al. 2012), and to a lesser extent amphetamines (Uhart and Wand 2009). A relationship has also been shown between elevated cortisol and cognitive impairment in cocaine dependence (Fox et al. 2009).

While tobacco smoking produces acute dose-related effects on HPA hormones, endocrine effects of tobacco cessation are reported as modest (Pickworth and Fant 1998).

Abnormal glucocorticoid responsivity to stress is also associated with depression (Penninx et al. 2013) and with post-traumatic stress disorder (PTSD) with and without alcohol dependence (Brady et al. 2006).

Genetic, prenatal, and early developmental environmental factors play a role in disturbed HPA axis regulation in people with substance dependence. Thus alcohol exposure in utero (Weinberg et al. 2008), in utero cocaine and methamphetamine exposure (Kirlic et al. 2013), prepubertal trauma and chronic stress (Enoch 2011), and childhood neglect (Somaini et al. 2011) have all been implicated in abnormalities in HPA tone later in life. On the other hand, family history of alcohol dependence or heavy alcohol use has not been consistently been associated with cortisol levels or glucocorticoid responsivity (Mick et al. 2012; Huizink et al. 2009; Hardin and Adinoff 2008).

108.2.1.1 Clinical Issues

By contrast with the subclinical HPA disturbance in addiction, overt adrenal dysfunction is relatively uncommon. Among the so-called pseudo-Cushing's syndromes, depression and alcohol use are important causes. Frank hypercortisolism can rarely be caused by excessive alcohol use (Besemer et al. 2011), which is reversible upon alcohol abstinence. The differential diagnosis is difficult, as cortisol may fail to suppress on low-dose dexamethasone suppression tests, and midnight serum or salivary cortisol tests may give false positives; the dexamethasone/CRH suppression test is more specific; specialist consultation is usually required. Alcohol use itself can cause a false-positive result on 24 urinary cortisol assessments (Vilar et al. 2007).

Hypercortisolism has not been reported for other drugs. However, there are case reports of adrenal insufficiency in people using chronic opioids for pain, including

fentanyl (Oltmanns et al. 2005), tramadol, hydromorphone, and methadone, and it is reversible on cessation of opioid. It is unknown how commonly this occurs in people on maintenance treatment for opioid dependence. Untreated adrenal insufficiency can be fatal, and treatment with corticosteroids can improve quality of life where opioid use needs to continue.

A further important diagnostic consideration is the adrenal insufficiency of acute illness (Arafah 2006). Additionally chronic liver disease, in the addiction medicine context most commonly due to alcoholic liver disease or chronic viral hepatitis, can lead to HPA hyporesponsiveness, which in the case of cirrhosis is not related to its etiology (Zietz et al. 2003).

Arising out of animal or small human studies, several possible therapeutic interventions for stress response systems have been proposed as showing promise for the treatment of alcohol dependence. These include the alpha adrenergic blocker prazosin for reducing stress- and cue-induced craving (Fox et al. 2012), the glucocorticoid receptor antagonist mifepristone which in rats prevented escalation of alcohol intake and compulsive responding to alcohol vapor (Vendruscolo et al. 2012), CRF receptor antagonists (Logrip et al. 2011), and the beta adrenergic blocker propranolol which reduced operant alcohol-reinforced responding in rats (Gilpin and Koob 2010). It has been proposed that measures such as cortisol and cortisol/corticotropin (ACTH) ratio may help predict risk of relapse (Sinha 2011). Naltrexone and acamprosate may have effects to prevent the decline of ACTH and cortisol during early alcohol abstinence (Kiefer et al. 2006).

Awareness of possible lifelong neurohormonal effects of in utero exposure to drugs and alcohol should inform counseling for pregnant women and other women of childbearing age.

108.2.2 Gender, Sex Hormones, and Addiction

There is large evidence of sexually dimorphic responses to addictive substances in animals and humans. Broadly speaking, men are at higher risk of alcohol dependence and have higher rates overall of drug use, and women are at higher risk for initiation, a "telescoped" trajectory to dependence for most drugs studied, and have higher rates of relapse (Carroll and Anker 2010). While these differences reflect to some extent social and cultural factors and may reflect pharmacokinetic factors such as lower lean body weight, smaller liver size, and slower metabolism, especially with alcohol and cannabis (Fattore et al. 2009), sex hormonal factors have a role, from puberty on (Kuhn et al. 2010).

The higher risk for males of alcohol dependence (Lenz et al. 2012) appears to be related in part to the actions of testosterone itself. Preclinical studies, and to a lesser extent human studies, suggest also estrogen may facilitate drug use, while progesterone may be protective, attenuating responses to cocaine, alcohol, and nicotine (Anker and Carroll 2010; Lynch and Sofuoglu 2010). Progesterone treatment increased ratings of negative subjective effects and decreased ratings of positive

effects from nicotine in smokers (Sofuoglu et al. 2009). Both progesterone and testosterone reduced cocaine self-administration in female rhesus monkeys, supporting previous evidence that progesterone may be a protective factor (Mello et al. 2011).

There are differences according to female hormonal status: acute doses of alcohol reduced progesterone levels in women both using and not using oral contraceptives (OCs), while only women on OCs showed increases in estrogen levels and there appears little effect of alcohol on these hormones in postmenopausal women (Sarkola et al. 1999; Longnecker and Tseng 1998). The relationship of smoking behaviors to estradiol and progesterone in women is complex, varying over the menstrual cycle and specifically with the ratio of progesterone to estradiol (Schiller et al. 2012).

It is proposed that sex hormones act throughout life causing both *transient* and also *permanent* ("organizational") effects on the brain, such that in utero and early childhood, exposure to sex hormones can contribute to the risk of developing alcohol dependence (Lenz et al. 2012). Additionally, alcohol and cocaine exposure in utero can increase HPA tone throughout later life, and this phenomenon is also sexually dimorphic (Weinberg et al. 2008; Chaplin et al. 2010).

108.2.2.1 Clinical Issues

Accumulating evidence that progestins mitigate or modify and alter the effects of cocaine, alcohol, and nicotine in humans, while conversely drugs can increase progestin levels, suggests a role of progestins in homeostatic response to drug effects and possibilities for their therapeutic use in addiction (Anker and Carroll 2010; de Wit 2011).

In recently abstinent smokers, gender differences in the reinforcing effects of nicotine appear related to differential availability of the β(2)*-nicotinic acetyl chlorine receptor, which was correlated with progesterone levels in female smokers; the authors suggest potential relevance for the effectiveness of nicotine receptor-mediated smoking quit therapies in women (Cosgrove et al. 2012). Blunted HPA axis reactivity associated with alcohol dependence was, surprisingly, not found in a study of abstinent women (Adinoff et al. 2010), raising the possibility that this effect is sexually dimorphic; this may have a bearing on the finding that long-acting injectable naltrexone for alcohol dependence was not significantly effective for women (Garbutt et al. 2005). Women have heightened pain perception and pain-related distress compared with men, for reasons including psychological coping style and possibly hormonal milieu: studies suggest the importance of menstrual cycle phase and a U-shaped relationship of estrogen with pain experience (Paller et al. 2009).

More research is needed into the treatment implications of gender-based differences in drug use initiation, craving and relapse, and the possibility of gender-specific interventions. Similarly, clinicians might consider that stage of menstrual cycle may be important in relation to quit and relapse from drugs and alcohol, though much more research is needed into this phenomenon before specific inferences can be drawn for clinical practice.

108.2.3 Disturbance of the HPG Axis and Gonadal Hormones

Psychoactive substance-related disturbances of the hypothalamic-pituitary-gonadal (HPG) axis are most prominently related to alcohol and opioid use. While alcohol has complex actions including direct toxic effects on the gonads, liver disease, and central nervous system opioid effects, by contrast, the action of opioids is mainly through their action on opioid receptors.

As with the HPA axis, changes in the HPG axis were extensively investigated in the early day of MMT. Hormonal changes and related clinical manifestations, including hypogonadism in males and menstrual irregularities in women, were found to be common in heroin addiction and generally, gradually, to improve with MMT (Schmittner et al. 2005; Kreek et al. 2002; Zhou et al. 2010). Nonetheless varying degrees of hypogonadism have been shown to be prevalent in men receiving MMT (Bliesener et al. 2005; Hallinan et al. 2009) and men receiving opioids for chronic pain, in which case it is more clearly treatment emergent (Daniell 2002). In cross-sectional studies, men on buprenorphine maintenance have not had lower testosterone levels than controls, but a case series of buprenorphine-associated hypogonadism shows that this can occur (Bliesener et al. 2005; Hallinan et al. 2009; Colameco and Zimmerman 2008).

Ample evidence attests to the potential of chronic opioid use to cause hypogonadotropic hypogonadism, in both men and women, owing to opioid-mediated increase of tonically inhibitory hypothalamic dopaminergic tone. In women this may include both low estradiol and testosterone levels; the mechanism of the latter may include suppressed adrenal androgen production (Daniell 2008).

Both cannabis and alcohol use reduce luteinizing hormone (LH) secretion, partly mediated in both cases by cannabinoid type 1 receptors at the level of the hypothalamus. However, neither cannabis nor tobacco smoking has been consistently associated with hypogonadism in humans; indeed male tobacco smokers have been found to have higher testosterone levels than nonsmokers (Brown and Dobs 2002; Blanco-Munoz et al. 2012), and tobacco smoking was associated with higher levels of adrenal androgens in women (Daniell 2006). Nor is there evidence of hypogonadism associated with cocaine.

Symptoms of hypogonadism may be relatively specific, such as hypoactive sexual desire, erectile dysfunction, and reduced sperm quality and quantity in men and hypomenorrhea, amenorrhea, and other menstrual irregularities in women. Less specific clinical features include low mood and energy, loss of muscle strength and mass, and osteoporosis, in both sexes.

Dehydroepiandrosterone sulfate (DHEAS) deficiency has been reported in pregnant women on methadone maintenance during pregnancy, relative to controls (Facchinetti et al. 1986), and in men and women chronically using sustained-action prescribed opioids (Daniell 2006). DHEA and its sulfate are the most abundant steroid hormones in humans and are primarily of adrenal origin (but also from the fetus in pregnant women). Their production is ACTH and probably CRH dependent, and the mechanism of opioid-associated deficiency may be CRH inhibition. DHEAS deficiency is associated with similar symptoms to testosterone

deficiency. The prevalence and clinical importance of DHEAS deficiency in opioid-dependent people require further investigation.

Hypogonadism associated with heavy alcohol use is found in both men and women and with liver cirrhosis of whatever cause (Kaymakoglu et al. 1995). Women with cirrhosis related to alcohol and other causes commonly develop amenorrhea which frequently shows low LH and intact response to gonadotropin-releasing hormone, indicating a hypothalamic rather than pituitary cause (Bell et al. 1995). In men several mechanisms are at work including impaired LH binding to Leydig cells, reduced testicular steroid hormone formation, and actions of alcohol at the level of the hypothalamus (Van Steenbergen 1993).

Male hypogonadism and the commonly, but not universally, associated signs of feminization with liver cirrhosis appear to be multifactorial, with elevated estradiol, DHEAS, and serum hormone-binding globulin (SHBG) and reduced free and total testosterone concentrations commonly found, and these changes related to Child's cirrhosis grade; the hypogonadism appears to be of hypothalamic origin (Kaymakoglu et al. 1995; Handelsman et al. 1995). Both hormone changes and sexual dysfunction were reported to be more severe in cirrhotics where alcohol was the cause (Bannister et al. 1987).

Heavy chronic alcohol use also causes hypogonadism in the absence of severe liver disease. Ethanol intoxication and withdrawal in males are associated with low androgen levels and elevated SHBG, and these tend to improve with abstinence (Iturriaga et al. 1999). Male alcoholics during withdrawal showed low mean levels of testosterone and SHBG, with elevated follicle stimulating hormone (FSH) and LH declining during recovery (Ruusa et al. 1997). About a third of male alcoholics were hypogonadal at the beginning of withdrawal management, while 1 in 5 developed hypogonadism during withdrawal, the majority recovering slowly over time (Kruger et al. 2006). A group of young male heavy alcohol users were found to have low mean plasma testosterone with both low LH and FSH, suggesting hypothalamic/pituitary impairment and evidence of impaired antioxidant function, which could impair function of Leydig and Sertoli cells (Maneesh et al. 2006).

Studies of gonadal hormone testing in relation to alcohol use in women have given heterogenous results, probably reflecting menstrual cycle phase and menopausal status, acute versus chronic effects of alcohol, presence or absence of liver and other disease, and clinical versus population samples. Low testosterone, elevated estradiol, and decreased FSH in premenopausal women have been reported in women drinking alcohol, though inconsistently (Verkasalo et al. 2001). Half of a group of 30 alcoholic women showed low progesterone and a third had low LH during early withdrawal; in addition to HPG suppression and alcohol-induced increase in prolactin, toxic effects of alcohol on the ovaries are suggested to explain these findings (Augustynska et al. 2007).

108.2.3.1 Puberty

In animal studies, alcohol consumption can delay female puberty (Dees et al. 2009), but few studies are available for the effect of prepubertal drug and alcohol use in humans. Girls who used alcohol before puberty had four times the odds of delayed

puberty compared with nonusers; more modest effects of alcohol and tobacco were noted in delayed breast development (Peck et al. 2011).

While several studies have shown early menarche to be associated with higher risk of initiation of substance use and of alcohol abuse, possibly reflecting psychosocial and hormonal factors, a large Canadian population study has not found alcohol, tobacco, or other drug use to be associated with age of menarche (Al-Sahab et al. 2012). Early puberty may be associated with higher levels of later substance use because the adolescent risk period is entered at a younger age (Patton et al. 2004).

108.2.3.2 Human Fertility

There have been fewer studies of the effects of alcohol and other drugs on fertility in women than in men. Alcohol reduces sperm quality and quantity both through reduced testosterone and direct toxic effects on the Sertoli cells of the testes, but is not associated with male infertility in population-based studies or infertility clinic samples (La Vignera et al. 2013). Sperm quality has been shown in two studies to be impaired in heroin users and men on MMT, though no information was provided on tobacco or alcohol use in these studies; it is possible that this improves on MMT when there is no additional heroin use (Ragni et al. 1988; Cicero et al. 1975). Tobacco smoking was associated with reduced sperm quantity and quality in men and impaired fertility in women, in a recent literature review (Sadeu et al. 2010), but this was not the case for other drugs studied. There is modest evidence for a negative effect of cannabis on sperm concentration and morphology in men (Kolodny et al. 1974), and a case control study of women with primary infertility showed significantly increased risk of ovulatory infertility in women who had recently smoked cannabis (Mueller et al. 1990; see Brown and Dobs 2002) for a review of preclinical evidence regarding cannabis and fertility). Tobacco use is a possible confounder in clinical studies of cannabis and fertility; most cannabis smokers also use tobacco.

In a case control study of women with infertility, odds ratio for ovulatory infertility were 1.3 (95 % CI 1.0, 1.7) for moderate and 1.6 (95 % CI 1.1, 2.3) for heavier alcohol drinkers, compared with nondrinkers (Grodstein et al. 1994). A prospective study of couples planning first pregnancy found dose-related lower rates of conception among women drinking alcohol (Jensen et al. 1998). By contrast a large prospective population study did not find alcohol use (or caffeine use) to be associated with reduced ovulatory fertility after adjusting for confounders including parity (Chavarro et al. 2009), which may reflect low prevalence of higher alcohol use in this sample.

Anovulation or oligoovulation can be reasonably inferred from menstrual disturbance including amenorrhea. Treatment emergent amenorrhea is common in women treated with opioids for chronic pain. It is common for menstrual periods to return even after prolonged amenorrhea in methadone-treated heroin users (Schmittner et al. 2005). Ovulation can occur despite amenorrhea in opioid-dependent women.

Testosterone and anabolic-androgenic steroids are available on prescription for medical indications, including wasting associated with AIDS and with chronic corticosteroid use. They are also commonly available off prescription and used

by sportsmen to improve performance and "body builders" to increase muscle bulk and strength. Anabolic-androgenic steroid dependence is now a recognized entity, described as developing in about 30 % of AAS users, and appears to involve endogenous opioid and mesolimbic dopaminergic pathways. There are similarities to other substance dependence syndromes including continued use despite awareness of harms and a withdrawal syndrome, albeit mild, on a par with nicotine. There are also differences including low dependence liability compared with other drugs and the relative lack of intoxication, euphoria, or other immediate psychoactive reinforcement but rather psychological reinforcement in terms of body image and other desired effects (Hildebrandt et al. 2011).

108.2.3.3 Clinical Issues

Chronic pain is common in opioid-dependent people and in alcohol-treatment-seeking populations, both of which groups may be at risk of hypogonadism. Although the relationship between chronic pain and alcohol use has been little studied, it is likely that dependence may arise out of self-medication of chronic pain with alcohol, as also with opioids, including over-the-counter and illicit sources. Pain sensitivity may be increased in hypogonadism, and there is some evidence for therapeutic benefit of estrogens and testosterone in hypogonadal states and post-menopausal women, for improving pain management (Daniell 2002, 2008).

While an opioid dose relationship with hypogonadism has not been consistently demonstrated in cross-sectional studies, this may reflect interindividual variation in opioid tolerance and pharmacokinetics. In practice, hypogonadism and its symptoms commonly abate with reduced opioid dose or weaning. Opioid rotation may facilitate reduction of opioid load, as may use of non-opioid pain medications and therapies. Men on MMT might benefit from transfer to BMT: this may amount to an opioid dose reduction as buprenorphine is a partial agonist opioid.

The place of hormone replacement for opioid treatment-related hypogonadism is not clearly established in guidelines (Katz and Mazer 2009). However, in some cases, hormone replacement may be indicated where opioid therapy is required long term, whether for chronic pain or opioid dependence, and where symptoms of hypogonadism are onerous or are affecting treatment adherence (Daniell 2002; Hallinan et al. 2009). Several studies suggest low testosterone in males to be a risk factor for suicidality (Sher 2002). The benefits of androgen replacement in HIV-infected men with hypogonadism are well established (Ponte et al. 2009).

Diagnosis of opioid-related hypogonadism in women can be made on the basis of amenorrhea or oligomenorrhea with or without menopausal symptoms, earlier in life than the expected menopause, with low estradiol and testosterone levels but normal or low FSH and LH (in contrast to the postmenopausal state, where FSH and LH are raised).

In men the diagnosis of hypogonadism is relatively straightforward. Owing to pulsatile and diurnal variability of testosterone levels, assays should be performed on morning samples and on more than one occasion. Clinicians should bear in mind that there may be a degree of acute opioid dose-related suppression of testosterone and time blood tests accordingly. Published guidelines for a threshold for androgen

supplementation treatment vary from total testosterone 6.8 nmol/L (200 ng⁄dl) to 10.4 nmol/L (300 ng⁄dl), but most recommend about 8 nmol/L (230 ng⁄dl) (Smith and Elliott 2012). Measurement of total testosterone may suffice (Conway et al. 2000). Measurement of gonadotropins (LH and FSH) enables distinction between primary and secondary (hypogonadotropic) hypogonadism. In the case of the latter, FSH and LH are low or normal, indicating the lack of an appropriate pituitary response to low testosterone. In this case the possibility of pituitary disease, most commonly a pituitary adenoma or hemochromatosis, requires measurement of other pituitary hormones including prolactin and TSH and iron studies.

Given the established risk of osteoporosis in hypogonadal men and women (including postmenopausal women) and the established benefits of hormone replacement to preserve and even improve bone density, bone densitometry should be performed if available, where hypogonadism is persistent, especially where there are other risk factors such as chronic liver disease (see Sect. 108.2.7).

The decision whether or not to treat hypogonadism depends on an assessment of whether it appears symptomatic (low mood, energy, muscle strength, sexual dysfunction), whether the person is likely to benefit from hormone replacement, possible side effects and contraindications (in men these include obstructive sleep apnea, structural heart disease, and prostatic cancer – prostate-specific antigen surveillance and digital rectal prostatic examination are indicated), and the acceptability of alternative management including reducing opioid doses. It may be considered inappropriate to prescribe hormone replacement where there is ongoing problematic alcohol or illicit opioid use. In the absence of randomized controlled trials of androgen replacement for opioid-related hypogonadism, treatment decisions should be made on an individual basis.

Treatment of hypogonadism in women is generally some form of hormone replacement with estrogen with or without progestins in oral, transdermal, or intravaginal forms depending on the symptoms being treated and potential side effects including possibly increased risk of breast cancer and atherosclerotic disease (Katz and Mazer 2009). There is little evidence for testosterone supplementation in hypogonadal women except for hypoactive sexual desire (see ▶ Chap. 109, "Sexual Function and Alcohol and Other Drug Use").

Impaired sperm production and persistent hypogonadism are possible consequences of use of pharmaceutical androgens or anabolic steroids, whether prescribed or nonprescribed, but most described cases involve nonprescribed use of supra-therapeutic doses. The implications for male fertility of androgen replacement for hypogonadism or wasting states are unclear. It is suggested that any assessment of androgenic steroid use should include consideration of persistent consequences upon cessation of their use (Tan and Scally 2009).

Although benefits of DHEAS replacement treatment for deficiency states have been demonstrated for other conditions including depression, the place of DHEAS replacement in opioid-dependent people requires further investigation.

There are high rates of unplanned pregnancy in substance-dependent populations. Given that menstrual periods can return even after prolonged amenorrhea in substance users, especially with stabilization of opioid-dependent women on opioid

pharmacotherapy and with abstinence in alcohol-dependent women, it is important to consider issues of contraception in counseling and medical practice in this population.

Given the strong evidence for reduced fertility with tobacco smoking, and the more modest evidence suggested risk attributable to alcohol and cannabis, it is prudent to recommend cessation of these substances where fertility is a problem.

108.2.4 Prolactin, Gynecomastia, Oxytocin, and Addiction

Mesolimbic dopaminergic pathways are central to the reinforcement of most addictive substances. Dopamine also acts in the tuberoinfundibular pathway as a prolactin inhibitor. There is, as with steroid hormones, evidence that prolactin is stress responsive and plays an important modulating role in the pathogenesis of addiction for several substances. For example, there is evidence of a negative correlation of serum prolactin and craving in women during alcohol withdrawal (Hillemacher et al. 2005) and of increased prolactin reserve in alcoholics during withdrawal (Basile et al. 1981).

Endogenous oxytocin is emerging as playing a central role in "empathogenic" effects of MDMA and GHB. Alcohol also stimulates release of oxytocin from the posterior pituitary, and in animals oxytocin administration can prevent development of tolerance to ethanol and opiates and self-administration of methamphetamine (Rettori et al. 2010; McGregor and Bowen 2012).

Frank hyperprolactinemia is associated with the use of numerous medications, including antidopaminergic agents such as antipsychotics, as well as with alcohol. There are case reports of hyperprolactinemia in alcoholic men and women, and animal studies suggest the mechanism to involve both increased prolactin release and stimulation of lactotrope growth in the anterior pituitary (Sarkar 2012). Cannabinoids, by contrast, inhibit prolactin release (Rettori et al. 2010), and there is no reported association of cannabis use with hyperprolactinemia (Brown and Dobs 2002).

Heroin users have been found to have acutely elevated prolactin levels, which appears to normalize with MMT where, in contrast to opioid treatment for chronic pain, clinically relevant hyperprolactinemia is uncommon in the absence of liver disease (Kreek et al. 2002; Hallinan et al. 2009; Moshtaghi-Kashanian et al. 2005; Trajanovska et al. 2013; Rhodin et al. 2010).

Cocaine is reported as causing acute suppression but chronic elevation of prolactin; while chronic cocaine users had higher prolactin levels than controls, elevation outside normal ranges was uncommon, and prolactin levels also do not predict treatment response (Walsh et al. 2009; Patkar et al. 2004) (Gorelick and Wilkins 2006). Chronic methamphetamine users during abstinence had higher prolactin levels than controls (Zorick et al. 2011), but clinical hyperprolactinemia has not been reported for amphetamine use.

Prolactin elevation may be asymptomatic or be associated with amenorrhea and other menstrual disturbances, sexual dysfunction, galactorrhea, and gynecomastia. The relationship between gynecomastia and hyperprolactinemia is complex.

Both gynecomastia and hyperprolactinemia may occur in chronic liver disease: suggested mechanisms include gynecomastia-inducing properties of prolactin and altered estrogen/androgen ratios.

Gynecomastia may occur without hyperprolactinemia, and while prolactin levels have been reported as higher in men with gynecomastia, there appears to be no relationship between prolactin levels and gynecomastia in cross-sectional studies of people with liver disease (Farthing et al. 1982). Grun (1985) reported the prolactin levels of cirrhotic women to be no higher than controls, suggesting that cirrhosis per se does not cause hyperprolactinemia. Farthing et al. (1982) found progesterone was raised in 72 % of men with liver disease, suggesting a possible causative role for progesterone in gynecomastia in this context. Men with alcoholic liver disease had increased circulating levels of androstenedione compared with men with idiopathic hemochromatosis, in whom gynecomastia is rare (Kley et al. 1985).

Animal studies suggest maternal alcohol consumption can interfere with prolactin and oxytocin function during lactation and in non-lactating women (see Heil and Subramanian (1998) for a review). Moderate doses of alcohol reduced milk production and ejection in lactating women, and lactating women with a family history of alcoholism were shown to have a blunted prolactin response to breast stimulation and an alcohol challenge (Mennella and Pepino 2010).

108.2.4.1 Clinical Issues

Hyperprolactinemia in the absence of an obvious cause will usually prompt investigation for a possible pituitary adenoma, which involves at least the assessment of other pituitary hormonal function and examination of visual fields. Where there is a high probability of it being related to drugs, the clinician may feel it is not necessary to perform expensive (CT, MRI) imaging studies of the pituitary fossa. A plain X-ray of the pituitary fossa is seldom helpful.

Hyperprolactinemia is commonly asymptomatic but can be associated with anovulation and oligo- or amenorrhea and causes reduced milk production in lactating women. It is considered a cause of sexual dysfunction (see ► Chap. 109, "Sexual Function and Alcohol and Other Drug Use"). Where hyperprolactinemia is symptomatic with the use of psychoactive drugs, dose reduction or discontinuation may be necessary.

The probability diagnosis of gynecomastia in men with chronic liver disease or heavy alcohol use should generally be tested with ultrasound imaging and hormone profiling, as breast cancer in men and prolactin-secreting adenomas are important diagnoses which should not be missed. Galactorrhea may uncommonly be associated with methadone use, as may gynecomastia, which may improve with dose reduction. In this connection, Krause (2012) advises caution in attributing causality where there is association: neither methadone in particular nor opioids in general, nor amphetamines, are statistically significantly associated with gynecomastia in the published literature.

When measuring prolactin levels in people on MMT, it should be borne in mind that an acute opioid dose-related elevation of prolactin, though diminished, persists in MMT (Bart et al. 2003). Blood testing should be timed accordingly.

Trials of intranasal oxytocin in conditions manifesting deficits in social behavior, including autism and schizophrenia (De Berardis et al. 2013; Domes et al. 2013), have shown early promise, and some hopes are held for oxytocin for addiction treatment, especially in amphetamine dependence, specifically for social deficits seen with narrowing of the behavioral repertoire and neglect of nondrug-related activities (McGregor and Bowen 2012).

Information about the presence of alcohol in breast milk and possible consequences of alcohol for production of breast milk is important for counseling against alcohol use by breast feeding women.

108.2.5 Thyroid Function and Addiction

With the exception of alcohol and tobacco, thyroid disturbance is not commonly reported as arising from use of addictive substances. Methadone-maintained patients showed elevations of total T3, T4, and thyroxin-binding globulin compared with controls; however, free T3 and T4 and thyroid-stimulating hormone (TSH) were normal, confirming the clinically euthyroid condition of subjects. These and similar changes reported in heroin users changes likely represent changes in thyroid binding globulin and are generally not significant clinically (Kreek et al. 2002). Neither cannabis nor psychostimulants have been associated with increased prevalence of thyroid disorders.

Tobacco smoking is a risk factor for Graves disease and Graves ophthalmopathy (Stan and Bahn 2010; Asvold et al. 2007), and this risk reduces on tobacco cessation. Smoking also appears to reduce thyroid autoantibodies and reduce risk of hypothyroidism (Asvold et al. 2007; Mehran et al. 2012). The mechanisms may involve tobacco constituents other than nicotine.

Several lines of animal research converge to suggest a possible role of the hypothalamic-pituitary-thyroid (HPT) axis in the neurobiology of alcohol dependence, including craving, withdrawal, and relapse (Rasmussen 2003; Hashimoto et al. 2011).

In humans, most studies have assessed alcoholics during withdrawal or abstinence rather than ongoing drinking; liver disease, depression, stress, and other drug use are confounders for assessing thyroid function in alcoholics. Blunting of the TSH response to thyrotropin-releasing hormone (TRH) has been a common finding, and this often persists into abstinence (Hermann et al. 2002). Measurement of T4 and T3 during alcohol withdrawal have given highly variable results, which may reflect confounding factors including liver disease, changes in assays, effects of withdrawal treatment, and heterogenous trait and state psychological conditions within the study populations (Ozsoy et al. 2006). Liappas et al. (2006) have reported normalization of thyroid function tests after alcohol withdrawal and correlation of thyroid hormones and mood. A toxic effect of alcohol on the thyroid, with reduced thyroid hormone production causing chronically elevated TRH and downregulation of TRH receptors, is posited as a unifying mechanism for these various effects (Hermann et al. 2002).

Relationships between alcohol craving and free T3 (direct) and TSH (inverse) have been demonstrated in alcohol-dependent patients treated with baclofen (Leggio et al. 2008).

108.2.5.1 Clinical Issues

Addiction medicine clinicians should be alert to the possibility of thyroid disorders and to the wide range of possible causes in their patient populations. Hypo- and hyperthyroidism are standard differential diagnoses where there are comorbid mood or anxiety disorders.

Both subclinical and clinical hypothyroidism have been associated with clinical depression and cognitive impairment and may increase the relapse risk among alcoholics. It has been suggested that subclinical hypothyroidism can contribute to cognitive impairment and depression which may diminish capacity for alcohol abstinence (Hermann et al. 2002; Sher 2002). FT3 levels were elevated and correlated with number of traumatic events and increased arousal in soldiers with PTSD both with and without alcohol dependence (Karlovic et al. 2004).

Clinicians should bear in mind that calcitonin levels may be elevated in chronic alcoholism (Vantyghem et al. 2007) and by tobacco smoking (d'Herbomez 2011) which can cause confusion in diagnosis and follow up of medullary thyroid cancers.

108.2.6 Appetite Factors, Obesity, Diabetes, and Addiction

There is emerging evidence of the involvement of several appetitive hormones not only in the intake of food but also in the neurochemistry of substance dependence, especially in alcohol dependence and craving. In the central nervous system (CNS), these include the satiety factor leptin and orexin, which is appetite-stimulating. Derived from the gut, circulating peripherally but also active in the CNS, is the appetite-stimulating peptide ghrelin.

Leptin and ghrelin are involved in the hypothalamic regulation of energy homeostasis and also integrated at the level of the hypothalamus with prolactin and ACTH, thereby connecting appetite regulation with the HPA axis (Wurst et al. 2007), with mesolimbic reinforcement pathways, and with the orexigen neuropeptide Y (Leggio et al. 2011).

Ghrelin, which is increased by physiological stress (Schellekens et al. 2012), was positively correlated with alcohol craving in men in early abstinence (Koopmann et al. 2012) and is important in alcohol reward (Leggio et al. 2011). In animal models, leptin appears important in mediating dopaminergic reward for alcohol, cocaine, and amphetamines (Jerlhag et al. 2010). While leptin plasma concentrations correlated positively with nicotine craving in withdrawing tobacco smokers, orexin plasma concentrations correlated negatively with nicotine craving (von der Goltz et al. 2010). Orexin is released into the VTA in response to several drugs (Borgland et al. 2010) and was strongly positively correlated with alcohol withdrawal symptoms (von der Goltz et al. 2011).

Much interest centers on neurohormonal commonalities of substance dependence and "behavioral addictions," especially food addiction (Grosshans et al. 2012; Volkow et al. 2013). Food-induced activation in human mesolimbic reinforcement pathways was found to be correlated with plasma concentration of leptin (Grosshans et al. 2012). Smokers with pathological eating behavior had evidence of raised leptin levels (Koopmann et al. 2011).

Insulin resistance and leptin resistance are both hallmarks of obesity, leptin resistance apparently contributing to food craving (Pandit et al. 2011). Insulin signaling modulates effects of drugs on dopamine neurotransmission in human mesolimbic reinforcement pathways, providing a link between the "metabolic milieu" and hedonic centers for feeding: the clinical relevance of this for addictive substances remains to be elucidated (Daws et al. 2011).

Endogenous opioids, mainly though the mu-receptor, also play a role in promoting motivation for food intake (Olszewski and Levine 2007). Weight gain is common during methadone maintenance treatment, and while this is commonly an increase from a status of low body mass index (BMI) or underweight in people using illicit opioids, towards normality (Okruhlica and Slezakova 2012), obesity does develop in some people on MMT (Szpanowska-Wohn et al. 2004). One year of MMT normalized the decreased serum leptin (but not the decreased serum adiponectin and increased resistin concentrations) found in 12 heroin addicts compared with controls (Housova et al. 2005).

Like heroin users, stimulant users are commonly underweight. Amphetamine was widely prescribed in the 1950s and 1960s as obesity treatment, especially in the USA, and dependence commonly ensued. Of interest is the fact that cocaine- and amphetamine-regulated transcript (CART), an endogenous psychostimulant neuropeptide shown to mediate some exogenous psychostimulant-related behaviors, is also a satiety factor.

In utero exposure to tobacco smoking is associated with obesity later in life (Lisboa et al. 2012). Tobacco smokers have lower BMI than controls but higher abdominal adiposity, largely accountable by lifestyle differences, but heavier smokers have higher BMI than lighter smokers; all smokers are at risk of weight gain on cessation (Pisinger and Jorgensen 2007). Both tobacco smoking and nicotine replacement treatments are associated with insulin resistance (Chang 2012), and this like obesity is a risk factor for type 2 DM. Despite the known effects of cannabis to increase appetite, a large general population study has found prevalence of obesity to be lower in cannabis users than in nonusers (Le Strat and Le Foll 2011).

The association of alcohol with body weight, obesity, and related complications is complex. There is some evidence that low-level and frequent alcohol use may have a protective effect against obesity, compared with nondrinking, whereas higher-level and binge-style drinking increases the odds of overweight and obesity (Arif and Rohrer 2005). A large prospective study of Caucasian men showed alcohol consumption to be unassociated with central obesity, negatively associated with incidence of the metabolic syndrome and HDL concentrations, and positively associated with higher fasting glucose concentrations (Stoutenberg et al. 2013).

Number of weekly drinking occasions was found to be a risk factor for obesity independent of total alcohol intake (Dumesnil et al. 2013). In another large community study, moderate-to-high consumption of alcohol and of beer and spirits was associated with later development of high waist circumference, whereas moderate-to-high wine consumption appeared to have the opposite effect (Vadstrup et al. 2003). Acute alcohol intake increases insulin resistance, but chronic alcohol use has a U- or J-shaped relationship, with insulin resistance and prevalence of metabolic syndrome increasing with alcohol intake over 40 g/day in men and probably less in women; hepatic steatosis may have a role in this insulin resistance (Alkerwi et al. 2009; Ramirez et al. 2013).

Most of the apparent benefit of low-dose alcohol use in reducing risk of coronary heart disease is thought to be related to beneficial effects on cholesterol – with reduced LDL and increased HDL. However, heavier alcohol use is associated with elevations of triglycerides and hypertension, with increased risk of coronary heart disease and mortality from other causes.

108.2.6.1 Clinical Issues

Chronic alcohol use tends to worsen hyperglycemia and may worsen insulin resistance, being thus a risk factor for type 2 diabetes mellitus (T2DM). The metabolism of alcohol via the alcohol dehydrogenase pathway depletes the body of nicotinamide adenine dinucleotide (NAD), which is necessary for gluconeogenesis. Consumption of alcohol in a fasting state can contribute to risk of hypoglycemia, in both diabetics and nondiabetics, owing to impaired gluconeogenesis and reduced cortisol and growth hormone response to hypoglycemia. Such hypoglycemia may respond poorly to therapeutic glucagon injection, owing to depletion of liver glycogen stores.

Heavy alcohol use can cause ketoacidosis in both diabetic and nondiabetic people, especially T2DM, owing a combination of insulin resistance, decreased gluconeogenesis, fasting and depletion of glycogen, and dehydration. This ketoacidosis is usually nonhyperglycemic and beta-hydroxybutyrate predominates over other ketones (Umpierrez et al. 2000), which can lead to negative results on standard ketone tests of serum and urine.

Recent cocaine use has been reported associated with increased risk of diabetic ketoacidosis (DKA), owing to a combination of poor treatment adherence and possibly metabolic effects of catecholamines (Nyenwe et al. 2007). There are case reports of DKC associated with MDMA use (Gama et al. 2010); however, this has not been reported for amphetamines.

Chronic hepatitis C is associated with increased risk of diabetes mellitus and insulin resistance, which reciprocally are associated with more rapid HCV disease progression and poorer outcomes from interferon-based treatments (Badar et al. 2012). Both acute and chronic alcoholic pancreatitis may progress to diabetes mellitus; tobacco smoking is also independently associated with chronic pancreatitis (Law et al. 2010).

For diabetics using insulin or oral hypoglycemic agents, poor adherence to medications, neglect of nutrition, and unawareness of the warning signs of hypoglycemia that may result from use of psychoactive drugs, especially but not only

alcohol, are often harmful and dangerous. Hypoglycemia of whatever cause, including frank malnutrition, and preference for simple sugars or alcohol over complex carbohydrates can also lead to symptoms closely resembling anxiety and panic, which should be borne in mind in evaluating patients who appear to "self-medicate" anxiety with psychoactive drugs.

Metformin and troglitazone are potentially dangerous where there is hepatic impairment, as for instance with alcoholic liver disease or chronic viral hepatitis in injection drug users.

While recovery from underweight is welcome, development of overweight and obesity on MMT is of concern, especially given the high prevalence of chronic HCV in this population and the additional risk of hepatic steatosis. Dietary deficiencies including high proportion of total energy derived from sugar and low dietary fiber have been identified in women on MMT (Zador et al. 1996) and are likely to contribute to risk of obesity and diabetes as well as the unpleasant but under-recognized symptoms of chronic constipation.

Weight gain after tobacco smoking cessation and independently increased risk of T2DM are important clinical problems, especially in people who use other drugs and/or alcohol, for whom smoking may be a "last remaining pleasure" but the greatest health risk. Weight gain is common after people quit tobacco smoking and can be a common reason for failure to quit or relapse after quitting. While they are used, bupropion, fluoxetine, NRT, and varenicline all reduce the weight gain of smoking cessation, but the effect is not demonstrably sustained; only exercise interventions show convincing benefit (Farley et al. 2012).

The nexus of addictive and appetitive factors is nicely illustrated by the case of cannabinoid antagonists (rimonabant and taranabant), which have been trialed rather for weight reduction and smoking cessation, than for treatment of cannabis dependence (possibly reflecting the more substantial commercial possibilities of pharmacotherapies for these indications). Sadly, safety issues have limited the development of cannabinoid antagonists to date.

Among other potential therapies in the future, it is suggested that ghrelin antagonists might affect alcohol-seeking behavior (Leggio 2010); leptin has been proposed as a potential treatment for obesity; in an animal study, the unselective opioid antagonist naltrexone decreased both hedonic and incentive types of motivation, where the μ-selective antagonist GSK1521498 decreased only incentive motivation, suggesting its potential usefulness as a possible treatment of binge eating (Giuliano et al. 2012).

108.2.7 Bone Metabolism

Use of a number of psychoactive drugs appears to increase risk of disorders of bone metabolism, principally osteopenia and osteoporosis. A challenge for the epidemiologist in understanding causation and the clinician in treating these conditions is that drug exposures and other risks including liver disease, dietary deficiency, poor exercise, and sunlight exposure are commonly multiple in the one person.

From population-based studies, including twin studies, the risk of tobacco smoking for osteoporosis is unequivocal: risk is greatest for reduced bone mineral density (BMD) at the hip, is greater in men than women, is less in premenopausal women, increases with age and total exposure, and decreases eventually with smoking cessation; fracture risk is also increased, independently of BMD (Ward and Klesges 2001). Lower bone mineral density has been shown in adolescent girls who smoke before menarche (Lucas et al. 2012) and was evident in young male military recruits who smoked tobacco, despite their relatively short smoking histories (Eleftheriou et al. 2013). Mechanisms that have been proposed include reduced calcium absorption, effects of smoking on weight – increased body weight short of marked obesity being generally protective against osteoporosis – and altered estrogen production and metabolism (Wong et al. 2007).

Evidence for alcohol is more equivocal. Like smoking, heavy alcohol use is identified as highly prevalent in men presenting with osteoporosis (Peris et al. 2008), but meta-analyses of population-based studies suggest a J-shaped association of increasing alcohol consumption with fracture risk and a positive linear relationship with mineral bone density, i.e., alcohol may increase risk of falls but be protective against osteoporosis (Berg et al. 2008). Population studies however may not capture risk of higher-level alcohol use. High rates of vertebral fractures and low bone density have been identified in alcohol-dependent men and women (Clark et al. 2003; Peris et al. 1995). Osteoporosis is common in people with severe liver disease (Monegal et al. 1997; Uretmen et al. 2005), but where there is no liver disease or hypogonadism, mineral bone density in men with alcohol dependence has not consistently differed from controls and generally not in women (Malik et al. 2009; Odvina et al. 1995). Unaccounted factors including nutritional status, smoking, and amount of alcohol used might explain these inconsistencies.

Several mechanisms have been proposed to explain the range of effects of alcohol on bone, from increased estrogen levels protecting bone with moderate alcohol use to oxidative stress and impaired osteoblast activity with heavier drinking. Among the more consistent findings have been low serum vitamin D and the bone formation marker osteocalcin in heavy alcohol users. Among postmenopausal low-level alcohol users, abstinence from alcohol increased and resumed alcohol use decreased osteocalcin and the resorption marker C-terminal telopeptide, suggesting that alcohol inhibits bone turnover in this female population (Marrone et al. 2012). The osteopenic state in alcoholism is characterized by decreased bone formation and remodeling rather than increased bone resorption and remodeling as occurs with hypogonadism (Chakkalakal 2005). Several studies suggest the reversibility of changes in bone formation markers and bone density with prolonged abstinence.

Two studies have reported low BMD in methamphetamine users compared with controls: Japanese prison convicts measured at the calcaneus by Achilles ultrasound bone densitometer (Katsuragawa 1999) and hospitalized Korean methamphetamine users assessed by DEXA (Kim et al. 2009a); neither study controlled for other major causes of reduced bone density. BMD was assessed in a baseline cohort of 210 HIV-negative men who have sex with men as part of an HIV prophylaxis trial: the

use of amphetamines (OR = 5.9) and inhalants (OR = 4.6) was significantly associated with low BMD (Liu et al. 2011). There are no published studies of the specific effects of cocaine on bone metabolism in humans, nor for cannabis. Preclinical research of interest includes the role of the cocaine-amphetamine-related transcript (CART) in bone metabolism and the role of cannabinoid CB2 receptors, which are expressed in osteoblasts and osteoclasts: the CNR2 gene which encodes CB2 is associated with low bone mineral density in women (Bab et al. 2009).

Low BMD has been reported in users of chronic opioids in a number of settings. In people treated with opioids for chronic pain, hypogonadism is an important treatable cause of osteoporosis (Fortin et al. 2008). Low bone density has been reported in recent heroin users in two studies (Pedrazzoni et al. 1993; Wilczek and Stepan 2003): former heroin addicts did not differ from controls, and after a year of methadone maintenance, osteoresorption and osteoformation markers, though not bone density, normalized. Also a majority of patients (74 %) on injectable heroin maintenance treatment were found to have low bone mineral density (Dursteler-MacFarland et al. 2011).

Osteoporosis was reported in 35 % and osteopenia in 48 % of MMT patients in Boston, a high latitude North American city, with male gender, lower weight, and heavy alcohol use significantly associated with lower BMD, and high prevalence (52 %) of low vitamin D in the same MMT population, for which black or Hispanic ethnicity was a risk factor (Kim et al. 2006, 2009b). Mean BMD was also low for men, but not women, on MMT in New Zealand (Grey et al. 2011). These studies have used reference ranges or populations rather than control groups for BMD. Three studies comparing people with HIV with HIV-negative people at risk of HIV have found methadone treatment to be an independent risk factor for lower BMD in men and women and for decline in BMD in women (Arnsten et al. 2006, 2007; Sharma et al. 2011); other risk factors included HIV seropositivity, HCV seropositivity, older age, non-black race, lower body weight, postmenopausal status, age, and tobacco smoking.

108.2.7.1 Clinical Issues

In populations using alcohol and other drugs, comprehensive assessment and management should involve attention to issues of bone health. This may involve screening for osteoporosis using dual-energy X-ray absorptiometry (DEXA) where available; insurance cover for these tests may be limited. Among evidence-based indications for screening are hypogonadism, chronic liver or kidney disease, and previous pathological fractures. While hypogonadism, tobacco smoking, and alcoholism are reported as independent risk factors for secondary osteoporosis in males, none of these emerged supported in a recent meta-analysis for an American College of Physicians guideline for DEXA screening (Liu et al. 2008).

While vigilance for osteoporosis in people treated with chronic opioids, including methadone, is suggested, there are no generally accepted guidelines for who should have DEXA, gonadal hormone testing, or vitamin D testing in these populations. Screening should probably be targeted rather than universal, considering all of the potential risk factors identified above (Fortin et al. 2008).

It is prudent to carry out vitamin D testing in high-risk populations, such as men and women who have limited sun exposure for reasons of dress culture or lifestyle and people with darker skin pigmentation especially those living at high latitudes. However, this test is expensive, highly subject to assay and seasonal variability, and probably not needed to assess response to treatment. It may be more practicable in many cases – without testing for deficiency – to counsel adequate sunlight exposure and recommend vitamin D supplementation where this is not feasible or sufficient.

Management of actual, or risk of, low bone density should be comprehensive, including support for smoking cessation and moderation of alcohol use, calcium supplementation, increase of physical activity, and attention to dietary issues, especially where there is low body weight (Mosekilde et al. 2013). Treatment may include testosterone replacement for hypogonadal males; however, it should be borne in mind that low bone mineral density was commonly seen in men treated with opioids for chronic pain who had normal testosterone (Fortin et al. 2008). Similarly, an early menopausal state in women on chronic opioids may prompt consideration of hormone replacement therapy.

Where there is osteoporosis, antiresorptive agents including the bisphosphonates, the selective estrogen receptor modulators and denosumab, and bone-forming agents including parathyroid hormone and teriparatide may be used subject to all the usual considerations for safety and cost-effectiveness.

108.2.8 International Perspectives

As with many areas of medicine and public health, research into endocrine manifestations of addictive disorders has been greatest in Western societies, though there have been substantial contributions from East Asian countries and, in the case of opioid use, countries of the Middle East, especially Iran, albeit mainly for men.

Reflecting this, information is best for drugs commonly used in Western societies, especially alcohol, opioids, cannabis, cocaine, and amphetamines. Even in those societies, information is scant for drugs, such as inhalants, used by the most marginalized groups. Information is almost entirely lacking for some types of drug use common in other cultures, such as khat, kava, coca chewing, or inhalant use.

On the other hand, research from Western multicultural and multiethnic cultures, especially from the USA, does provide some reassurance about commonalities across ethnic groups for endocrine effects of major drug classes. In general one might suppose that endocrine processes are likely to be broadly similar across ethnicities, but this remains supposition in the absence of specific research, which remains to be done.

Further, there are clear sociocultural and ethnic difference in risks of certain endocrine problems common in users of AOD, especially diabetes mellitus and metabolic syndrome, vitamin D deficiency and its complications, access to expensive investigations (such as DEXA) or treatments, and prevalence of AOD risk factors for endocrine disease, the awareness of which must inform appropriate public health and clinical interventions to reduce harms and improve quality of life.

108.3 Conclusion

Endocrine manifestations of addictive disorders and their treatments are probably more often subclinical than clinically overt and requiring treatment. Understanding the range and scope of these potential endocrine effects has the benefit of helping the clinician maintain vigilance for clinically important disturbances when they occur. It can underpin a broad understanding of hormonal and neurohormonal factors that predispose to and perpetuate addiction and of emerging research directions for treatments. It can provide an important counterpoint to perceptions that addiction is a moral failing or weakness of the will: sometimes our patients, even more than their critics, need to be reminded of how *physiological* the process of addiction is.

Acknowledgments The author gratefully acknowledges Dr. Gavin Bart's helpful comments on this manuscript.

Sexual Function and Alcohol and Other Drug Use

109

Richard Hallinan

Contents

Abstract

Alcohol and other drugs have actions in limbic-hypothalamic hedonic motivational pathways that normally subserve basic biological functions including sexual behaviors. They may also have a range of other physiological and psychological effects on sexual function.

Psychoactive drugs are often used to facilitate or enhance sexual behaviors, but they can also cause sexual dysfunction. Their use can be associated with risky or harmful sexual behaviors.

Pharmacotherapies commonly used in addiction treatment, including opioid pharmacotherapies, sedative/hypnotics, antidepressants, and antipsychotics, can negatively affect sexual function, with implications for treatment adherence and effectiveness. Further, common psychological and physical comorbidities in people with substance use disorders may cause sexual dysfunction.

An understanding of these issues can help clinicians working in the field of addiction better to appreciate motivations for continuing or reducing drug use, can inform motivational and harm reduction interventions, and can improve understanding of issues around treatment adherence. While there are challenges for clinicians in speaking about sexuality with their patients, they are an important part of comprehensive assessment and treatment planning. The clinical benefits of addressing these issues, ranging from reducing sexual risk behavior to improving quality of life of people receiving pharmacotherapies, can be substantial.

109.1 Introduction

The impact of alcohol and other drugs on human sexuality can be considered across three domains: the deliberate use of alcohol and drugs to facilitate or enhance sexual behaviors, their association with risky or harmful sexual behaviors, and their association with sexual dysfunction (Palha and Esteves 2008).

Despite much research, there remain difficulties in comprehensively describing the effects of alcohol and other drugs (AOD) on human sexual function. Human sexuality and its disorders are complex and multifactorial. There remain uncertainties even in the definitions of normality and dysfunction in human sexuality, with sexuality differing greatly between males and females, and across the human lifespan; conceptions of normality vary too across cultures. One must distinguish between acute effects and chronic effects in heavy or dependent users of alcohol and other drugs.

Epidemiologically, moreover, there are three distinct types of study populations for AOD-related sexual dysfunctions: clinical populations with sexual dysfunctions, clinical populations with substance use disorders, and population studies, which generally shed light only on commonly used substances.

109.2 Substances and Sexual Dysfunction

109.2.1 Models and Neurochemical Substrates of Normal Sexual Function

In order to understand the effects of alcohol and other drugs on sexual function, and to identify and manage sexual dysfunction where it occurs, it is important to have an idea of what is normal.

Since Masters and Johnson in the 1960s, and with various amendments (Kaplan, Lief, and Levine, among others), the human sexual response has been described as

proceeding in linear fashion through phases of desire, excitement, orgasm, and resolution. Progressive editions of DSM correspondingly defined disorders of reduced or impaired desire, arousal, and orgasm, adding premature ejaculation (PE) in the case of men and dyspareunia and vaginismus in women; ICD 10 broadly resembles DSM-IV in this respect.

However, the linear model has been challenged for women, and a cyclic, interconnected model proposed instead, with overlap between phases, especially desire and arousal, and reflecting the complexity of sexual motivation, the importance of intimacy, and a broader view of sexual satisfaction. In men too desire and arousal may not be so easily separated (Brotto 2010). In the move toward DSM-V, the merging of desire and arousal disorders, incorporation of a polythetic approach, recognizing subtypes of arousal disorder, refining criteria of distress and duration, and addition of hypersexual disorder are currently debated (Brotto 2010; Segraves 2010; Reid et al. 2012).

Estimates of the typical frequency of sexual activity derived from the work of Kinsey in the USA appear unduly sanguine in the light of more recent population studies, and it is unlikely that experiences in "Western" societies can be simply extrapolated to other cultures.

A current model for sexual responsiveness in mammals including humans posits a dynamic balance of excitatory and inhibitory forces, across all domains of sexual function (Pfaus 2009). Notwithstanding substantial heterogeneity, there are also important commonalities among the neurochemical substrates of reward and reinforcement of the essential biological functions of feeding and sexual activity, and those of drugs and alcohol, most clearly increased dopamine activity in the nucleus accumbens (Lajtha and Sershen 2010; Olsen 2011).

Sexual excitatory factors include dopaminergic pathways which control attention to incentive stimuli, behavioral responses, and parasympathetic outflow to genital areas; melanocortin; the "bonding hormone" oxytocin; and noradrenaline, which has an "inverted U"-shaped relationship with sexual behavior, whereby states of fear or anxiety reduce excitation. There are complex interplays among these factors, and their tone is set hormonally by estradiol and testosterone and also by gonadotropins directly. Testosterone is important for sexual desire and arousal in both men and women, and estrogen in arousal in women, including genital swelling and lubrication. Peripherally these hormones modulate mechanisms involving nitric oxide synthase, vasoactive peptides, prostaglandins, and serotonin, which act to increase genital blood supply (Pfaus 2009).

The evolutionary value of inhibition of mammalian sexual function is likely dual: to allow refractory periods and to avoid conflict within the species. Inhibition can be divided into two aspects, satiety and executive (prefrontal) inhibition. Evidence from the feeding literature suggested serotonergic mediation of satiety. Opioids may have a dose-related rewarding function, inducing satiety at higher doses. Endocannabinoids also appear to have a role in sedation after orgasm. Sedation in itself is likely to play a role in sexual responsiveness.

To these ideas of incentive, reward, satiety, and sedation might be added the more general idea, from addiction studies, of salience, as exemplified by the neglect of essential biological functions (feeding, exploration, and copulation) in animal models of addiction.

The central role of dopaminergic, serotonergic, and opioid-mediated processes in normal human sexuality points to the potential effects of prescribed and nonprescribed psychoactive substances in human sexuality.

109.2.2 How Common Is Sexual Dysfunction? Evidence from Population Studies

Meta-analysis of population studies suggests high prevalences of sexual *difficulties* in women and men. Approximately two thirds of women report *difficulty* with sexual desire, one third difficulty with orgasm, one third difficulty with arousal, and a quarter of sexual pain, with wide ranges around these estimates (Hayes et al. 2006). However, only a proportion of the women were distressed by these difficulties, and symptoms were often not persistent; probably fewer women meet DSM or IDS criteria for sexual disorders (Segraves and Woodard 2006). Difficulties with erection are reported by 30–40 % of men, with premature ejaculation 10–20 % and delayed orgasm less common. These relative prevalences are reflected in frequency of clinical presentation for sexual dysfunction (Nobre et al. 2006).

In general, while prevalence of sexual difficulties increases with age in both men and women, associated distress declines with age (Derogatis and Burnett 2008). Only a proportion of older men with ED are concerned about it (Corona et al. 2010). Erectile dysfunction (ED) and PE however can be common even in young men (Mialon et al. 2012). Similarly, older women report increasing levels of low libido with age, but the percentage who are distressed by this remains unchanged across the age groups (West et al. 2008).

109.2.3 Deliberate Use of Psychoactive Substances in Sexual Behavior

Nonclinical population studies show that drugs and alcohol are commonly used deliberately and strategically for sex-related purposes, with differences among drugs in their perceived effects and uses: cocaine often to prolong sex, alcohol to facilitate encounters, and MDMA to increase desire, closeness, and satisfaction but which may reduce erection and delay orgasm (Zemishlany et al. 2001; McElrath 2005; Bellis et al. 2008). Opiate users are less likely than other drug users to attribute positive sexual effects to their drug (Rawson et al. 2002). Amphetamine and cocaine are most commonly reported to be pro-sexual, but some people may report the opposite. Both perceived effects and expectancies about drug use are largely heterogenous, varying demographically and by gender, especially for cocaine (Rawson et al. 2002). Women may believe or perceive effects of drugs in men to be different from their own

(El-Bassel et al. 2003), and the perceived effects of drugs and alcohol may be context dependent, with the impact of cocaine being largely mediated by social context of use.

Some evidence suggests the use of drugs as deliberate enhancement of sexual function or as self-medication for sexual difficulties (mainly premature orgasm but also arousal difficulties), with sexual difficulties an important factor in the initiation of drug use (La Pera et al. 2008; Mintz et al. 1974). Oral erectile dysfunction agents are commonly used by recreational and dependent users of alcohol and illicit drugs to increase sexual pleasure or performance and may be a marker for sexual risk among gay men (Prestage et al. 2009).

109.2.3.1 Alcohol, Drugs, and Sexual Risk Behaviors

Recreational drug use has been associated with high rates of unprotected sex (Riley et al. 2001; McElrath 2005). Stimulant users are reported as having higher numbers of sexual partners, higher rates of providing sex for money or drugs, and higher rates of sexual risk behavior (Molitor et al. 1999; Lejuez et al. 2005; Weatherby et al. 1992). Disinhibition and impulsivity may underpin increased risk behaviors. While overall alcohol use may be associated with sexual risk behavior among women, data do not support increased occasion by occasion risk (Beckman and Ackerman 1995; Taylor et al. 1999).

While sedative/hypnotics and GBH are sometimes implicated in "date rape" cases, by far the most common identified substance is alcohol (Palha and Esteves 2008).

109.2.4 Understanding the Etiology of Sexual Dysfunction

Assessment and management of sexual dysfunction in any clinical context requires understanding of its multifactorial origins.

109.2.4.1 Hormonal Factors

In women, testosterone and DHEAS peak in early adulthood and decline rapidly and progressively after that so that levels are halved by age 40 (Davison and Davis 2011). By contrast, decline of testosterone in men is progressive from about age 40. Men have 10–16 times the level of testosterone compared to women, so the slow decline with age does not impact on hormonal drive and libido until much older ages.

Androgen deficiency is common in men presenting with ED (Kohler et al. 2008) and androgen replacement has benefit for sexual function in hypogonadal men (Bhasin et al. 2007, 2010), though not for the normal testosterone decline of aging. A large population-based cohort of older men showed no association of testosterone or sex hormone-binding globulin (SHBG) and erectile dysfunction, except in men with increased luteinizing hormone (LH) levels suggesting primary testicular disease (Kupelian et al. 2006).

Although androgen deficiency has not been unequivocally associated with female sexual dysfunction, several studies have shown benefit of testosterone therapy on sexual desire, arousal, orgasm, and satisfaction in naturally or surgically menopausal women (Davison and Davis 2011). There remains a challenge in

understanding changes with menopause as distinct from aging itself; declining estrogen after menopause is the cause of vaginal dryness and dyspareunia (Dennerstein and Hayes 2005). Postmenopausal status increased the risk of sexual dysfunction in middle-aged women, while postmenopausal hormone replacement use was protective (Chedraui et al. 2009).

Hyperprolactinemia and hypothyroidism are also causes of sexual dysfunction in both genders. While hyperprolactinemia commonly manifests with sexual dysfunction, hyperprolactinemia is an uncommon cause of male sexual dysfunction and is not necessarily mediated by reduced testosterone (Buvat 2003; Bhasin et al. 2007).

109.2.4.2 Vascular and Neural Factors

Normal sexual function requires intact vascular and neural function to the genital areas. Neuropathy may include autonomic or reduced tactile sensation, especially in genital areas. Endothelial disease (Braun et al. 2000) is a common cause of ED in men. Sexual dysfunction in diabetes is probably mediated by both vascular disease and neuropathy and multiple sclerosis through neuropathy.

109.2.4.3 Bodyweight, Obesity, Sleep Apnea, and Exercise

Overweight and obesity are increasingly implicated as risk factors for male sexual dysfunction, principally ED (Shamloul and Ghanem 2013). ED prevalence was threefold high among men aged 20–45 years with obesity (Andersen et al. 2008). ED has a U-shaped relationship with weight (Cheng and Ng 2007), that is, underweight is also a risk factor. Janiszewski and Janssen et al. (2009) reported in a large general male population, abdominal obesity and physical inactivity were associated with erectile dysfunction independent of body mass index. Physical activity itself appears protective against ED in cross-sectional studies (Cheng and Ng 2007).

Obstructive sleep apnea is also independently associated with ED (Budweiser et al. 2009) as it disturbs REM sleep, which is the time during sleep when most nocturnal erections occur. Fewer nocturnal erections are a factor in the development of chronic diffuse corporeal fibrosis, leading to ED. This is preventable with early CPAP.

109.2.4.4 Other Medical Illnesses

Numerous other medical illnesses can cause sexual dysfunction. Chronic liver disease, especially liver failure, is related to sexual dysfunction independent of alcohol use (Durazzo et al. 2010). Also illnesses affecting general constitution and fitness, such as chronic heart disease and lung disease.

109.2.4.5 Psychological Factors

Distress from sexual dysfunction appears to be not only age but relationship dependent, in both genders. Postmenopausal status and presence of sexual dysfunction in the male partner increased risk of sexual dysfunction in middle-aged women, while partner faithfulness and menopausal hormone replacement use were protective (Chedraui et al. 2009). In men, self-esteem and depression mediate the effect of erectile dysfunction on quality of life (Ponizovsky 2008). Continued alcohol use by alcohol-dependent

men has negative impacts on sexual intimacy in the relationship which improved with abstinence (Nirenberg et al. 1990). Marital conflict may be an important factor in reported sexual dysfunction in male alcoholics (O'Farrell et al. 1997).

109.2.4.6 Psychiatric Disorders and Their Treatment

A key issue is distinguishing between preexisting and treatment-emergent sexual dysfunction in people with mood (dysthymia and major depression), anxiety (especially posttraumatic stress, social anxiety/phobia, and obsessive-compulsive disorders), and psychotic disorders, in whom psychotropic medications are used. In each of these groups of disorders, there are high rates of sexual dysfunction, generally in the direction of hypofunction (Clayton and Balon 2009). Anxiety and depression are also associated with PE in men (Quek et al. 2008). As with opioid pharmacotherapies (see below), sexual emergent side effects can affect psychiatric treatment adherence (Serretti and Chiesa 2011).

While SSRIs appear mainly to affect orgasm, and antipsychotics primarily desire, all phases of sexual function can be affected by psychotropic medications. Controlled studies are best for antidepressants, including tricyclic and SSRIs, and for antipsychotics. There appears to be a hierarchy among antidepressants regarding treatment-emergent sexual dysfunction with prevalences ranging from 25 % to 80 %. Among SSRI/SNRIs, on meta-analysis sertraline, venlafaxine, and citalopram have higher prevalence of sexual dysfunction than escitalopram and fluvoxamine. Several other types of, primarily non-serotonergic, antidepressants (including agomelatine, bupropion, moclobemide, mirtazapine, and nefazodone) do not significantly differ from placebo (Gregorian et al. 2002; Serretti and Chiesa 2009).

Sexual dysfunction is also common in people treated with antipsychotic agents, with no significant difference found between risperidone, quetiapine, and olanzapine (Nagaraj et al. 2009); these drugs may also be associated with hyperprolactinemia. Although hyperprolactinemia and sexual dysfunction were both common in men on second-generation antipsychotics, they were not correlated with each other (Johnsen et al. 2011).

For benzodiazepines and mood stabilizers, evidence is relatively lacking in humans (Labbate 2008; Clayton and Balon 2009). Benzodiazepines, including diazepam, clonazepam, and alprazolam, have been associated with treatment-emergent male sexual dysfunction (Fossey and Hamner 1994).

109.2.5 Sexual Dysfunction Related to Substance Use and Dependence

109.2.5.1 Tobacco and Cannabis

In men, tobacco smoking is clearly related to risk of vasculogenic ED, which may be atherogenic, and the risk appears to be cumulative with packet years of smoking and persist in former smokers (Tengs and Osgood 2001; Millett et al. 2006; Chew et al. 2009). ED may occur despite higher LH and testosterone in

current smokers (Corona et al. 2005). Evidence is lacking for specific effects of tobacco smoking on arousal in women, though other risks/indicators of endothelial disease (metabolic syndrome, obesity, diabetes, and coronary heart disease) are associated with female sexual dysfunction (Miner et al. 2012).

Daily cannabis use has been associated in one study with difficulty achieving orgasm in men, but not sexual dysfunction in women (Smith et al. 2010); in another with inhibited orgasm and dyspareunia (Johnson et al. 2004). Other studies have shown benefits of cannabis for erectile function (Shamloul and Bella 2011). The effects of cannabis use on sexual function are hard to disentangle from those of tobacco, as tobacco is often mixed with cannabis when the latter is smoked, and where cannabis is used in other ways than smoking, tobacco smoking is typically also common.

109.2.5.2 Alcohol

Moderate alcohol use in men has been found in several cross-sectional studies to confer protection from ED (Bacon et al. 2003; Chew et al. 2009; Millett et al. 2006). A meta-analysis (Cheng and Ng 2007) also reported a protective association for alcohol and ED, even at levels 80 g/day and higher. However, in two large Chinese population studies, even moderate alcohol use was associated with increased risk of ED (Lee et al. 2010). Among midlife women, alcohol intake (along with older age and vaginal dryness) was associated with lower levels of passionate love for the partner (Tomic et al. 2006).

Heavy alcohol use and alcohol dependence are common in populations with sexual dysfunction (Fagan et al. 1988; Haro et al. 2006). Alcohol-dependent men have been reported in several studies in a wide range of countries to have sexual dysfunction including premature ejaculation, ED, and reduced desire (Mandell and Miller 1983; Fahrner 1987; Arackal and Benegal 2007; Dissiz and Oskay 2011). Sexual dysfunction is also reported for alcoholic women, though evidence is less (Jensen 1984). In the absence of severe liver disease or hypogonadism, male sexual dysfunction improves with abstinence (Schiavi et al. 1995; Van Thiel et al. 1983).

Pach and Szurkowska et al. (2007) found high prevalence of erectile dysfunction in alcohol-dependent men: this was not associated with total testosterone and prolactin concentrations, though gonadotropin levels were significantly higher in the group of men with erectile dysfunction, consistent with a toxic effect of ethanol on the testes.

Autonomic neuropathy commonly goes unrecognized in alcoholics and appears to be dose related and potentially reversible on abstinence; in heavy male alcohol users, erectile dysfunction may be the only symptom of parasympathetic neuropathy (Villalta et al. 1989; Monforte et al. 1995; Ravaglia et al. 2004).

109.2.5.3 Opioids

Chronic users of opioids including heroin, and opioid pharmacotherapies for dependence and for chronic pain, have high prevalence of sexual dysfunction, consisting in hypoactive sexual desire and arousal difficulties in both genders, and increased ejaculatory latency in men (Pfaus and Gorzalka 1987; Daniell 2002).

There is good evidence for both treated and untreated opioid-dependent men, including numerous studies in heroin users from a range of countries and cultures (Hallinan et al. 2008; Bang-Ping 2009) and several studies of opioid substitution treatment (Bliesener et al. 2005; Hallinan et al. 2008; Quaglio et al. 2008; Nik Jaafar et al. 2013). Erectile dysfunction appears to be less common in men on buprenorphine than on methadone, though it must be noted these were not randomized treatment populations (Bliesener et al. 2005; Hallinan et al. 2008). The evidence is less strong for women than men; what published evidence there is also supports reduced sexual interest, emotional arousal, and orgasm satisfaction in women on MMT compared with controls (Teusch et al. 1995).

Several studies from the early days of methadone maintenance treatment (MMT) addressed this issue in opioid-dependent women and men, suggesting either improvement or little change from prior heroin use (Wieland and Yunger 1970; Garbutt and Goldstein 1972). Garbutt and Goldstein prospectively studied 120 entrants into MMT, and while average "climax" and "impotence" scores improved at 27 weeks, compared with baseline, the majority of the 30 % who dropped out of treatment reported loss of sexual function as a major reason. More recent studies of men on MMT and BMT have given mixed results for ED with opioid pharmacotherapy showing improvement (Babakhanian et al. 2012; Cioe et al. 2013), deterioration (Zhang et al. 2011), or no change (Chen et al. 2012) compared with prior heroin use. By contrast with heroin users entering opioid pharmacotherapy, where prior sexual dysfunction is common, sexual dysfunction in men treated with opioids for chronic pain is more clearly "treatment emergent" (Daniell 2002).

Cross-sectional studies of the relationship between methadone dose and sexual dysfunction have given mixed results, the majority finding no association (Crowley and Simpson 1978; Teusch et al. 1995; Hallinan et al. 2008; Nik Jaafar et al. 2013; Brown et al. 2005). However, this may not reflect the impact of opioid dose in any individual, owing to large interindividual variation in the pharmacokinetic and pharmacodynamics of methadone; and clinical experience is that methadone dose reductions often improve sexual dysfunction (Espejo et al. 1973; Teusch et al. 1995; Mintz et al. 1974). Similarly, relationship between testosterone levels and erectile dysfunction has sometimes, but not consistently, been shown in cross-sectional studies of opioid users (Cioe et al. 2010).

Most reported studies identifying orgasmic difficulties in men do not show the direction of the dysfunction: commonly used and convenient research tools such as the IIEF and the Arizona Sexual Experiences Scale (ASEX) do not distinguish between PE and delayed orgasm. Where it has been studied, premature ejaculation is found to be much more common in men using heroin and on methadone treatment than in general community studies, and opioids may be used deliberately by some men to manage this problem (Al-Gommer et al. 2007; Chekuri et al. 2012). There is conflicting evidence on whether the PE precedes opioid use, one study suggesting that PE may be a factor in the initiation of illicit drug use (La Pera et al. 2008).

While opioid antagonists have been trialed as treatment for erectile dysfunction, and prima facie one would expect their use in treatment of opioid dependence would eliminate opioid-related sexual dysfunction, the only study available of sexual

dysfunction in men on naltrexone maintenance treatment found high rates of erectile dysfunction, comparable with those on buprenorphine maintenance, consistent with the multifactorial etiology of sexual dysfunction in opioid-dependent men. However, PE was the most common dysfunction in these men (Ramdurg et al. 2012).

109.2.5.4 Stimulants

In clinical populations with substance use disorders, cocaine use is commonly associated with impaired sexual, especially orgasmic, function (Cocores et al. 1988; Kim et al. 1992; Henderson et al. 1995; Rawson et al. 2002; Kopetz et al. 2010) but also reduced sexual desire and performance (Weatherby et al. 1992).

Primary dependent (mostly oral) amphetamine users in treatment had also had high rates of sexual dysfunction, though less than those of dependent opiate, mostly injecting, users (Gossop et al. 1974).

Bang-Ping et al. (2009) reported IIEF scores of 721 men in a compulsory drug treatment facility, interviewed shortly after their entry into treatment. All IIEF domains scored significantly lower than controls for the substance users, whose ED prevalence overall was 36 %. Odds ratios for ED were significantly higher relative to controls for heroin (4.8) and amphetamines (3.2) but not for MDMA users. 47 % of heroin users reported reduced sexual desire, while 28 % of ATS users did so; 23 % of ATS users reported increased sexual desire; however, the sexual desire scores of this subgroup were still significantly lower than controls. The heterogenous nature of actual or perceived drug effects is further reflected in the fact that about half of the men in this study reported increased, while about 15 % decreased, ejaculatory latency.

109.2.6 Clinical Assessment and Management of Sexual Dysfunction in People with Substance Use Disorders

Fundamental to the assessment of sexual dysfunction in people with substance use disorders is consideration that there may be several contributing factors. These include:

1. The actions of the substances themselves
2. Psychiatric and medical comorbidities, as described above
3. The psychosocial context including partner status, self-esteem, and relationship issues
4. The effects of treatments, especially with dopamine antagonists, serotonergic agents, and opioids, but also non-psychotropic medications such as beta-blockers, antihistamines, NSAIDS, and thiazide diuretics (Clayton and Hamilton 2010).

Few patients may volunteer information about the impact of substance-related sexual disturbance on their lives. Most men with treatment-emergent sexual problems on MMT had not mentioned their concerns owing to embarrassment (Hanbury et al. 1977). Furthermore, low sexual desire may not constitute a symptom – if anyone complains it may be the partners. Clinical presentation

may also be indirect, with depression, relationship problems, under-dosing or poor treatment adherence with opioids and other medications, and even dropping out of treatment.

Clinicians can develop skills to incorporate inquiry about sexual matters as part of comprehensive assessment and ongoing assessment in a way that puts patients at their ease. For example, it may be helpful to inquire about sexual dysfunction as one of other common medication-associated symptoms: in the case of opioids, these include sweating, constipation, and disturbances of menstruation.

It should be clarified which phases of sexual response are involved, desire, arousal, and orgasm, as this may determine the focus of management. Also important in assessment is the effect that sexual dysfunction is having on their lives, and whether it is affecting their attitude to treatment in any way. Unless there is distress, sexual dysfunction may not need specific management.

For people continuing to use drugs or alcohol, discussion of sexual function may be important in motivational interventions. Abstinence may come at a perceived or actual cost to one's sex life; equally, sexual dysfunction resulting from alcohol or drug use may be a salient motivation toward abstinence (Palha and Esteves 2002). Sexual contexts, cues, and triggers may be important for risk of relapse, to be considered in relapse prevention strategies (Rawson et al. 2002).

Where "self-medication" of premature ejaculation with alcohol or other drugs is causing problems, discussion of alternatives might reduce harms and risk of dependence or relapse. The SSRIs fluoxetine, paroxetine, and citalopram, and also tramadol, have shown benefit for treatment of premature ejaculation, though tramadol may not be effective longer term (Alghobary et al. 2010; Dadfar and Baghinia 2010; Wu et al. 2012). Their use for the indication of PE is off-label; recently the short-acting SSRI dapoxetine has been approved in a number of countries specifically for the indication on PE. Other treatments include local anesthetics such as topical lignocaine and the Masters and Johnson "squeeze technique" which usually involves participation of the partner.

Drug treatment services and other settings where brief intervention can be carried out provide opportunities for discussing drug-related sexual risks and promoting safe sex.

There is little specific evidence to guide *treatment* of sexual dysfunctions arising out of substance use and its disorders. In the absence of such evidence, the clinician must integrate more general evidence into clinical practice.

109.2.7 The Example of Opioid Pharmacotherapy

Where sexual dysfunction is identified in the setting of opioid pharmacotherapy, comprehensive evaluation is needed, and management is likely to be multifaceted, with consideration of:

- Mood, anxiety, and psychotic disorders and related psychotropic medication use including antipsychotics, "antidepressants," and sedative/hypnotics

- Other potentially treatable or reversible risk factors for sexual dysfunction including tobacco smoking, alcohol and other drug use, sleep apnea, and obesity (noting that exercise may be protective against sexual dysfunction)
- Issues related to poor self-esteem, including obesity and poor dentition
- Hormonal status, especially hypogonadism and hyperprolactinemia
- Partner status and relationship issues

Set within the larger issue of treatment planning, people may be prepared to tolerate side effects of pharmacotherapies if these are discussed, and their identification may provide a rational and structured context for goals in treatment.

Pharmacological strategies for hypoactive sexual desire include hormone replacement where there is hypogonadism. Centrally acting pro-dopaminergic and anti-serotonergic medications are the focus of current research (Stahl 2010). The centrally acting dopaminergic agent apomorphine is currently only available in Europe, and its use is limited by side effects especially nausea (Miner and Seftel 2007). One open-label uncontrolled study has reported successful use of the dopamine antagonist bromocriptine to treat sexual dysfunction in MMT (Shinderman and Maxwell 2000) on the thesis of likely hyperprolactinemia; however, prolactin levels were not measured, and hyperprolactinemia was uncommon in a cross-sectional study of men on MMT (Hallinan et al. 2008).

In both men and women with sexual dysfunction emergent with opioid, antidepressant or antipsychotic therapy, dose reduction, changing medications to alternatives with lower reported rates of sexual side effects, timing of medication in relation to planned sexual activity, and addition of phosphodiesterase type 5 inhibitors (PDE5-I) are all plausible strategies, though studies of these approaches are lacking (Schmidt et al. 2012; Rothschild 2000). As well as having favorable profiles for sexual side effects in monotherapy, the antidepressants bupropion, trazodone, and mirtazapine have shown benefit as add-on treatment to SSRIs. One open-label study has shown benefit of the serotonin antagonist and reuptake inhibitor trazodone for ED in men on MMT (Tatari et al. 2010).

Despite lack of a consistent dose relationship of sexual dysfunction to methadone dose in cross-sectional studies, it is likely that sexual dysfunction is dose related in any one individual and that dose reductions can help, provided this does not lead to relapse into other opioid use. With the same caveat, cross-sectional studies showing less prevalent sexual dysfunction in men on buprenorphine than methadone suggest possible benefit of switching medication.

109.2.7.1 Specific Issues for Women

Systemic testosterone may have a role for hypoactive sexual desire in surgically and naturally postmenopausal women (Davis et al. 2004; Nappi 2007). It is only approved for limited indications in a few European countries, although off-label use is common (Fooladi and Davis 2012). Typically transdermal formulations are used (Nappi 2007); oral administration of androgens should generally be avoided. Side effects including hirsutism, deepening of the voice (the latter can be irreversible), male pattern alopecia, and clitoromegaly can be troublesome, and these

should be discussed with patients when considering therapy. Longer-term risks include the possible increase in cardiovascular disease, as LDL cholesterol is elevated in laboratory tests in women on testosterone replacement. Another concern is the possibility of breast cancer with prolonged use: published studies are inadequate in duration to provide clear assurance, and most conclude that there is still a long-term possibility that this may be likely (Davis 2009). The use of testosterone in premenopausal has even fewer data to substantiate its use long term, and careful counseling must be used if this should be considered as treatment off-label.

Systemic estrogens with or without progestins can improve menopause-related symptoms, including reduced genital arousal and lack of vaginal lubrication. Topical estrogens may be preferred for equal efficacy and absence of systemic side effects and lower risk of breast cancer. Systemic HRT should be considered in postmenopausal women who use testosterone replacement, as the use of an unopposed sex steroid may add to long-term risks.

Evidence does not support benefit for estrogen treatment to increase sexual desire (Davis et al. 2004); indeed, estrogens might reduce desire. Estrogen-containing oral contraceptives were associated with lower circulating free androgens in premenopausal women with hypoactive sexual desire, partly due to increased SHBG (Warnock et al. 2006).

The PDE5 inhibitor sildenafil, in lower doses than are used in men, shows benefit for female sexual dysfunction related to multiple sclerosis, spinal cord injury, diabetes, and secondary to antidepressant use (Brown et al. 2009). Limited evidence exists for effectiveness of the melanocortin receptor agonist bremelanotide in women with arousal disorder (Safarinejad 2006).

109.2.7.2 Specific Issues for Men

PDE5-I are clearly effective for erectile dysfunction of a broad range of etiologies. They may be beneficial where erectile dysfunction is a side effect of opioid pharmacotherapy and where opioid dose reductions are likely to be counterproductive. They have advantages including on-demand effectiveness and absence of long-term side effects, but disadvantages including high cost (Stroberg et al. 2007). However, some men who have ED do not respond at all, or if so not longer term, to PDE5 inhibitors, and for some, these drugs are contraindicated. Currently available alternatives include intracavernosal injections.

In counseling, one should bear in mind that orgasmic dysfunction itself may contribute to erectile dysfunction, and loss of confidence and relationship stress can play a large role in perpetuating ED. Involvement of the partner in counseling may be helpful, and nondrug aids such as “cock rings” and vacuum devices are cheap and easily available or can be improvised.

The decision for androgen replacement in men should be informed by the possibility of placebo response and consideration and counseling regarding the possibility that initial benefit for sexual symptoms may not be sustained (Conway et al. 2000). Testosterone replacement for erectile dysfunction in hypogonadal males has shown benefit for erectile function, but not for sexual

desire or orgasm satisfaction (Chiang et al. 2009). In a cross-sectional study of men on MMT, testosterone accounted for only about 15 % of the variance in erectile function scores, while others have shown no association with testosterone levels, giving some perspective to the potential limits of androgen replacement for sexual dysfunction (Hallinan et al. 2008).

It is questionable whether androgen replacement should be considered where heavy alcohol use or uncontrolled opioid use continues. Concerns about excessive or otherwise inappropriate use of androgens can be minimized by prescribing transdermal formulations or limited supply and supervised administration of injected formulations.

109.2.7.3 Setting the Management of Sexual Dysfunction Within the Relationship

Relationship conflict can be a contributing factor in sexual dysfunction, which thus needs to be understood within the context of the sexual relationship. In management, it can be helpful to place the sexual problem within the context of the relationship rather than the individual. Schiavi (1990) suggests the need to consider the larger psychosocial context for sexual dysfunction in alcohol dependence in men.

At the same time, it must be recognized that people with AOD problems often have high levels of social dislocation, including disrupted or lacking intimate relationships. A high proportion of men on OST had no current regular sexual partner (Hallinan et al. 2008), whereby economic factors, low self-esteem, poor dentition, chronic viral infections, and many other factors may play a role. The capacity to elicit information about forms of sexual experience other than heterosexual intercourse, including "self-pleasure" (masturbation), is important in comprehensive assessment of sexual function and may pose special challenges in some cultures.

109.2.8 International Perspectives

Knowledge about the nexus of sexuality and AOD use is limited in many ways. Research has been greatest in Western societies, though there have been substantial contributions from East Asian countries and, in the case of opioid use, countries of the Middle East, especially Iran, albeit mainly for men. Indeed, there is generally much more information available about sexual dysfunctions for men than women, and in some countries, the sexual lives of women may be considered of low importance or not to be talked about. Discussion of sex altogether may be taboo in some cultures.

Instruments such as the International Index of Erectile Function (IIEF), while validated across a large number of countries and cultures, are designed for assessment of sexual function based on heterosexual intercourse within a partner relationship: estimates of prevalence of erectile dysfunction based on IIEF may be inflated by inclusion of men without partners. Numerous screening and research instruments can be used for both men and women, but few are widely validated, all having advantages and disadvantages: for clinicians, the challenge in any setting is to develop sensitive and culturally appropriate techniques of inquiry.

As with endocrine manifestations of addictive disorders, information is almost entirely lacking for some types of drug use common in certain cultures, such as khat, kava, coca chewing, or inhalant use. On the other hand, research from Western multicultural and multiethnic cultures, especially from the USA, does provide some reassurance about commonalities across ethnic groups.

109.3 Conclusion

Human sexuality is complex, and its disorders are often multifactorial, comprising a wide range of physiological, pathological, psychological, sociological, and cultural factors. Clinicians working in the field of AOD may find this very challenging, even daunting. However, the clinical benefits of addressing these issues, in a range of settings from reducing sexual risk behavior to improving quality of life of people receiving pharmacotherapies, can be substantial.

It is likely that better understanding of the relationship between sexuality and AOD use can enable more effective prevention, treatment, and harm reduction for AOD use, across all cultures, and therefore should be the focus of diverse future research endeavors.

Acknowledgments The author gratefully acknowledges Dr. Lesley Yee's helpful comments on this manuscript.

Abstract

Substances of abuse can result in a multitude of systemic comorbidities. This is particularly true for metabolic and hormonal abnormalities which might complicate underlying medical conditions or may lead to new ones. This impact on the endocrine system depends on the type and length of exposure to substances of abuse and also the presence of any comorbid medical condition.

Sometimes their effects may be temporary and may mimic organic endocrine disorders such as Cushing's syndrome or hypothyroidism or hyperthyroidism. Abstinence may lead to reversal of these effects. Medical therapy may not be needed in these cases.

However, sometimes their effects may be either permanent, such as accelerated bone loss, or temporary but leading to severe symptoms from labile glycemic control or erectile dysfunction, necessitating treatment. The importance of the recognition of the effects of these substances of abuse on the endocrine system derives from the observation that abstinence from these substances helps reverse some of these effects.

In this review, we explore the various common substances of abuse and their impact on the endocrine system. Here we discuss the physiologic and laboratory abnormalities one might expect to find in the setting of substance abuse. We also discuss the endocrine disorders these individuals might be at a risk for, which may need either medical management of these primary endocrine effects or modification of the management of their comorbid medical conditions.

110.1 Introduction

The endocrine system is a complex interplay whereby some endocrine glands act directly in response to a stimulus, e.g., insulin in response to hyperglycemia, or indirectly through mediating hormones, such as releasing hormones from the hypothalamus. This chapter will review the effects of alcohol, amphetamines, tobacco, and cocaine on the endocrine system.

The hypothalamus is the coordinating center of the endocrine system. It consolidates signals derived from upper cortical inputs, autonomic function,

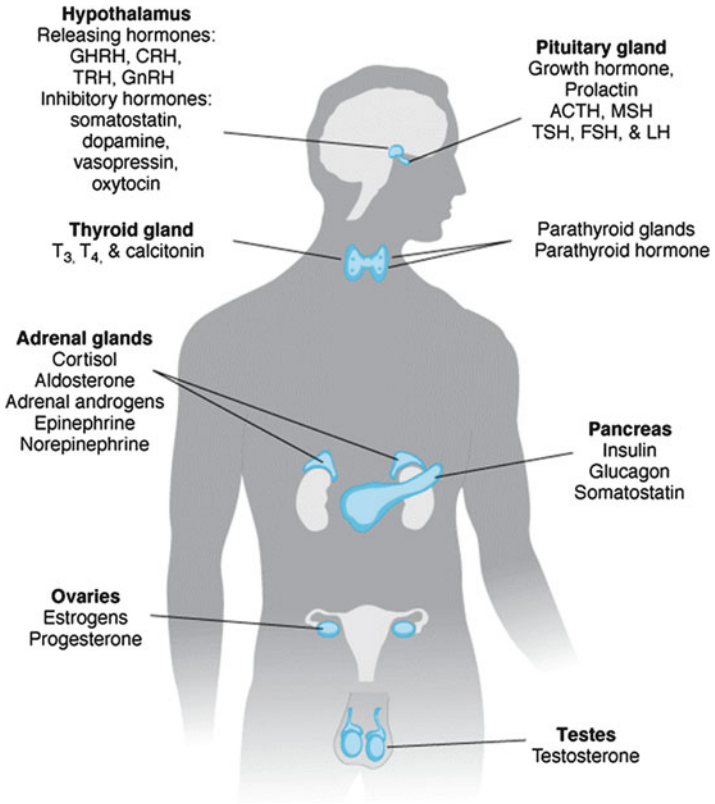

Fig. 110.1 Hormones secreted by the Endocrine Organs

environmental cues, and peripheral endocrine feedback. The hypothalamus receives input from virtually all other areas of the central nervous system and uses it to provide input to the pituitary. The hypothalamus controls output of the anterior pituitary by means of hormones, and it controls the output of the posterior pituitary or neurohypophysis by direct stimulation or inhibition. The interaction between the hypothalamus, the pituitary gland, and the other endocrine glands is a feedback control system (Emanuele and Emanuele 1997). Figure 110.1 is an overview of the feedback loops illustrating the key role of pituitary function on the thyroid, adrenal, and gonadal organs.

Drugs of abuse often disrupt the hypothalamic-pituitary-endocrine axis, causing the endocrine glands to either over- or underproduce. Disruptions of the endocrine system occur in various ways. Some chemicals mimic a natural hormone, fooling the body into overresponding to the stimulus or responding at inappropriate times. Others will directly affect various endocrine glands leading to overproduction or underproduction of hormones.

The effects of different drugs of abuse on the endocrine system are multiple and complex. These substances impair both the functions of the glands that release

hormones and the tissues to which they are being sent. The type, length, and pattern of exposure; level of intoxication and withdrawal; and coexisting medical problems often predict the degree of endocrine disruption. In this chapter, we summarize the effects of both acute and chronic exposures of different drugs of abuse, on the endocrine system addressing basic and clinical evidences performed on animal and human models.

110.2 Alcohol

The effects of alcohol on endocrine function are dependent on the type, length, and pattern of alcohol exposure; level of intoxication; and coexisting medical problems. Malnutrition and liver dysfunction must also be considered when assessing the impact of alcohol on hormonal status.

110.2.1 Effects of Alcohol on the Adrenal Gland

Alcohol causes an activation of the hypothalamic-pituitary-adrenal (HPA) axis resembling Cushing's syndrome, a disease stemming from an excess of cortisol, called alcohol-induced pseudo-Cushing's syndrome (Emanuele and Emanuele 1997). This is clinically similar and sometimes indistinguishable from true Cushing's syndrome. The condition is characterized by abdominal obesity and stria, with evidence of hypercortisolism on a 24 h urine collection. Cortisol levels are particularly higher during an episode of acute intoxication and begin to decline during withdrawal, returning to baseline levels appropriate in a normal person after complete abstinence (Kutscher et al. 2002). The features of this pseudo-Cushing's syndrome would completely disappear after at least 2–4 months of abstinence (Kutscher et al. 2002). There is no need to treat this pseudo-Cushing's syndrome.

Besides the physical stigmata of Cushing's, disruption of the HPA axis by chronic alcohol exposure can result in medical consequences including abdominal obesity, hyperinsulinism, glucose intolerance, and depression of the immune system. Chronic hypercortisolemia itself has been known to suppress the immune system. Both alcohol intoxication and withdrawal may potentially alter immune function via other neuroendocrine mechanisms such as disrupted sympathetic nervous system and elevations of other pituitary hormones producing abnormalities in the function and distribution of immune cells (Kutscher et al. 2002). While individuals are predisposed to infections due to hypercortisolemia during the intoxication phase, the basal cortisol level returns to near normal in the first week of abstinence. However, the responses of cortisol and ACTH are blunted to corticotropin-releasing hormone (CRH) within the first 2 weeks after abstinence from alcohol (Adinoff et al. 1990). This might contribute to a depressed response to stresses, such as infections during this phase.

110.2.2 Effects of Alcohol on Thyroid Function

Many studies have been done where different effects were seen on the thyroid hormone levels in alcoholics. In a few studies it was shown that chronic alcoholism was associated with lower thyroid gland volume and T3 and T4 secretion, presenting as a euthyroid sick syndrome (ESS) in the setting of normal TSH. Alcohol disrupts thyroid function at several steps starting from damage to the deiodinases used in the thyroid hormone synthetic and conversion pathways to an increase in the TBG seen in patients with alcoholic liver disease and fibrosis and reduction in thyroid volumes seen in patients with cirrhosis (Hermann et al. 1997). Damage to the deiodinases has been implicated in intracellular hyperthyroidism resulting in symptoms of withdrawal like hallucinations, tremors, anxiety, palpitations, and diaphoresis. However, while this is happening at an intracellular level, the TSH response to TRH becomes blunted in subjects going through alcohol withdrawal. This mimics the signs and symptoms of peripheral hypothyroidism.

Interestingly, patients with chronic alcohol exposure have been found to have a lower incidence of solitary thyroid nodules and multinodular goiter (Knudsen et al. 2001).

110.2.3 Effects of Alcohol on Gonadal Hormones

110.2.3.1 In Men

Chronic alcohol abuse produces sexual dysfunction and impairs sperm production in both animal models and humans (Emanuele and Emanuele 2001). It was observed that alcohol not only reduced synthesis of testosterone resulting in low testosterone levels but also impaired the secretion of LH in response to low testosterone levels, by directly causing Leydig cell dysfunction. Another mechanism that results in male hypogonadism includes its disruption of the inhibitory effect of dopamine on prolactin. This results in an increased prolactin secretion which suppresses gonadal testosterone synthesis leading to impotence and infertility (Emanuele and Emanuele 1997, 2001).

The consequences of low levels of testosterone in adult men have resulted in a variety of health issues including osteoporosis, decreased muscle and prostate function, anemia, altered immune function, and decreased reproductive ability (Klein and Duwall 1994; Jackson and Klerekoper 1990; Azad et al. 1991). Each of these conditions can cause significant health problems. Younger men who have had low testosterone in adolescence due to alcohol abuse are more prone to these health effects than older men (Emanuele and Emanuele 2001).

The obvious treatment of alcohol-induced male hypogonadism might be cessation of alcohol. Although one can assume that the testosterone levels will return to normal, there are no studies that have proven this. Similarly, although not directly studied, testosterone replacement therapy can be offered to men and may help with improved muscle strength and libido. Dopamine agonists like bromocriptine may not be effective to treat alcohol-induced hyperprolactinemia as ethanol itself can

reduce bromocriptine's ability to reduce prolactin secretion (Oomizu et al. 2003). Alcohol can also cause neuropathy, which in turn can also lead to impotence (Emanuele et al. 1998). Thus, multifactorial causation of sexual dysfunction and infertility should be kept in mind in alcoholic men.

110.2.3.2 In Women

Moderate drinkers, i.e., women who have more than three drinks per day, had significant menstrual problems ranging from anovulation and delayed ovulation to infertility and an increased frequency of spontaneous abortions (Mendelson and Mello 1998). Acute alcohol consumption was associated with an increase in estrogen levels (Emanuele and Emanuele 1997), which suppresses FSH (Mello et al. 1993) leading to impaired folliculogenesis and impaired function of the corpus luteum resulting in infertility from anovulation. Alcohol also directly suppresses progesterone secretion from the corpus luteum, thus putting a woman at risk of spontaneous abortions. Also, alcohol-induced hyperprolactinemia can contribute to menstrual irregularities and amenorrhea (Emanuele and Emanuele 1997). Prolactin should be measured in all evaluations of the hypothalamic-pituitary-gonadal (HPG) axis.

The consequences of alcohol on the fetus are well known, causing fetal alcohol syndrome. Yet, there is a growing understanding that women trying to conceive should be counseled to stop drinking any alcohol so as to maximize their pregnancy capability.

110.2.4 Effects of Alcohol on the Pancreas

Chronic alcohol consumption by itself can lead to chronic pancreatitis and new onset diabetes from insulin deficiency. However, in patients with preexisting diabetes, alcohol affects glycemic control in various ways, depending on whether the alcohol ingestion is acute or chronic and whether it is consumed in the fed or fasted state (Emanuele and Emanuele 1997).

110.2.4.1 Effects on Blood Glucose While in the Fed State

While in the fed state, occasional alcohol ingestion (acute) with meals does not produce clinically significant effects on blood glucose in diabetic males or females (Emanuele et al. 1998). However, long-term consumption of alcohol (chronic) in well-nourished diabetics can lead to clinically significant elevated fasting blood glucose, as well as high hemoglobin A1c levels. The mechanism involved here could be due to increased insulin resistance or reduced insulin secretion or both (Emanuele et al. 1998). Also, chronic alcoholics may show noncompliance with their dietary and medication regimens leading to poor control of blood sugars.

110.2.4.2 Effects on Blood Glucose in the Fasting State

Diabetics consuming alcohol in the fasting state can experience serious life-threatening complications of hypoglycemia induced by alcohol. This occurs due to impaired glycogenolysis due to rapid depletion of stores in the liver while fasting

and shutdown of gluconeogenesis in the liver by alcohol metabolism. Unlike nonalcoholic diabetics, the individual with both diabetes and alcoholism often has hypoglycemic unawareness and does not sense the classic symptoms of hypoglycemia, i.e., shakiness, sweating, restlessness, nervousness, and palpitations. This can lead to delayed recognition of hypoglycemia, resulting in delayed treatment and even death.

In type 1 diabetics, consuming alcohol in a fasting state can have grave consequences as they also have a delayed recovery from hypoglycemia, due to alcohol-mediated impairment of counter-regulatory responses to hypoglycemia (Adinoff et al. 1990). As stated above, impaired cortisol response during the withdrawal phase can also aggravate any hypoglycemia.

Heavy drinkers are also at risk for alcoholic ketoacidosis in the fasting state, from depletion of glycogen stores and low levels of insulin, in addition to being at risk of hypoglycemia. Chronic heavy drinkers are also at risk of alcoholic pancreatitis from hypertriglyceridemia which can also contribute to the risk of pancreatitis. Chronic pancreatitis can further cause progression of diabetes in type 2 diabetics, from insulin-resistant to insulin-deficient diabetes. Finally, chronic alcohol consumption can impair liver function, thus creating contraindications to the use of metformin and thiazolidinediones in type 2 diabetics.

110.2.5 Effects of Alcohol on Bone Metabolism

Chronic alcohol consumption can lead to impaired bone growth and repair leading to reduced bone density and fractures (Sampson 1998). This occurs at various levels; alcohol leads to malabsorption of calcium from the gastrointestinal tract resulting in low calcium levels in the blood, which in turn increases parathyroid hormone (PTH) levels. This leads to bone resorption and demineralization and poor bone density (Emanuele et al. 1998). Also, alcohol through its blunting effect on sex hormones has a direct suppressive effect on the osteoblasts, impairing bone remodeling and repair and further increasing the risk of fractures (Emanuele and Emanuele 2001; Emanuele et al. 1998; Sampson 1998). The common scenario includes low serum calcium, high PTH levels, and low phosphorus levels. Low phosphorus levels brought about by high PTH promoting excretion of phosphate in the urine can further cause muscle weakness restricting the mobility of these patients (Sampson 1998).

110.2.5.1 Summary of the Alcohol Effects on the Endocrine System

Alcohol consumption, both acute and chronic, has both direct and indirect effects on nearly every hormonal system. Alcoholism is highly likely to result in a pseudo-Cushing's syndrome, suppression of gonadal hormones, abnormal thyroid function tests, hyperglycemia and blunted responses to hypoglycemia, and a predisposition to metabolic bone disease. The patient who suffers from acute or chronic alcohol use should be thoroughly evaluated for possible hormonal dysregulation and aggressively treated.

110.3 Amphetamine/Methamphetamine

110.3.1 Effects of Amphetamines on Thyroid Function

The signs and symptoms of amphetamine abuse are similar to those of thyrotoxicosis and include restlessness, tremor, hyperactive reflexes, irritability, weakness, palpitations, cardiac arrhythmias, diarrhea, excessive sweating, and increase in basal metabolic rate. In fact, some have suggested that these signs and symptoms are in fact due to hyperthyroxinemia. Amphetamine-treated animals showed increase in TSH 30 min after treatment and elevation of T4 120 and 180 min after treatment, and T3 was not significantly altered by treatment, suggesting that the amphetamines stimulate thyroid hormone secretion through the hypothalamic or pituitary level (Morley et al. 2008).

110.3.2 Effects of Amphetamines on the Adrenal

Amphetamines increase serum corticosterone concentration after acute administration; however, chronic or repeated amphetamine injections reduce normal elevation of plasma corticosterone (Budziszewska et al. 1996), although in other studies, amphetamine has shown no consistent change in plasma cortisol (Feinberg et al. 1981).

110.3.3 Effects of Amphetamines on the Gonads

The effect of amphetamines on sexual function is variable. While some reported amphetamine users experienced decreased sexual drive, other amphetamine dependents have described an increased sexual libido and intense orgasm. There are also some noteworthy findings that reveal a low dose of amphetamine increases a male's sexual libido and that a high dose and frequent use of amphetamine can trigger several sexual dysfunctions such as decreased sexual drive, prolonged erection, delayed ejaculation, prolonged sexual intercourse, and multiple orgasms (Abel 1985). In an animal study, methamphetamine has showed a dose-dependent decreased percentage of normal sperm morphology and sperm count and induced apoptotic cell activities within the seminiferous tubules (Nudmamud-Thanoi and Thanoi 2011).

110.3.4 Effects of Amphetamines on Growth Hormone

Amphetamine use is correlated with increments in growth hormone and elevation, suggesting excitatory control by dopaminergic system (Brown et al. 1978).

110.3.4.1 Summary of the Effects of Amphetamines on the Endocrine System

There are very mild effects of amphetamine use on the endocrine axis, and most of these are variable. Because of the overlap between symptoms of amphetamine overdose and hyperthyroidism, thyroid function tests should be measured in this population.

110.4 Marijuana/Cannabis

Marijuana is one of the most widely used illicit substances, and there is growing interest in the pharmacological strategies and therapeutic possibilities of this drug, as it becomes legalized in more US states. While known to modulate neuroendocrine function, the precise acute and chronic dose-related clinical consequences of marijuana and its active component delta-9-tetrahydrocannabinol (THC) in humans are still unclear (Ranganathan et al. 2009; Ashton 2001; Brown and Dobs 2002).

110.4.1 Acute vs. Chronic Effects

Animal models have demonstrated that cannabinoid administration acutely alters multiple hormonal systems, including the suppression of the gonadal steroids, growth hormone, prolactin, and thyroid hormone and the activation of the HPA axis. These effects are mediated by binding to the endogenous cannabinoid receptor in or near the hypothalamus. Many of these acute effects, however, are transient as tolerance likely develops (Brown and Dobs 2002).

The long-term consequences of marijuana use in humans on the endocrine systems remain unclear. Chronic cannabis use appears to carry reproductive risks, both to the mother during pregnancy and childbirth and to the fetus and neonate, although these areas need further study (Brown and Dobs 2002). The full extent of long-term health risks of chronic cannabis use (if today's young smokers continue the habit) may require a latent period of 10–20 years to be revealed (Ashton 2001).

110.4.2 Effects of Marijuana on Thyroid Function

In animals, THC decreases circulating TSH, T3, and T4 levels (Hillard et al. 1984); reduces iodine accumulation (Miras 1965); and decreases the release of radioactive iodine from the thyroid (Lomax 1970). These effects are reversed by administration of exogenous TSH, suggesting a hypothalamic site of action. With chronic administration of THC, the thyroid depressant effect of cannabinoids is lost, which again may indicate the development of tolerance. Data are scarce regarding the effect of cannabinoids on thyroid function in humans (Brown and Dobs 2002).

110.4.3 Effects of Marijuana on the Adrenals

THC raises plasma cortisol levels in a dose-dependent manner, but frequent users show blunted increases, likely due to tolerance, relative to healthy controls (Ranganathan et al. 2009).

110.4.4 Effects of Marijuana on the Gonads

Exposure to THC, the main psychoactive constituent of marijuana, impairs human reproductive potential by disrupting the menstrual cycle, suppressing oogenesis, impairing embryo implantation and development (Bari et al. 2011), and reducing prolactin levels and inhibiting milk production and maintenance of lactation (Bonnin et al. 1993; Ranganathan et al. 2009; Brown and Dobs 2002) in women and by increasing ejaculation problems, reducing sperm count and motility, generating loss of libido and impotence (Bari et al. 2011), and gynecomastia (Harmon and Aliapoulios 1972; Brown and Dobs 2002) in men.

110.4.5 Effects of Marijuana on the Neuroendocrine Regulation of Feeding

The endocannabinoid system has a role on brain reward pathways, enhancing the hedonic value of food. Cannabinoids stimulate appetite and food intake, likely through the activation of central cannabinoid (CB1) receptors in hypothalamic feeding centers (Brown and Dobs 2002).

110.4.5.1 Summary of Cannabinoid Effects on the Endocrine System

Cannabinoids can affect various neuromodulatory systems in both the acute and the chronic exposures. While acutely its effects are mainly seen on the adrenals and the gonads, data have not focused on long-term use, which will likely be more commonly observed as marijuana becomes legal.

110.5 Tobacco/Smoking

Smoking has known to be associated with many cardiovascular diseases, as well as cancers. Smoking however also affects the endocrine system affecting almost every part of it.

110.5.1 Effects of Cigarettes on the Adrenals

Nicotine is a strong activator of the HPA axis. Smoking as little as two cigarettes consistently activates the HPA axis of habitual smokers. However, while being

a habitual smoker only induces small changes of basal HPA axis activity, smoking induces an attenuated responsiveness of the HPA axis to psychological stress (Rohleder and Kirschbaum 2006). The ACTH and cortisol levels were higher after smoking cigarettes containing higher level of nicotine than controls (Mendelson et al. 2008). This was also shown to have some role in developing an addiction to nicotine especially when the user is under any kind of psychological stress.

Smoking also increased DHEA levels by stimulating the HPA axis. Increases in DHEA levels may contribute to the mood-elevating effects reported after cigarette smoking, as well as to the alleviation of anxiety and depression (Picciotto et al. 2002).

However, similar increases in ACTH, cortisol, and DHEA levels were not seen after the use of low-dose nicotine cigarettes. Low levels of cortisol and DHEA have also been seen in early abstinence and nicotine withdrawal and may be associated with a relapse. Studies have also shown that nicotine replacement may not increase cortisol levels similar to cigarettes, thus also contributing to a relapse from smoking cessation (Mello 2010).

110.5.2 Effects of Cigarettes on the Gonads

Approximately 30 % of women of reproductive age and 35 % of men of reproductive age in the United States smoke cigarettes. Available data indicate that up to 13 % of infertility may be attributable to cigarette smoking (Pfeifer et al. 2012).

There is good evidence that semen parameters and results of sperm function tests are 22 % poorer in smokers than in nonsmokers and the effects are dose dependent (Pfeifer et al. 2012). In men, higher FSH and LH and lower testosterone levels were seen with increased smoking in a study (Mitra et al. 2012). Nicotine, one of the toxic components in cigarette smoke, had been reported to inhibit androgen biosynthesis and Leydig cell growth (Bergmann et al. 1994; Funabashi et al. 2005) which might be responsible for the observed decline in testosterone among the heavy smokers. A high FSH level is usually diagnostic of primary testicular failure, a condition in which the seminiferous tubules in the testes do not produce sperm normally, because they are damaged. Reduced testosterone levels and mutation in the androgen receptor gene, due to exposure to nicotine, may impact the feedback to LH, resulting in elevated LH levels.

In women, smoking appears to accelerate the loss of reproductive function and may advance the time of menopause by 1–4 years. There is evidence that smoking is associated with increased risks of spontaneous abortion and ectopic pregnancy. Gamete mutagenesis is one possible mechanism whereby smoking may adversely affect fecundity and reproductive performance in the offspring. There is good evidence that smokers require nearly twice the number of IVF attempts to conceive as nonsmokers (Pfeifer et al. 2012).

The adverse effects of sidestream and passive smoking are now established, and there is good evidence that nonsmokers with excessive exposure to tobacco smoke may have similar reproductive problems as smokers.

110.5.3 Effects of Smoking on Thyroid Function

Current smoking lowers serum TSH (Mehran et al. 2012) by about 0.3 mU/l (Weirsinga 2013). The effect is dose dependent and disappears slowly after cessation of smoking. The effect is not associated with ambient iodine intake and is accompanied by a slight rise of serum FT3 and FT4. This might be mediated by activation of the sympathetic nervous system stimulating the production and release of thyroid hormone.

Interestingly, smoking reduces the risk of Hashimoto's thyroiditis (diminishing the occurrence of TPOAb and TgAb and autoimmune hypothyroidism) by about 40 %. This effect might be related to activation of nicotine receptors on immune cells.

Current smoking increases the risk of Graves' hyperthyroidism about twofold and of Graves' ophthalmopathy about threefold (Weirsinga 2013). Current smoking is associated with a higher recurrence rate of Graves' hyperthyroidism, a higher risk on Graves' ophthalmopathy after 131I therapy, and a less favorable outcome of Graves' ophthalmopathy treatment with steroids or retrobulbar irradiation. Cessation of smoking reduces the risk of Graves' disease and ophthalmopathy (Vestergaard 2002).

Current smoking carries a risk for nontoxic goiter and multinodularity. It also increases thyroid size by about 3 ml in men and 1 ml in women. Thiocyanate in cigarette smoke is a competitive inhibitor of thyroidal iodine uptake and is goitrogenic. This is more commonly seen in iodine-deficient areas (Weirsinga 2013).

Current smoking reduces the risk of differentiated thyroid carcinoma by about 40 %. The effect is more pronounced for papillary than follicular cancers and the effect may disappear after cessation of smoking. The effect might be related to some extent to lower TSH and lower body mass index in current smokers (Weirsinga 2013). Further studies are required to analyze the contrasting effects of smoking on the thyroid.

110.5.4 Effects of Cigarettes on the Pancreas

Smoking reduces the risk of developing type 1 diabetes mellitus because of a possible inhibitory effect on autoimmune processes (Rasouli et al. 2013). However, it was associated with a higher risk of developing type 2 diabetes mellitus as well as worsening control of diabetes due to increasing insulin resistance. This effect was seen more in obese individuals as compared to lean men or those with lower BMI <25 (Rasouli et al. 2013).

Heavy smokers had larger waist circumference and abdominal obesity, which plays a role in worsening insulin resistance (Yun et al. 2012). However, the same study also showed that the overall BMI was lowest in current smokers, intermediate in never smokers, and higher in former smokers, reflecting a possible effect of nicotine on appetite suppression and increased metabolic rate.

Thus, while smokers weighed less than the nonsmokers, the fat distribution was more central, contributing not only to impaired insulin resistance but also puts a person at risk for dyslipidemias, hypertension, and cardiovascular disease.

110.5.5 Effects of Cigarettes on Bone Metabolism

Cigarette smoking affects bone health by reducing the bone mineral density, thus increasing the risk for osteoporosis. This has been observed in postmenopausal and aging-related bone loss (Lee et al. 2013). Cigarette smoking leads to increased fracture rates of the hip, spine, and distal radius and other osteoporosis-associated fractures. The mechanism for this is unclear, but likely related to nicotine-induced vasoconstriction, causing tissue hypoxia and increased bone turnover activity (Lee et al. 2013) This not only increases the risk of sustaining a fracture but also impairs bone healing and the risk of osteonecrosis. Studies have shown that smokers are at higher risk for nonunion and delayed union of fractures and have increased incidence of osteomyelitis than nonsmokers (Castillo et al. 2005).

110.5.5.1 Summary of Smoking Effects on the Endocrine System

Smoking is one of the strongest risk factors for cardiovascular disease. Its effects on the endocrine system, particularly the reproductive axis, are not as well known. The effect of cigarettes on subfertility in the mother and male fetus can have profound effects on the next generation.

110.6 Cocaine

Cocaine is a powerfully addictive stimulant drug made from the leaves of the coca plant native to South America. It produces short-term euphoria, energy, and talkativeness in addition to potentially dangerous physical effects like raising heart rate and blood pressure. Cocaine abuse and dependence continues to be one of the nation's most serious drug abuse problems, and the associated social and economic costs include a number of adverse effects on health.

Drugs like cocaine affect mood, stress, cognition, and energy; these drugs may lead to or potentiate depressive symptomatology and reduced quality of life.

110.6.1 Effects of Cocaine on the HPA Axis

Cocaine interacts with many neurohormonal systems in the brain and has both direct and indirect effects on the anterior pituitary, and adrenal hormones. Both acute and chronic exposures to cocaine have been shown to result in increased levels of ACTH and thus cortisol, resulting in associated effects from cortisol excess such as impaired glucose tolerance and insulin resistance, raised BP, and immune suppression (Mello and Mendelson 1997). Cortisol excess and the use of

cocaine by itself can affect body composition negatively impacting cardiovascular health (Brown et al. 2006).

Cocaine also has a dopamine agonist action similar to a MAO inhibitor and has mood-elevating effects in cocaine abusers. In addition to that, prolactin levels are found to be decreased in this population as dopamine has an inhibitory effect on prolactin secretion (Mello and Mendelson 1997). Its dopamine agonistic actions also contribute to elevated heart rate and blood pressures seen in cocaine abusers.

110.6.2 Effects of Cocaine on the Gonads

Cocaine administration leads to reduced circulating testosterone levels, in men, likely through reduced LH release (Mendelson et al. 2001). The resulting male hypogonadism can lead to multiple metabolic complications, including decreased sexual function, reduced lean body mass and bone mass, and adverse cardiovascular health (Brown et al. 2006). Alterations in LH secretion were also associated with dysfunctional mood in both men and women. In women, cocaine use was also reported to be associated with reduced secretion of LH and disruption of menstrual cycle (Mello and Mendelson 1997).

110.6.3 Effects of Cocaine on Thyroid Function

Thyroid hormone levels, both T3 and free T4, have been reported to be normal in patients abusing cocaine (Burke and Dhopesh 1993). However, there has been a case report of hyperthyroidism in a cocaine-abusing patient, but no definite causal association has been proven yet.

In one such study, TSH response was found to be blunted to TRH administration in a cocaine-using population, which might present a hyperthyroid-like picture. TSH was found to be more responsive to TRH during a period of abstinence from cocaine, in the same study (Vescovi and Pezzarossa 1999).

110.6.4 Effects of Cocaine on Growth Hormone

TRH was found to stimulate GH secretion in patients with a history of cocaine dependence, during a period of abstinence. This was seen in the same study which studied the response of TSH to TRH (Vescovi and Pezzarossa 1999).

110.6.5 Effects of Cocaine on the Pancreas

Cocaine abuse makes patients with type 1 diabetes mellitus at risk for diabetic ketoacidosis (DKA) (Ng et al. 2004). It may also be an independent risk factor for development of recurrent DKA in type 2 diabetics, either directly or through

Table 110.1 Substance abuse and associated endocrine abnormalities

Drug	Adrenal	Thyroid	Gonads	Pancreas (diabetes mellitus)	Bone
Alcohol	Cortisol ↑	Euthyroid sick syndrome: TSH remains normal; T3 and T4 are lowered	In men: ↓LH and testosterone Sperm count ↓ Impotence Infertility	In the fasting state: Hypoglycemia Impaired counter-regulatory response to hypoglycemia Alcoholic ketoacidosis	Calcium malabsorption, ↑PTH ↓Phosphorus ↓Bone density ↑Risk of fractures Muscle weakness
			In women: Anovulation Menstrual irregularities Infertility Spontaneous abortions	In the fed state: Fasting blood sugars↑ Hemoglobin A1C↑	
Amphetamine	Acute: ↑cortisol Chronic: ↓cortisol	Hyperthyroxinemia: TSH, T4, T3 same	Variable, sexual desire orgasm		
Marijuana	Cortisol ↑	TSH, T3, and T4 ↓	In men: Ejaculation problem Sperm count and motility ↓ ↓Libido Impotence Gynecomastia		
			In women: Disrupt menses		

(*continued*)

Table 110.1 (continued)

Drug	Adrenal	Thyroid	Gonads	Pancreas (diabetes mellitus)	Bone
			Oogenesis↓ Impairs embryo implantation and development ↓Prolactin		
			↓Milk production and maintenance of lactation		
Tobacco	Cortisol↑	TSH ↑FreeT4, ↑FreeT3	In men: Damage to the seminiferous tubules Poor sperm quality Leydig cell dysfunction – >low testosterone Androgen receptor mutation ↑LH ↑ FSH	↓Risk of autoimmune diabetes	↓Bone mineral density
	DHEA ↑: elevates mood and relieves anxiety	↑Risk of Graves' hyperthyroidism and ophthalmopathy		↑Risk of developing type 2 diabetes	Accelerated bone loss
		↓Risk of Hashimoto's thyroiditis		Worsening insulin resistance and glycemic control in type 2 diabetics	Osteoporosis
		↑Risk of nontoxic thyroid goiter and multinodularity	In women: Gamete mutagenesis Spontaneous abortions Ectopic pregnancy		↑Fragility fractures
		↓Risk of differentiated especially papillary carcinoma			Impaired bone healing Osteonecrosis
Cocaine	Cortisol ↑	Both T3 and T4 usually tend to be normal	In men: ↓LH and Testosterone	Stimulates secretion of counter-regulatory catecholamines increasing risk of diabetic ketoacidosis and hyperosmolar hyperglycemic syndrome	Reduced bone mass due to its effects on testosterone
	In pituitary: Dopamine agonistic effects similar to MAO inhibitors – elevates mood	TSH less responsive to TRH	Sexual dysfunction In women: ↓LH Menstrual irregularities Mood disruptions in both men and women		

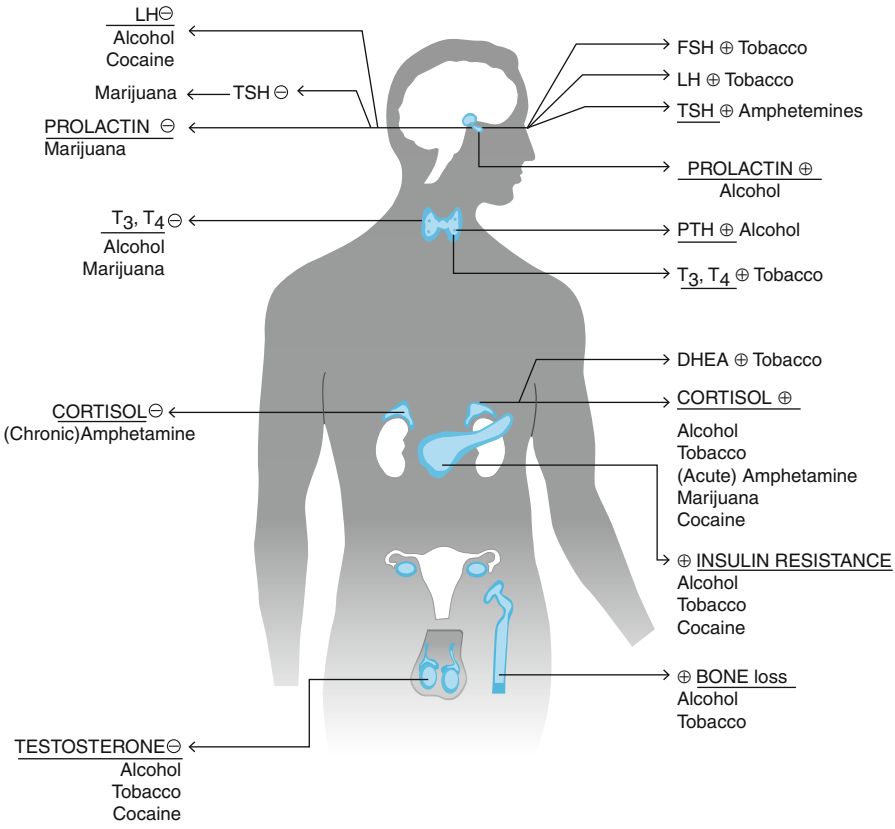

Fig. 110.2 Schematic Summary of the Hormonal Effects of the Substances of Abuse

noncompliance with glucose-lowering medications (Nyenwe et al. 2007). In fact, hyperosmolar hyperglycemic nonketotic state was the initial presentation of new onset diabetes mellitus (Abraham and Khardori 1999). These complications may be seen mainly due to the stimulatory effect of cocaine on counter-regulatory hormones by stimulating release of catecholamines such as epinephrine from the adrenal medulla.

110.6.5.1 Summary of Cocaine Effects on the Endocrine System

Cocaine has direct and indirect effects on several neuromodulatory systems. It leads to multiple systemic effects by affecting glycemic control, the adrenals, and the gonads.

110.7 Conclusion

Substances of abuse put people at risk for numerous endocrine abnormalities and metabolic complications. These abnormalities in themselves can have long-term

sequelae affecting the addict's health. A good history and physical exam, including a detailed history review of the endocrine axes, will help to identify possible endocrine disorders. Endocrine abnormalities are common in the population and can be present as an underlying comorbidity, or drugs of abuse can cause or aggravate underlying endocrine problems. Health-care providers need to know what possible defects may arise in the setting of polysubstance abuse to be able to treat and thus prevent long-term metabolic complications (Table 110.1, Fig. 110.2).

Abstract

Patients with substance use disorders are seen frequently in perioperative settings. It has been estimated that every third patient undergoing surgery is smoking; every fifth patient has alcohol use disorders such as hazardous use, abuse, harmful consumption, or dependence; every tenth patient is alcohol dependent; and every twelfth patient is consuming drugs regularly. Many patients use more than one substance regularly. Substance use disorders do vary in severity. Substance use is associated with significant somatic and psychiatric morbidity. Perioperative complications occur more often, even if underlying pathophysiological changes are subclinical. As an example, bleeding time can be prolonged, infection rate can be increased, cardiopulmonary complications can occur, or wound healing can be impaired even without clinical signs of, e.g., manifest liver cirrhosis and cardiovascular or lung disease. Patients with substance use disorders can safely undergo procedures under anesthesia. There are a variety of evidence-based treatment options to treat or prevent complications related to substance use. By secondary or tertiary preventive measures in a multimodal interdisciplinary concept, the increased risk can be significantly reduced. Elements are systematic screening, including the use of questionnaires and biomarkers, systematic diagnostic evaluation, brief interventions, tailored advice and information, patient-centered communication, tailored anesthesia, detoxification, abstinence, rehabilitation, psychosocial therapy, stepped care, monitoring of withdrawal symptoms, and prevention of withdrawal symptoms with pharmacological substitution therapy, monitoring and prevention of complications, goal-oriented therapy, symptom control, stress reduction, prevention of secondary injury, complex interdisciplinary treatment strategies, and teaching and training of the staff.

111.1 Introduction

Patients with substance use disorders (SUD) are seen frequently in perioperative settings. It has been estimated that every third patient undergoing surgery is smoking; every fifth patient has an alcohol use disorders such as hazardous use, abuse, harmful consumption, or dependence; every tenth patient is alcohol dependent; and every twelfth patient is consuming drugs regularly. These patients require medical care more often and more extensively. Substance use is associated with somatic and psychiatric morbidity. Perioperative complications occur more often, even if underlying pathophysiological changes are subclinical. As an example, bleeding time can be prolonged, infection rate can be increased, cardiopulmonary complication can occur, or wound healing can be impaired even without clinical signs of, e.g., manifest liver cirrhosis and cardiovascular or lung disease (Spies et al. 2001b; Tønnesen et al. 2009; Kork et al. 2010).

The term "substance use disorder" describes a continuum ranging from risky use over heavy use, hazardous use, abuse, harmful consumption to dependence. As we observe often similar morbidity among risky users as in dependent patients, it

seems to be more appropriate from the clinical point of view to describe relevant perioperative issues in all patients with substance use disorders without focusing on patients with physical dependence, with compulsive drug-seeking behavior, and with tolerance or with withdrawal. For didactic reasons alcohol, nicotine, and drug use disorders are described in distinct chapters as usual. However, many patients use more than one substance regularly.

In contrast to many other medical conditions, patients with SUD do often not get adequate treatment in the perioperative context. This has been related to underreporting and underasking. A variety of factors have been described: stigma or fear of stigma, lack of time and resources, lack of training, projections, and many (false) myths about the origin of these disorders. Early detection of SUD and their associated risk is essential to reduce complications, but an SUD is often suspected after complications occurred (Spies et al. 2001b; Runge et al. 2001; Tønnesen et al. 2009; Kork et al. 2010). Intoxication or acute delirium can interfere with the clinical presentation of other severe conditions (e.g., traumatic brain injury and alcohol intoxication, delirium, and thiamine deficiency). Therefore, the evaluation of all patients with SUD requires well-directed and proactive diagnostic approaches (Neumann and Spies 2003).

Many pathophysiological changes and organ dysfunctions in relation to substance use are potentially reversible by abstinence. The extent of recovery depends on the progression of the disease (Tønnesen et al. 2009).

The patient-doctor interaction is somehow different from what is seen in addiction centers. Patients undergoing surgery are usually expecting to receive the best surgery with a minimal risk, but are not actually seeking treatment for SUD. A comprehensive preoperative risk assessment is standard and substance use is a risk factor. Risks and risk-reducing options are discussed in order to reach informed consent. Most patients found alcohol intervention relevant in relation to surgery. Therefore, all steps should be explained to patients in their own language. Patient preferences should be explored. A working alliance should be established. The FRAMES concept (feedback, responsibility, advice, menu of behavioral changes, empathy, self-efficacy) summarizes useful elements of the communication. Patients with relevant psychiatric (co)morbidity should be seen by a psychiatrist (Spies et al. 2006b; Kork et al. 2010; Lau et al. 2011; Pedersen et al. 2011).

When a SUD is suspected, a brief intervention should be offered. Interventions like motivational interviewing are directive non-confronting and ambivalence accepting. Bridging into specific treatment can be appropriate. Open issues in this context are optimal strategies for communication, shared decision making, and psychoeducation including training and implementation of substance use medicine in the surgical facilities. The optimal architecture of a stepped care system is of great interest and might differ between health systems (VA/DoD 2009; NICE 24 2010; NICE 100 2010; NICE 115 2010; Spies et al. 2006b; Kork et al. 2010; Lange et al. 2011).

There is a risk of relapse ("drug reinstatement") in rehabilitated patients with a history of substance use and dependency after stressful events such as trauma or

surgery. Therefore, these patients should benefit from a careful and emphatic psychoeducation. They might need support also by addiction medicine professionals at some time after the event. This should be planned early.

As science and the health care develop rapidly, it is highly recommended to familiarize with today's guidelines ("systematically developed statements to assist physicians and, if necessary, other healthcare professionals and patients with decisions about appropriate health care in specific clinical circumstances") as only a systematic, formal, and group consensus approach is able to catch up with the developments in the field (Woolf et al. 1999).

111.2 Substance Use Disorders

111.2.1 Alcohol: Clinical Relevance

One of ten hospitalized surgical patients suffers from alcohol dependency; two might have an alcohol use disorder, and if they undergo surgery, they have more complications and length of stay is longer (Spies et al. 2001).

Among some patient groups, even higher rates of heavy drinking or alcohol dependency were reported: more than 25 % in patients with injury and 50 % of patients with aerodigestive system cancer. There is a variety in the clinical presentation of alcohol use-related morbidity in the different settings (e.g., younger trauma patient vs. older cancer patient vs. patients admitted for detoxification). Programs offered for the rehabilitation of addicted patients after detoxification might not attract other patient groups, e.g., young trauma patients. Even patients with addictions are rarely seen by addiction specialists, but frequently come in contact with health professionals in surgical or emergency units (Spies et al. 1996a, b, 2001b; Neumann et al. 2006; Neumann and Spies 2003).

AUD patients have a higher somatic and psychiatric morbidity: Postoperative or posttraumatic complications rate is two- to fivefolds higher. Chronic heavy drinking affects various systems as the nervous system, the cardiovascular system, the liver, the muscle, and the stress response and the immune system. The direct toxic effect of alcohol might be aggravated by malnutrition. Alcohol promotes carcinogenesis.

It has been consistently shown that patients who report heavy daily drinking (i.e., $>$60 g of alcohol) have an increased postoperative morbidity and more complications with increased postoperative healthcare use, including longer stays in the hospital and ICU and more second operations. Postoperative or posttraumatic morbidity is two- to fivefold increased: Infections and sepsis, cardiac complications (arrhythmia, congestive heart failure), bleeding and secondary hemorrhage, "acute respiratory distress syndrome" (ARDS), other surgical complications, alcohol withdrawal syndrome, and death occur more often. Therefore, length of stay is prolonged; requirement for critical care is increased. Also postoperative healthcare use is increased. Hospital and ICU stay is prolonged. Secondary operations are more often required. Already a consumption of more than two drinks a day has been associated in some reports with an increased risk. Interestingly, when diagnosing

dependency, information about consumption is not required (Tønnesen et al. 1992, 2009; Spies and Rommelspacher 1999; Spies et al. 1996a, b, 2001b; Moss and Burnham 2006; NICE 115 2011; Rubinsky et al. 2012).

111.2.1.1 The Scope of the Problem

Critically ill alcoholic patients are more likely to develop serious **infections** than nonalcoholic patients, especially nosocomial pneumonia, sepsis, wound, and urinary tract infections. Chronic alcohol abuse is also associated with an increase of ARDS (acute respiratory distress syndrome) and the severity of MODS (multiple organ dysfunction syndrome) in patients with septic shock.

Immune functions are altered by chronic heavy drinking. Stress response to surgical trauma induced by the hypothalamic-pituitary-adrenal axis (HPA axis) is augmented in AUD patients. A hypercorticolism was observed after surgical stress. Not only was hypercorticolism associated with complications, but a therapeutical suppression of the hypercorticolism at the level of the HPA axis reduced complications (Spies et al. 2006a). The skin response of the delayed-type hypersensitivity (DTH) is already reduced after surgical trauma due to associated stress. However, among alcoholic patients who undergo surgery, the DTH response was already reduced preoperatively compared with nondrinkers, and this impairment was exaggerated to a significantly larger extent postoperatively. This corresponds to other findings: Preoperatively, the T helper 1 to T helper 2 cells ratio is depressed in long-term alcoholic patients. This is predictive of later onset of infections. It remains suppressed after surgery. Postoperatively, the cytotoxic lymphocyte (Tc1/Tc2) ratio is also decreased in long-term alcoholic patients and remains depressed for 5 days. Correspondingly, the interleukin (IL)-6/IL-10 ratio and the lipopolysaccharide-stimulated interferon/IL-10 ratio in whole blood cells are decreased after surgery in long-term alcoholic patients. These anti-inflammatory changes in the postoperative period are predictive of subsequent postoperative infections.

Many other alterations of specific and nonspecific immune defense are reported that contribute next to other factors (e.g., smoking or aspiration) to the increased infection rate (Tønnesen et al. 1992, 1999; Spies et al. 2001b, 2004, 2006a; Sander et al. 2002; Moss and Burnham 2006; Lau et al. 2009).

Wound healing is impaired in heavy drinkers. Collagen and total protein accumulation in wound granulation tissue was impaired in treatment-seeking alcoholic patients, and proline and total protein increased significantly after 8 weeks of abstinence (Tønnesen et al. 1992, 1999, 2012; Spies et al. 1996a, b, 2001b).

The coagulation system can be affected even without clinical relevant alcoholic liver disease mainly by an altered thrombocyte function. Bleeding time can be prolonged. Beneficial effects of low-dose alcohol on cardiovascular disease have been related to these effects (Spies et al. 2001a; Tønnesen et al. 2009).

Heavy drinking can induce **cardiomyopathy**. A reduced ejection fraction can be found, which is often subclinical. However, heart rate can be increased and arrhythmias occur more often perioperatively. Cardiac morbidity is also increased due to arterial hypertension and the impact of smoking (Tønnesen et al. 1992, 1999; Spies et al. 1996a, b, 2001a, b, 2006a).

Table 111.1 Differential diagnosis of delirium or alcohol withdrawal syndrome: "I WATCH DEATH" (Adapted from Spies and Rommelspacher 1999)

I	Infections
W	Withdrawal
A	Acute metabolic
T	Trauma
C	CNS
H	Hypoxia
D	Deficiencies
E	Endocrinopathy
A	Acute vascular
T	Toxins/drugs
H	Heavy metals

Stress due to surgery and trauma, infection, or withdrawal has a wide range of effects. Next to the abovementioned immune suppression changes in body fluid composition, electrolytes, catecholamines, and hormones are relevant (Tønnesen et al. 1992, 1999, 2009; Spies et al. 1996a, b, 2001a, b; Neumann and Spies 2003; Moss and Burnham 2006).

Alcohol is **neurotoxic**. In higher dosage/doses it affects the central and the peripheral including the autonomic nervous system. It alters neuronal transmission. It induces tolerance and withdrawal. Alcohol use is also associated with neurotrauma. There are many reasons for cognitive impairment or delirium or "acute brain dysfunction" in emergency or critically ill patients with alcohol use disorders. In acute situations, other reasons for delirium (e.g., infection, trauma, or others) are often misinterpreted as intoxication or alcohol withdrawal syndrome (Table 111.1). The clinical presentation of critically ill patients with a history of alcohol and/or drug misuse may differ from other patients. Delayed diagnosis of AUDs or related comorbidity (e.g., alcohol intoxication and head trauma, withdrawal state, vitamin deficiencies, drug use, significant psychiatric disorders, infections, etc.) may have severe consequences (Tønnesen et al. 1992, 1999, 2012; Spies et al. 1996a, b, 1999, 2001b; Neumann and Spies 2003; Moss and Burnham 2006; NICE 115 2011).

Wernicke's encephalopathy should be suspected in all clinical conditions which could lead to thiamine deficiency, and intravenous thiamine (before any carbohydrate, 200 mg thrice daily) is indicated in these patients. It is often undiagnosed during lifetime. For diagnosis, two of the following four signs are required (EFNS guidelines, Galvin et al. 2010): dietary deficiencies, eye signs, cerebellar dysfunction, and either altered mental state or mild memory impairment. Total thiamine in blood sample should be measured prior to thiamine administration, if possible. MRI should be used to support the diagnosis of acute WE.

Re-trauma rate was also higher compared to patients without AUD. Trauma has, therefore, been described as a recurrent disease (Neumann et al. 2004, 2006).

111.2.1.2 Alcohol Intoxication

Alcohol is a central nervous system depressant. The clinical presentation of the alcohol intoxication ranges therefore from symptoms due to disinhibition like euphoria and agitation to a more global depression such as coma. Alcohol intoxication is potentially life threatening due to respiratory insufficiency, respiratory failure, aspiration, electrolyte disorders, rhabdomyolysis, hypoglycemia, temperature deregulation, and cardiovascular depression, with tachycardia and hypotension. The risk of trauma is high while intoxicated. A delayed diagnosis and treatment of other critical conditions such as trauma add to the high risk of alcohol intoxication (Neumann et al. 2003; Moss and Burnham 2006; NICE 100 2010; NICE 115 2011; NICE 24 2010).

111.2.1.3 Alcohol Withdrawal Syndrome

AWS is still a potentially life-threatening state. About half of all alcoholic patients in intensive care undergo an untreated alcohol withdrawal syndrome. It occurs frequently in intensive care patients after reduction of the sedation. The range and severity of the symptoms of alcohol withdrawal varies: cognitive thought disorder, hallucinations, convulsions, and sympathetic hyperactivity resulting from the imbalance of various excitatory and inhibitory neurotransmitter systems. The alcohol withdrawal syndrome is typically a diagnosis of exclusion. First signs are autonomic symptoms such as sweating, tremor, nausea, anxiety, and restlessness. Grand mal seizures can occur. Delirium tremens is characterized by spatial and temporal disorientations, hallucinosis, ataxia, tremor, and autonomic dysfunction. Many conditions can mimic AWS or might occur concomitant. Other disorders associated with delirium should be quickly ruled out or treated, including hemorrhage, metabolic disorders, infection, intoxication, hypoxia, pain, or focal neurological lesions. Mortality is related to the quality of the treatment: 15 % mortality when untreated vs. 2 % mortality when treated (Spies et al. 1996a, b, 1999, 2001a, b, 2003; Moss and Burnham 2006; Bråthen et al. 2005; NICE 100 2010; NICE 115 2011; NICE 24 2010; Awissi et al. 2013; Ungur et al. 2013).

111.2.1.4 Gastrointestinal/Metabolism

The **GI system** is impacted by alcohol in many ways: parenchymal liver injury (reduced synthesis, reduced enzyme activities, portal hypertension), hepatitis, gastritis, pancreatitis, enteral translocation, anorexia, malnutrition (substrates, vitamins, etc.), ulcers, gastrointestinal bleeding, autonomous dysregulation, and malnutrition.

Pharmacodynamic or pharmacokinetic interactions, increased toxicity of medication, and altered metabolism are complex and beyond the scope of this chapter. Chronic alcohol use alters metabolism (e.g., cytochrome P450 2E1 induction resulting in increased toxicity of paracetamol) or neurotransmitter function (e.g., alcohol and narcotics interfere on GABA receptor function). Clinicians use the manufacturer's information.

111.2.2 Diagnosis

111.2.2.1 Diagnosis

An early diagnosis is essential. However, the prevalence of AUD is consistently underestimated, particularly in women and younger patients: One out of 14 patients was diagnosed with AUD by an anesthesiologist during the preoperative assessment, but with a computerized questionnaire, detection rate was one out of six patients (Kip et al. 2008).

The diagnosis of an AUD is based on the synopsis of medical and substance use-related history, physical examination, and on self-report (like structured interviews such as questionnaires), if available. More information is provided by paraclinical findings (laboratory, imaging) and collateral information. In intubated and analgosedated or in emergency situations, patients' self-report might not be available. Markers are helpful when self-report is not available or valid, e.g., after trauma. A complication might be the trigger for considering an AUD. The information from markers of acute and chronic alcohol consumption as well as indices of alcohol consumption-related changes in organ function (e.g., liver enzymes, metabolic indices, immune dysfunction) can add further information. Patients might have an extra benefit from anonymous and confidential programs parallel to the routine patient care (Neumann and Spies 2003).

111.2.2.2 Questionnaires

Systematic screening with questionnaires is recommended, e.g., with the ten-item Alcohol Use Disorders Identification Test (AUDIT). The AUDIT was designed to cover a range of AUD severity from risky use to dependence. The full AUDIT asks next to the three consumption questions (AUDIT-C) also for indicators of addiction (three questions) and about alcohol use-related negative consequences (four questions). The ten AUDIT questions sum up to a score between 0 and 40 points. The test is considered as positive once more than 8 points are counted; however, lower cutoffs for women (e.g., 5 points) have been recommended. Lower cutoffs can increase sensitivity. Every combination of answers resulting in at least 5 points reflects at least one alcohol use-related problem. It takes about 2 min to apply the AUDIT in paper-and-pencil or computerized versions. The use of a computerized version detected much more patients in a preanesthetic clinic compared to the clinical routine (Neumann et al. 2004, 2006; Kip et al. 2008; VA/DoD 2009; NICE 24 2010).

The three-item "AUDIT-Consumption" questions (AUDIT-C) can be a shorter alternative. It provides a rough quantity x frequency estimate plus one question addressing binging (five or more drinks/occasion). It was found to be clinically useful. An increased AUDIT-C (>8 points) up to a year before surgery has been clearly associated with postoperative complications. A cutoff of 4 points (men) and 3 points (women) of the AUDIT-C was recommended for screening; however, this corresponds also to patterns of low-risk alcohol use like small amounts of alcohol with a meal (VA/DoD 2009; Neumann et al. 2004; Kip et al. 2008; NICE 24 2010; Bradley et al. 2011; Rubinsky et al. 2012). The NIAAA (see Fig. 111.1)

General algorithm and clinical pathway for patients with substance use disorders
Structured AUD, NUD and DUD screening

- Do you drink alcohol? yes:
  - Alcohol Use Disorder Identification Test (AUDIT), or
  - abbreviated version, AUDIT-C or
  - NIAAA screen for risky drinking e.g. How many times in the past year have you had…
    -5 or more drinks in a day (men)
    -4 or more drinks in a day (women) (One standard drink = 12–14g in the (US)
  - Plus CAGE (if dependence is of interest)
- Do you consume drugs, yes:
  - DSM-IV criteria or ICD criteria
- Do you smoke? Yes
  - Fagerström

If questionnaire results are negative, history not available, questionnaire screening not applicable or reliable and patient undergoing major surgery, critical ill etc.

- Consider collateral information
- Consider the use of markers
  Laboratory testing:
  AUD: CDT, GGT, MCV, EtG, Peth
  NUD: CO-Hb, Cotinin
  DUD: substance or metabolite testing in urine, saliva or blood (depending on substance)
- Comprehensive assessment of comorbidity

If patient is positive

- Synopsis of clinical findings (Screening, history, physical examination, questionnaires, marker, collateral information) =>
- Diagnosis (ICD 10, DSM 4/5) =>
- Consider and discuss specific interventions, include the informed patient into the decision making process (shared decision making), psychoeducation, if appropriate
  Prophylactic, preventive Intervention =>
  - (Preventive) treatment
    - Pharmacological withdrawal prophylaxis,
    - Substitution,
    - Stress reduction…
    - Treatment (e.g. AWS, detoxification, rehab, self help groups…)
    - Abstinence
  - Risk communication,
    - brief Interventions, e.g. Motivational Interviewing
    - FRAMES
      - Feedback
      - Responsibility
      - Advice
      - Menu of behavioral change
      - Empathy
      - Self - efficacy
- Monitor for complications
- Monitor for continuous risky/unrisky use

If preventive treatment not necessary:

- Inform, endorse, confirm
- Maintenance or supportive therapy in former substance users,
- Reevaluation of substance use screening negative patients in special medical conditions

AUD, alcohol use disorder; DUD, drug use disorder; NUD, nicotine use disorder (adop. and modified from Kork et al. 2010).

Fig. 111.1 General algorithm and clinical pathway for patients with substance use disorders

recommended the "Single-Item Alcohol Screening Questionnaire" as a screener (VA/DoD 2009).

CAGE ("cut down," "annoyance," "guilt," and "eye opener") is a four-item questionnaire. It is brief and easy to remember. The strength is detection of patients with dependence, but the sensitivity for risky, nondependent use has been considered as too low. Interestingly, the CAGE questionnaire can be used as a self-assessment tool (may be used in addition to an appropriate screening method to increase patient's awareness to unhealthy use or abuse of alcohol) (Neumann and Spies 2003; NICE 24 2010; VA/DoD 2009).

111.2.2.3 Laboratory

Biomedical markers may provide additive, objective information about acute or recent consumption, intoxication, relapse, heavy drinking, hazardous or harmful alcohol use, or possible use-related organ dysfunctions. Biomarkers cannot differentiate between AUD with and without dependency. So far, no single laboratory test (e.g., for acute abuse, alcohol in blood or breath; for abstinence, metabolites such as ethyl glucuronide (EtG); for chronic heavy drinking, gamma-glutamyl transpeptidase (GGT), mean corpuscular volume of red blood cells (MCV), carbohydrate-deficient transferrin (CDT), phosphatidylethanol (PEth)) is reliable enough on its own to support the diagnosis of an AUD. In the clinical context, they can add important information, especially when questionnaires are not applicable or reliable. As laboratory parameters for alcohol abuse, MCV, γ-GT, and CDT are used. Sensitivity of the markers (e.g., MCV 34–89 %, γ-GT 34–85 %, CDT 12 or less -94 %) as well as specificity (MCV 26–91 %, γ-GT 11–95 %, CDT 82–100 %) can vary considerably according to gender, age, setting, drinking pattern and prevalence of more severe AUD, the prevalence of comorbidity, and the AUD criterion used. Markers of increased alcohol consumption can also be increased by nonalcoholic organ damage, e.g., non-alcoholic liver disease (Neumann and Spies 2003; Hannuksela et al. 2007; Neumann et al. 2009).

Phosphatidylethanol (Peth) is formed only in the presence of alcohol. It has reported sensitivities of 97–99 % and specificity of 100 % when differing heavy drinkers (60 g/day of alcohol and much more) from controls. However, the cutoff is not clear yet and Peth is not yet part of clinical routine. More research is needed to establish the role of this marker of chronic heavy drinking. Storage can be problematic, relevant in vitro formation and degradation has been described (Hannuksela et al. 2007; Niemela 2007 CCA).

Sensitivity of markers can be lower, when patients reduce their alcohol consumption preoperatively. Another reason for false-negative findings are blood loss and volume replacement in critically ill patients (e.g., after severe trauma; therefore, sampling of the blood should be done as early as possible, e.g., at admission or in the resuscitation room) (Spies et al. 2001; Hannuksela et al. 2007; Neumann et al. 2003).

Sensitivities, specificities, and predictive values vary considerably between the studies according to patient and control group characteristics and differing alcoholism criteria (Neumann and Spies 2003). In patient groups with a high prevalence

of severe AUDs, in older patients, and in patients with a continuous daily consumption (in contrast to occasional binge drinking), the sensitivity is usually higher, whereas comorbidity might interfere with specificity (Neumann and Spies 2003).

Percent CDT (CDT/total transferrin ratio) levels were elevated in patients drinking 50–80 g/day or more. Elevated values were found also among patients with end-stage liver disease and genetic variants. Total CDT levels are additionally affected by factors that raise transferrin levels such as iron deficiency, chronic illnesses, and menopausal status. The roles of female gender, low body mass index, chronic inflammatory diseases, and medication on CDT levels require further study. Sensitivity can be lower in women and patients with episodic heavy drinking or cutting down for some time and acute blood loss. Therefore, CDT should be determined early after admission (Neumann and Spies 2003). Early sampling in the emergency room and before volume resuscitation increased the sensitivity from 65 % to 74 % for CDT. Complication rate was increased in trauma patients with increased CDT (increased CDTect, absolute CDT values, Spies et al. (1998), discussed in Neumann and Spies 2003; %CDT, McKinzie et al. 2010).

Furthermore, the determination of markers of acute consumption (alcohol in blood, urine, breath) or markers of recent use (e.g., ethyl glucuronide , ethyl sulfate, urinary 5-HTOL/HIAA) can add important information of recent consumption and hangover. Blood, breath, or urine alcohol is detectable for several hours; however, metabolites are detectable for longer (e.g., EtG up to 80 h) even after consuming smaller amounts. They can be used to monitor abstinence (e.g., in obstetrics or liver transplantation). Alcohol consumption in the evening before surgery is related to postoperative morbidity. These biomarkers are usually not available as a point-of-care application except breath alcohol. There are unsolved methodological issues concerning cutoffs and possible reasons for false positives. Therefore, markers cannot be used without the clinical context (Neumann and Spies 2003; Hanunksela et al. 2007).

The determination of the blood alcohol concentration (BAC) is considered as standard in trauma care: Between 16 % and 39 % of trauma victims were BAC positive on admission, and 55–75 % of injured patients who were BAC positive had an alcohol abuse or dependence diagnosis. However, a substantial number of trauma patients with AUDs (11–45 %) are BAC negative (Runge et al. 2001; Neumann et al. 2003). A high blood alcohol concentration indicates tolerance, which itself is linked to dependence. Alcohol metabolites such as ethyl glucuronide may be used for monitoring abstinence since they can be detected for a longer period than alcohol from blood or urine. So far some promising markers are not available as a point-of-care application (Neumann and Spies 2003).

Other indices of altered organ function (e.g., liver enzymes, metabolic indices, immune function parameters) might add valuable information. These surrogate markers give valuable insights into the impact of AU on organ function (e.g., immune response) and might guide therapeutical interventions, but are not considered as alcohol abuse markers per se (Neumann and Spies 2003; Spies et al. 2004, 2006; Lau et al. 2009).

111.2.2.4 Screening and Diagnosis

All patients should be screened for AUD in a systematic approach in order to detect those patients who might benefit from evidence-based strategies to minimize the risk for a complicated perioperative clinical course. The use of an alcoholism-related questionnaire is recommended.

If self-report is not possible, not reliable, or negative, markers and collateral information should be used. All patients:

- Scoring positive (AUDIT: men $\geq$ 8/women $\geq$ 5).
- Scoring below the cutoff in a questionnaire or from those where a reliable history and/or questionnaire cannot be taken **and** with one or more positive biomarkers should undergo further assessment (Kip et al. 2008; Kork et al. 2010).

Confirmatory assessment includes a history of alcohol and substance use and consumption pattern, comorbidity, and the criteria for hazardous use or dependence (DSM/ICD); however, absence of earlier withdrawal symptoms does not exclude the possibility of an exaggerated stress response or withdrawal. Patients screened positive for AUD should further be evaluated in an interdisciplinary approach.

A clinically relevant alcohol abuse is defined in operative medicine as an intake of $\geq$ 60 g/day of alcohol; however, risky consumption has been defined as 30 g/day (men) or 20 g/day (women). High-risk patients with two or more positive biomarkers from different pathophysiological backgrounds are obvious candidates for preventive strategies (Neumann and Spies 2003; Tønnesen et al. 2009; Spies et al. 2001).

Consulting a specialist in substance abuse may be appropriate in order to provide advice on how to reduce long-term risk, e.g., to achieve abstinence. All patients being considered for high-risk surgery or having had a trauma should be offered counseling focusing on risk factors in relation to the operative treatment, diagnosis, and prognosis (e.g., in the preanesthetic evaluation). Alcohol is a risk factor. Especially in patients consuming 60 g of alcohol or more daily, options (e.g., remain abstinent for up to 4 weeks before elective surgery or receive preventive perioperative pharmacological prophylaxis targeting the stress response or withdrawal) should be discussed. Information and feedback on any pathological finding-associated alcohol consumption may contribute to the diagnosis. The patient-oriented communication style is ambivalence accepting, not confrontive, emphatic, but directive; one aim is a working alliance with the patient. It includes a feedback and advice about the risks and opportunities and it addresses patient's responsibility. Through these (brief) interventions longer-term changes in motivation might be achieved (Spies and Rommelspacher 1999; Neumann and Spies 2003; Neumann et al. 2004, 2006; Tønnesen et al. 1999, 2009).

One has to be aware that some patients are under triple stress during the evaluation: an operation, an AUD diagnosis, and the fear of stigma. Waiting patiently and reevaluating later can be an option. Approaching patients three times instead of one time before surgery doubled detection rate. The combination of laboratory markers and the CAGE questionnaire and up to three consultations can increase the detection rate from 16 % by clinical routine alone to 91 % in

surgical patients scheduled for upper digestive tract surgery (Martin et al. 2002). Markers might be used also as biofeedback. The patient might have a benefit to learn about the risk associated with a positive marker and the gain in health, when the marker normalizes (Neumann and Spies 2003). More research is needed to determine the value of biomarkers in the context of clinical decision-making algorithms.

111.2.3 Treatment and Prevention

111.2.3.1 Screening and BI

A brief intervention should be delivered at the point of care to all AUD patients, e.g., in the preanesthetic clinic. This approach is recommended by current guidelines. A consistent reduction of alcohol consumption by brief interventions was reported in primary health care, mainly in men. Also brief interventions were generally effective in hospital patients; however, some inconsistency was observed, especially in emergency settings (NICE 24 2010; NICE 115 2010; VA/DoD 2009). Effective screening and brief intervention strategy (feedback, advice, tailored information) can be provided by computer in many clinical settings (Neumann et al. 2006; Kip et al. 2008; Lange et al. 2011). A computerized questionnaire and brief report on lifestyle issues for surgical patients is available as a tool for quality management in Germany. It is applied by the German Anaesthesiological and Intensive Care Society (current access: http://www.dgai-lsa.de; username: HAI2008; password: dgai; Kork et al. 2010).

111.2.3.2 Choice of Anesthetics

Anesthetics should be given according to the clinical effect. As alcohol and inhalation agents as well as hypnotics work synergistically on the $GABA_A$ and on other receptors (NMDA, glycine) in intoxicated patients, a dose reduction is necessary as well as an increase in dosage in the withdrawal state. Muscle relaxants that are metabolized hepatically might have a prolonged effect in patients with a hepatic insufficiency; neuromuscular monitoring is recommended. Alternatives would be atracurium and cis-atracurium as relaxants. Alcohol consumption is not a contraindication for the use of inhalational anesthetics. Sevoflurane is normally metabolized to <5 % in the liver. However, also the induction of CYP2E1 could lead to an increased formation of plasma fluorides. Due to the small intrarenal metabolism of sevoflurane, nephrotoxic effects are not expected, but there are no studies on AUD patients at risk.

Regional anesthesia should be used only in patients able to cooperate and with adequate vigilance. The coagulation should be monitored and a careful history of coagulation disorders and medication that interferes with the coagulation should be obtained. Limitation for regional method is agitation of the patient and the lack of protection of the respiratory tract. In the phase of intoxication, regional procedures are contraindicated (Klotz and Ammon 1998; Neumann et al. 2003).

111.2.3.3 PACU

The patient can be transferred from the recovery room to the ward when sufficiently vigilant, cardiopulmonary stable, and pain-free. Monitoring for delirium is recommended (NuDesc, DDS, CIWAr). Regular monitoring includes the acid-base balance, electrolyte levels, and blood glucose levels. Hypokalemia and hypomagnesemia can occur during the early withdrawal. Inadequate drainage losses can be a sign of a coagulation dysfunction. In patients sobering up, acetaminophen should be used with caution (Martin et al. 2010; Spies et al. 1999, 2003; Otter et al. 2005; Riordan and Williams 2002; Moss and Burnham 2006).

111.2.3.4 Postoperative Treatment

It is not possible to draw a clear line between prevention and treatment of alcohol withdrawal syndrome. Both prophylaxis and treatment should be carried out symptom-guided in time (Spies and Rommelspacher 1999; Spies et al. 2003). All patients are therefore closely monitored by means of the "Revised Clinical Institute Withdrawal Assessment for Alcohol Scale" to monitor or compare scores used in intensive care (e.g., CAM-ICU, DDS, Lütz et al. 2010; Martin et al. 2010; Otter et al. 2005).

111.2.3.5 Therapy of Alcohol Withdrawal Syndrome

The diagnosis of an alcohol withdrawal syndrome can be made if other causes of delirium or complications such as bleeding, metabolic dysfunction, infections, ischemia/hypoxia, pain, or focal neurological symptoms are excluded (Table 111.1). Patient's history or laboratory tests should indicate an AUD. Alcohol withdrawal syndrome should be treated early. The severity of AWS in critically ill surgical or trauma patients as reflected by CIWA-Ar, however, is several times higher in ICU patients compared to psychiatric patients. The complex interactions between anesthesia, postoperative stress, trauma, infections, and other factors may enhance imbalances of transmitter systems and require a more effective therapy. The symptoms have to be closely monitored (Awissi et al. 2013; Moss and Burnham 2006; Martin et al. 2010; Spies and Rommelspacher 1999; Spies et al. 2003; Ungur et al. 2013).

If an alcohol withdrawal syndrome occurs, the use of more than one drug should be considered. Treatment should be symptom oriented: for agitation and seizures, benzodiazepines (first substance of choice, e.g., lorazepam, diazepam); for autonomic hyperactivity, alpha-2 agonists (clonidine or dexmedetomidine); and for hallucinations or productive-psychotic symptoms, neuroleptics according to the underlying transmitter imbalances: GABAergic (e.g., benzodiazepines, clomethiazole), dopaminergic (e.g., haloperidol), and noradrenergic system (e.g., clonidine). Dosage should be adjusted to the patient's clinical condition. Ethanol is obsolete in the manifest withdrawal state (Amato et al. 2011; Awissi et al. 2013; Spies and Rommelspacher 1999; Spies et al. 2003; Ungur et al. 2013).

Any delay or inadequacy of therapy may worsen symptoms. In contrast to a fixed-dose treatment, symptom-oriented treatment using a scoring system reduces time of treatment, can shorten the clinical course of AWS, and can reduce morbidity

use of medication, complication rates, time of ventilator support, and length of ICU stay when compared to a preassigned and fixed treatment plan. Different scores can be used in order to monitor delirium and to guide therapy. CIWA-Ar score was validated for normal wards, whereas the Delirium Detection Score (DDS) was validated for the ICU setting (Otter et al. 2005; Spies et al. 2003; Moss and Burnham 2006; Martin et al. 2010; Awissi et al. 2013; Ungur et al. 2013).

If simultaneously clonidine and haloperidol are used in the treatment of alcohol withdrawal syndrome, hypokalemia and hypomagnesemia should be avoided, as this can cause QT prolongation and arrhythmias. Clonidine can cause hypotension, bradycardia, AV block, and constipation. Electrolyte disorders should be treated, especially hypokalemia and hypomagnesemia (Moss and Burnham 2006; Spies and Rommmelspacher 1999).

111.2.3.6 Prophylaxis

Drugs used to prevent withdrawal are benzodiazepines, clomethiazole (per os), clonidine, and haloperidol or risperidon, usually in dosages that are lower than used for treatment. If indicated, a long-acting benzodiazepine can be given the evening before surgery (e.g., lorazepam) for premedication and a short-acting benzodiazepine in the morning of surgery (e.g., midazolam). In patients not adequately premedicated before the induction of anesthesia, midazolam IV can be titrated to the desired effect; additionally clonidine, haloperidol, or ketamine can be given intravenously, if there are no contraindications. The prevention of alcohol withdrawal syndrome on a peripheral ward is usually done with a single substance. Monitoring on the ward is required. If the requirement for monitoring is not met by the ward's resources, the patient must be moved to a monitoring or intensive care unit. It is important to reduce prophylactic dosage after symptom control, as this – in unintended continued treatment – includes even a potential for addiction. Preventive treatment may avoid AWS or attenuate its severity; transition from prevention to treatment is continuous (Spies and Rommmelspacher 1999; Spies et al. 2006).

In alcoholic patients, hypercortisolism can occur postoperatively after surgical stress. Pharmacological intervention by inhibition of the HPA axis (stress prevention) with morphine, low-dose ketoconazole, and ethanol in alcoholic patients could prevent the prolonged cortisol response to surgical stress, compared with placebo, and thus reduce the incidence of infection Spies et al. (2006a). For blockade of the HPA axis and to reduce infectious complications, perioperative infusion of low doses of ethanol (0.5 g/kg/day IV) or low-dose morphine (15 μg/kg/h) has been shown to be effective in one study. As this is not a sufficient pain treatment, pain should be monitored by visual analog scale (VAS) or numerical rating scale (NRS) and treated according to evidence-based hospital standards (Spies et al. 2006; Martin et al. 2010).

Perioperative administration of prophylactic medication, especially alcohol, requires an assessment of the motivation regarding a change in alcohol consumption and informed consent after shared decision making. Risk and options are communicated. This communication should have a big overlap with motivational interviewing and change talk (Kork et al. 2010).

111.2.3.7 Treatment of Wernicke's Encephalopathy

Intravenous thiamine (before any carbohydrate, 200 mg thrice daily) is indicated for the treatment of suspected or manifest WE. Oral substitution is initially inadequate. Hypoglycemic patients should receive thiamine latest when administering intravenous glucose (Galvin et al. 2010).

111.2.3.8 Preoperative Abstinence

Pathophysiological dysfunctions due to heavy drinking are potentially reversible. Immune response, stress response, alcoholic cardiomyopathy, bleeding time, frequency of hypoxia, and wound healing improve during abstinence within a time frame of weeks or months (Tønnesen et al. 2009; Spies et al. 2001a).

Two studies from Denmark (one among nondependent alcohol consumers (60–420 g/day) undergoing radical colorectal resection patients and one that included elective hip arthroplasty patients) showed an effect of 4-week preoperative abstinence and psychosocial counseling combined with disulfiram substitution on the overall complication rates including infection rate. Postoperative morbidity was reduced from 74 % to 31 % after colorectal surgery. There was no significant reduction of in-hospital and 30-day mortality (Tønnesen et al. 2009; Oppedal et al. 2012).

111.2.3.9 Addiction and Psychosocial Treatment

The alcohol-dependent patient should be seen early by an addiction specialist. The indication of ambulatory or inpatient detoxification before or after surgery should be evaluated. Alcohol-dependent patients may profit from anti-craving medication such as acamprosate, naltrexone, or alcohol deterrent medication such as disulfiram. Naltrexone can interfere with postsurgical pain therapy, if opioids are indicated. One large multicentre study by Anton et al. (2006) underlined the importance of medical management (Spies and Rommelspacher 1999; Anton et al. 2006; Tønnesen et al. 2009; Kork et al. 2010).

111.3 Tobacco Dependency, Nicotine Use Disorder (NUD)

As tobacco use is associated with cancer and cardiovascular or pulmonary diseases, smokers are overrepresented among these patients. Accordingly, the incidence of perioperative pulmonary complications, cardiovascular complications, impaired wound healing, and wound infection is increased. Smokers, who continue to smoke until surgery, have a higher two- to sixfold pulmonary morbidity compared to nonsmokers (Bluman et al. 1998; Møller et al. 2002; Tønnesen et al. 2009).

Smoking is usually reported spontaneously. Standardized questionnaires such as the Fagerström Test evaluate degrees of dependency and were used to guide therapy, e.g., nicotine replacement therapy. Different from the construct of the ICD or DSM dependence definition, the number of cigarettes is needed for a positive score (Heatherton et al. 1991).

An established point-of-care biomarker of acute smoking is carbon monoxide-hemoglobin (COHb). It is routinely determined in anesthesiology workplaces. CO binds to the hemoglobin and reduces the oxygen binding capacity of the hemoglobin significantly (up to 15 %). This might cause hypoxia even in patients without coronary heart disease and is associated also with wound complications. COHb predisposes for ST-segment depressions in stress situations. In addition, increased nicotine levels are associated with an increased sympathetic activity: There is an increased heart rate, increased blood pressure, and a reduced peripheral blood flow through vasoconstriction. Increased oxygen consumption meets a lowered oxygen supply. The net effect might result in a relative hypoxia. In patients with coronary heart disease, the incidence of myocardial ischemia increases significantly. Patients smoking immediately prior to surgery with elevated expiratory CO concentration (>35 ppm) showed more ST depressions. The half-life of COHb and nicotine is about 12 h, e.g., after abstaining overnight. In cardiac risk patients, an abstinence of 12–48 h reduces perioperative cardiac morbidity. A perioperative smoking cessation of 12–48 h is required (Zwissler and Reither 2005; Neumann et al. 2008; Tønnesen et al. 2009; Kork et al. 2010). COHb in blood was an excellent marker to detect current smoking in trauma patients. The cutoff of COHb should be lowered to 1.6 % in women and to 1.8 % in men (Neumann et al. 2008).

The pulmonary morbidity is two- to sixfold higher in patients smoking until the surgery. In smokers, the lung capacity and ciliary function are reduced; closing capacity is increased. The production of mucus is increased, but the secretion of pulmonary clearance reduced. This can also affect otherwise asymptomatic younger smokers. This is associated with an elevated pulmonary postoperative morbidity. In smoking patients undergoing elective surgery, pulmonary complications were 22 % vs. 5 %. In abdominal surgery, the rate may be even higher. Smokers are more frequently admitted to ICUs than nonsmokers (Zwissler and Reither 2005; Møller et al. 2002; Tønnesen et al. 2009).

Smoking lowers the pressure in the lower esophageal sphincter; however, this effect is fully reversible after 5 min. The emptying of solid but not liquid food particles from the stomach is delayed after smoking. In respect to acute smoking, there is no increased risk of aspiration neither to gastric volume nor to the acidity of the gastric juice. However, smokers experience less postoperative nausea and vomiting (PONV) (Zwissler and Reither 2005).

Smoking impacts on the immune function. This leads to an increased risk of infections. The immune system recovers after 2–6 weeks of abstinence from smoking, wound healing after 3–4 weeks, and the lung function after 6–8 weeks (Tønnesen et al. 2009).

More intensive smoking cessation programs are more effective than briefer interventions; however, briefer interventions might bridge the patient into more intensive programs that include nicotine replacement therapy (NRT), CO monitoring, and psychoeducation and counseling about the expected advantages and disadvantages of abstinence, side effects, withdrawal symptoms, diet and exercise, weight gain, and other issues. Six randomized trials have been published that evaluated preoperative smoking cessation with abstinence rates between 40 %

and 89 %. Three studies suggest that preoperative smoking cessation programs of 3–4 and 6–8 weeks duration are beneficial in respect to complications. Shorter periods of abstinence are not disadvantageous. A potential negative effect of a preoperative smoke stop had been reported in retrospective studies with considerable methodological weaknesses. Also postoperatively nicotine replacement is recommended, adapted to the degree of nicotine dependence (Fagerström test) (Bluman et al. 1998; Møller et al. 2002; Lindström et al. 2008; Sørensen and Jørgensen 2003; Tønnesen et al. 2009).

Wound healing is affected by smoking. Collagen production is impaired. The wound infection rate of sacral incisions in 78 volunteers was lower at 4–12 weeks after randomization, compared with smokers without cessation, but not after a week examined. No difference was observed between placebo and patch therapy (Sørensen and Jørgensen 2003; Møller et al. 2002; Tønnesen et al. 2009).

Nicotine represents a cholinergic agent. Therefore, in case of surgery without preoperative abstinence, nicotine replacement therapy (NRT) and other cholinergic agents like physostigmine are an option in these patients as adjunctive for treatment of pain and the potential of saving postoperative opioids. Perioperative NRT initiated before induction of anesthesia and maintained after surgery should be considered. Physostigmine 1.5 mg IV at the end of surgery then 1 mg/h for 24 h can be given as an cholinergic agent and for pain reduction, if no NRT was started. Cholinergic agents are basically emetogenic; PONV prophylaxis might be necessary (Møller et al. 2002; Beilin et al. 2005; Kork et al. 2010).

111.4 Opioids

111.4.1 Clinical Relevance

Patients with opioid dependency undergoing surgery might be polysubstance users with significant comorbidity or chronic pain patients treated with opioids. They are at risk for withdrawal. Complex individualized treatment strategies are required. Many patients were seen in emergency facilities. The effects of opioids are enhanced by CNS depressant drugs, e.g., ethanol and GABEergic medication. Respiratory depression (with aspiration (pneumonia), cyanosis, and/or pulmonary edema) and consecutive hypoxia are the most common causes of morbidity and death after acute opioid intoxication. This is associated with ST-segment changes, tachycardic arrhythmias, hypotension and congestive heart failure, and cerebral and spinal ischemia or nerve compression syndromes and muscle damage with consecutive crush syndrome or rhabdomyolysis after immobilization when intoxicated. Patients might suffer from acute and chronic infections including HIV and hepatitis, intravenous and polysubstance drug use-associated bacteriemia, heart valve pathologies, atherosclerosis from smoking, trauma, and psychiatric comorbidity. Peripheral and central venous access is often difficult (Hernandez et al. 2005; Kork et al. 2010). Relevant withdrawal symptoms are tachycardia, diarrhea, hyperhidrosis with dehydration next to mydriasis, and goose bumps.

111.4.2 Perioperative

Opioid-dependent hospital patients should receive a basal substitution ("baseline") with methadone or racemate plus opioids as clinically required for analgesia under the control of the vital signs and withdrawal parameters. Regional anesthesia alone or in combination with general anesthesia, NSAIDs, alpha-2 agonists (clonidine, lofexidine), and ketamine can be considered. Postoperatively, the need for analgesia can be increased in drug-dependent patients. Partial agonists (e.g., buprenorphin) should be avoided. Treatment should be symptomatic, e.g., NSAIDs, alpha2-agonists (clonidine, lofexidine) (APA 2006; Kork et al. 2010).

Clinical signs of over- and underdosage should be observed. Vital signs and symptoms of withdrawal (e.g., Objective and Subjective Opiate Withdrawal Scale, OOWS, SOWS) should be documented regularly. Written bedside standard operating procedures should clearly describe:

- In case of overdose: command breathing; administer oxygen and ventilation, eventually titration of naloxone.
- In underdosing: rescue medication (give opioids).

QTc time (ECG) has to be monitored. Under methadone medication, the QTc time can be prolonged, which is a risk factor for arrhythmias (APA 2006; Kork et al. 2010).

Laxatives (e.g., lactulose) are administered as adjuvant until the stool consistency has normalized. Adequate hydration replaces volume loss in hyperhidrosis (e.g., during withdrawal). Diverse drug interactions must be considered in patients with methadone substitution therapy. Methadone interaction with other medications should be anticipated. Manufacturer's information should be consulted, as enzyme induction (cytochromes) or inhibition concerns a variety of substance, (e.g., antiviral medication, carbamazepine, phenytoin, cimetidine, and rifampicin). Medication with sedating properties (e.g., benzodiazepines) can act synergistically and can cause respiratory depression. Partial antagonists (e.g., buprenorphine) can trigger withdrawal symptoms and are contraindicated in this case. Clonidine and lofexidine attenuate heroin or methadone withdrawal symptoms more effectively than placebo and can be perioperatively or intraoperatively applied once hemodynamic monitoring is available (Hernandez et al. 2005; APA 2006; Gowing et al. 2009; Kork et al. 2010). The pain treatment **in former opioid-dependent patients** is an understudied issue. There are concerns that this may trigger a relapse ("drug reinstatement") when mu agonists (or other psychoactive drugs) are potentially indicated in the perioperative period. Regional anesthesia or general anesthesia combining inhalation anesthetics with N2O, ketamine, and nonsteroidal anti-inflammatory drugs is not always possible. If indicated, titration of adequate amounts of a short-acting μ-agonist can be necessary; alpha-2 agonists can relieve withdrawal symptoms. Patients should be carefully informed (e.g., about craving) and educated about the small but relevant risk of relapse. This should be documented, and written informed consent should be obtained. Possible treatment options should be discussed, including post-hospital psychosocial and medical care. Any relapse is a potentially life-threatening situation. Opioid-related death occurs

often in former users. Some patients seem to be unaware of the decreased tolerance and use opioids in usual doses. Patients should be educated about these phenomena (Kork et al. 2010).

In the first days of the postoperative period, opioid substitution therapy is continued. In addition, opioids are administered for analgesia. Increased demand in comparison to "opioid-naive" patients can be expected (Kork et al. 2010).

In the emergency situation, preoperative switching to methadone is not possible in opioid-dependent patients. Symptomatic patients are treated if necessary and the presence of withdrawal symptoms with a μ-agonists. A regional anesthesia should be considered (Kork et al. 2010).

The consequences of drug-induced respiratory depression with consequent hypoxia or atelectasis, aspiration, cardiovascular symptoms, neurological symptoms, nerve compression and damage, and polysubstance comorbidity have to be evaluated. Next to the ABCDE (airway, breathing, circulation, disability, evaluation) approach, an ECG, cardiac enzymes, echocardiography, chest X-ray, imaging, lab and drug screening, and neurological and psychiatric evaluation are helpful (Hernandez et al. 2005; Kork et al. 2010).

Naloxone carefully titrated is one option to treat overdose. This is also helpful to establish the diagnosis. The effect of naloxone lasts only about 30–60 min. In emergency situations, naloxone administration can be potentially harmful. The initiation of (immediate) withdrawal stress in patients with impaired organ function is potentially dangerous. Craving-associated drug-seeking behavior in the emergency situation after antagonist administration can cause difficult situations. Trauma or impaired organ function, severe prolonged hypoxia, suicide intention, or intake of other CNS depressants that are non-mu agonists cannot be ruled out. Cases of pulmonary edema have been reported after naloxone treatment. Intubation and ventilation by skilled personal might be of lesser risk (Osterwalder 1996; Kork et al. 2010).

Complex psychiatric and somatic morbidity requires individualized psychosocial and medical care. Brief intervention might bridge into more intensive treatment. Detoxification should be carefully planned, (e.g., cold, agonist assisted, symptomatic treatment, or opioid antagonist induction therapy (naltrexone), e.g., under anesthesia (APA 2006).

The opiate antagonist-induced withdrawal under anesthesia is indicated only in special cases and is not associated with a better outcome. This method must be performed under ICU conditions. Opiate antagonist application induces a pronounced withdrawal syndrome with an increase in catecholamine and a strong cardiovascular stimulation in opioid-dependent patients. Severe hypokalemia may occur. In published protocols, multiple doses of naltrexone were administered intragastral during several hours under general anesthesia. Relevant other side effects are severe electrolyte disorders, nausea, gastric reflux, diarrhea, and muscle and stomach pain. The procedure continues until the withdrawal symptoms have subsided or a negative challenge test (intravenous administration of naloxone). The naltrexone maintenance treatment should be carried out for several months in an interdisciplinary psychosocial treatment approach (APA 2006; Brewer et al. 1998; Hensel and Kox 2000; Kork et al. 2010; Schmidt et al. 1998).

111.5 Cocaine

111.5.1 Clinic

The central and peripheral reuptake inhibition of norepinephrine, dopamine, and serotonin is responsible for the stimulatory effects of cocaine resulting in a stimulation of the CNS and the sympathetic system with pronounced cardiovascular and cerebrovascular effects and related complications. It has also a local anesthetic effect. The pathogenesis of ischemic complications is multifactorial: increased oxygen demand with a fixed or limited myocardial oxygen supply, myocardial vasoconstriction, and increased platelet aggregation tendency. By the chronic use of cocaine, there is a depletion of dopamine and other neurotransmitters and a decrease in dopamine receptors D2. This is associated with depression and the so-called crash. Therefore, all patients with a history of cocaine as well as stimulant use should be carefully evaluated, especially for cardiovascular and neurological morbidity (Egred and Davis 2005; Hernandez et al. 2005; Hollander and Henry 2006).

111.5.2 Therapy

Treatment of patients with chest pain and ECG changes includes oxygen, benzodiazepines, nitrates, and acetylsalicylate. Benzodiazepines can reduce the elevated blood pressure, tachycardia, and anxiety. Calcium channel blockers and alpha-blockers may be given in addition. Beta-blockers without alpha-blockade are contraindicated for the treatment of cocaine-induced hypertension and tachycardia. They increase the cocaine-related mortality, possibly due to increased α-adrenergic stimulation, e.g., coronary spasm. The 1-selective blocker esmolol along with an infusion of sodium nitroprusside or the administration of calcium antagonists can be used. The indications for thrombolytic therapy should be made cautiously in the context of cocaine use. If symptoms persist, catheter revascularization seems to be safer (Egred and Davis 2005; Hernandez et al. 2005; Hollander and Henry 2006).

111.5.3 Urgent and Emergency Intervention

Cocaine is rapidly metabolized and is therefore difficult to detect in the blood, but it can be detected in the urine up to 6 days after ingestion. The sympathomimetic effect may persist beyond the actual phase of intoxication. A cardiopulmonary and neurological evaluation should be performed. A drug screening reveals drug use. In addition to injuries, often associated with violence, chest pain is common among cocaine-induced symptoms in the ED patients. Cardiac troponin I or T is more specific compared to the CK-MB or even myoglobin for acute myocardial infarction after cocaine use. There is a high rate of false-positive myoglobin and creatine kinase values, especially in rhabdomyolysis. Acute cocaine ingestion can have cardiotoxic effects and is related to sudden death. ECG findings are abnormal in

56–84 % of patients with cocaine-associated chest pain. It should be noted that the sensitivity of the ECG is only 36 % and specificity is 90 %. Regional anesthesia during cocaine intoxication is not recommended because local anesthetics have similar pharmacological effects as cocaine and might potentiate toxicity. If general anesthesia is required in an urgent situation, avoid the potentiating substances, e.g., adrenergic stimulants, ketamine, etomidate, aminophylline, MAO inhibitors, tricyclic antidepressants, acetylcholinesterase inhibitors, muscle relaxants with autonomic side effects, local anesthetics, and volatile anesthetics with stimulating properties. The sympathomimetic effect of cocaine can make the assessment of the intravascular volume or blood loss difficult, so more extended monitoring next to arterial (and central venous) pressure measurement and monitoring of urine and hemodynamic stabilization before induction of anesthesia is important. As part of the intensive inpatient treatment, possible withdrawal symptoms are observed. Cerebral blood flow is reduced. First signs are lower blood pressure, hypothermia, and miosis. Benzodiazepines and clonidine can be considered (Egred and Davis 2005; Hernandez et al. 2005; Hollander and Henry 2006).

111.5.4 Elective Procedure

Patients with cocaine abuse have a higher risk of cardiovascular disease, also after the intoxication phase. The sympathomimetic effect can be prolonged and withdrawal also can be a risk for a cardiovascular event. Benzodiazepines in an adequate dosage can be given for premedication. Any stimulating medication should be used with caution, including those inhalation anesthetics or muscle relaxants such as pancuronium with autonomic side effects that sensitize the myocardium to catecholamines. The total intravenous anesthesia is preferred (Egred and Davis 2005; Hernandez et al. 2005; Hollander and Henry 2006).

111.6 Other Drugs

It is beyond the scope of this chapter to describe all specific features of abused drugs with an addictive potential relevant for anesthesia. Synthetic drugs are increasingly used. Clinically important is a heterogeneous group of stimulatory, entactogenic ("touching the inside"), hallucinogenic, or hypnotic drugs with overlapping properties. As a general rule, symptomatic treatment, screening for drug use, and consulting expert help (e.g., poison control center) can be recommended for critically ill patients with suspected drug use. A systematic diagnostic approach might reveal unexpected morbidity, as acute and chronic use has been related to a wide spectrum of neurological, cardiovascular and pulmonary, metabolic, and infectious/immunological complications even in younger undergoing smaller procedures: Diagnostic strategies that include, e.g., a full lab, drug screen, echocardiography, or imaging, should be considered early. Patients with suspected intoxication should be monitored

continuously. Street drugs may be mixed with many other relevant substances (Steadman and Birnbach 2003; Hernandez et al. 2005). Many patients use more than one drug, e.g., many self-medicate in order to overcome withdrawal symptoms, such as "the crash" that comes after taking stimulants or sedatives. A distinction between intoxication, withdrawal, and neurological insult is often difficult, and important other causes for delirium should be ruled out (Table 111.1, Kork et al. 2010; Spies and Rommelspacher 1999).

111.6.1 Stimulants, Entactogens, and Hallucinogens

Ecstasy (e.g., MDMA), amphetamines, and LSD act more or less stimulating. Tachycardia, hypertension, dizziness, panic attacks, or visual illusions can occur. Clinical important complications are cardiac arrhythmias, hyperthermia, renal failure, hepatotoxicity, multiorgan failure, rhabdomyolysis, hyponatremia and cerebral edema, seizures and intracranial hemorrhage, altered consciousness, or sudden death (Hernandez et al. 2005; Hall and Henry 2006). When used in dance marathons, extreme dehydration and hyperthermia up to 42 °C might occur or hyponatremia due to excessive water intake. Cerebrovascular accidents and complications due to acute anxiety and panic disorders may also occur (Hernandez et al. 2005; Hall and Henry 2006).

111.6.2 Treatment of Acute Intoxications

The treatment of acute stimulant intoxication is symptomatic. Dehydration and hyperthermia is treated with external and internal cooling, rehydration, antipyretics, correction of electrolyte imbalance and (metabolic) acidosis, and sedative and anticonvulsant therapy. Intubation and ventilation can be required. A sedative, antianxiety, and anticonvulsant treatment with benzodiazepines is usually indicated. Seizures can be treated with benzodiazepines or barbiturates. Arterial hypertension can be treated with urapidil, clonidine, nitroprusside, nitrates, or labetalol; beta-blockers alone without alpha-blockade should be avoided. The spectrum of cardiovascular complications and side effects is similar to cocaine stimulants (myocardial vasoconstriction, increased oxygen demand with a fixed or limited myocardial oxygen supply, and increased platelet aggregation propensity). Dantrolene is also recommended for hyperthermia, if temperature is >39 °C after initial treatment. It was considered probably safe and effective. The association with malignant hyperthermia is controversial. Clomethiazole or diazepam was effective in animal experiments for hyperthermia. Antipsychotic drugs are contraindicated as they might lower the seizure threshold, and it is difficult to differentiate the clinical presentation from the neuroleptic malignant syndrome. Hyponatremia should be carefully corrected. Metabolic acidosis should be corrected (especially when the QT interval is prolonged). In case of organ failure, conventional supportive ICU therapy is provided. Especially dangerous is the concomitant use of tricyclic antidepressants and monoamine oxidase inhibitors with MDMA.

Excessive release of serotonin leads to cerebral seizures, tremors, loss of consciousness, ventricular fibrillation, and death (Steadman and Birnbach 2003; Hernandez et al. 2005; Hall and Henry 2006; Grunau et al. 2010).

111.6.3 Elective Procedure

If patients undergo procedures in the drug-free interval, a careful evaluation is necessary as outlined above. A history of seizures, a decreased hepatic and renal function, and coagulation disorder infections are of interest in all patients. All anesthetics should be titrated according to the effect (Kork et al. 2010). PCP and LSD might prolong succinylcholine via inhibition of plasma cholinesterase (Hernandez et al. 2005). Patients with MDMA-induced hyperthermia in the history should undergo a trigger-free anesthesia (Hernandez et al. 2005; Hall and Henry 2006; Steadman and Birnbach 2003). A brief intervention addressing risky use should be delivered. An interdisciplinary psychosocial counseling and treatment plan should be initiated early (Kork et al. 2010).

111.7 Cannabis

The risk profile of cannabis, also used in a dependent way, is predominantly characterized by an increased pulmonary morbidity due to smoking. During intoxication it has some dose-dependent effect on the sympathetic activity; an increase is followed by a decrease, thus tachycardia or hypotension and bradycardia. Components of cannabis might have relevant antiemetic, analgesic, anticonvulsant, and appetite increasing effects (Hernandez et al. 2005).

111.8 GABAergic Substances

Gamma-hydroxybutyrate is abused increasingly. The effect is dose dependent, may be influenced by consuming other drugs, and ranges from euphoric-relaxing effect to drowsiness and deep sleep with subsequent coma and possible respiratory depression. Side effects – nausea, vomiting, hypotension, respiratory distress, confusion, myocloni, and convulsions – were observed. It is used as K.O. drops or as a growth hormone releaser among bodybuilders. After intake it can cause a pronounced amnesia. It is not detected by routine drug screening (Steadman and Birnbach 2003; Hernandez et al. 2005). Many patients are dependent from benzodiazepines or are using them to cope with symptoms of withdrawal or comorbidity. Relevant interactions on the pharmacodynamic and pharmacokinetic level have to be considered. In these patients, an altered GABA receptor function can be assumed. All anesthetics should be titrated to the desired effect. Neuromonitoring is recommended to avoid intraoperative awareness. Abrupt withdrawal causes anxiety and may cause seizures and should be avoided. Also hypnotics are misused

and have been linked to dependency. Not only healthcare providers have misused propofol in a risky or dependent way. In short-acting hypnotics, the range between the desired effect and relevant respiratory depression is narrow, especially in combination with other substances (Steadman and Birnbach 2003; Hernandez et al. 2005; Tan et al. 2011; Lader 2011).

111.9 Conclusion

Dependent patients with SUD can safely undergo procedures under anesthesia. In general, SUD and related complications can be successfully treated. By secondary or tertiary preventive measures in a multimodal interdisciplinary concept, the increased risk can be significantly reduced.

Elements are:

- Systematic screening, using questionnaires/markers
- Systematic diagnostic evaluation
- Brief interventions, tailored advice, and information
- Patient-centered communication style
- Individually tailored anesthesia
- Detoxification
- Abstinence
- Rehabilitation
- Psychosocial therapy
- Stepped care
- Harm reduction
- Monitoring and prevention of withdrawal symptoms, substitution therapy
- Monitoring and prevention of complications, goal-oriented therapy, symptom control, prevention of secondary injury, and stress reduction
- Complex interdisciplinary treatment strategies
- Teaching and training

Neurobiology of Chronic Pain and Opioid Analgesic Dependence and Addiction

112

Kelly S. Barth and Jeffrey J. Borckardt

Contents

Abstract

Pain is a highly prevalent worldwide issue, affecting 20 % of all adults. With increasing use of opioid analgesics over the past decade, there has been a concomitant rise in opioid analgesic abuse and dependence, particularly in the United States, Australia, and New Zealand. Many frontline clinicians receive little, if any, training or education in pain management or opioid analgesic pharmacology. In an effort to address this educational gap, the purpose of this chapter is to provide a basic and broad overview of (1) the neurobiology of pain (including classification and pathophysiology of acute and persistent pain), (2) the processes that occur naturally and pathologically when opioid analgesics are used for pain (including analgesia, tolerance, physical dependence, and addiction), and (3) an overview of the neurobiology specific to opioid analgesic addiction. The goal of this chapter is to improve the basic understanding of pain and opioid analgesic addiction for frontline clinicians.

112.1 Introduction

Pain is an enormous worldwide problem. Twenty percent of adults in the world suffer from pain and 10 % of adults are newly diagnosed with chronic pain each year (Goldberg and McGee 2011).

Though controversial, opioid analgesics are often prescribed for pain. In 2009, the estimated worldwide prevalence of current opioid use was between 0.5 % and 0.8 %, approximating 24–35 million people, including nearly 18 million people (5.9 % of the population) in the United States (United Nations Office on Drugs and Crime 2011).

Although not a uniquely American issue, US citizens, constituting less than 5 % of the world's population, have been consuming 80 % of the global opioid supply, including 99 % of the global hydrocodone supply (Manchikanti and Singh 2008). This places opioid analgesics as the most commonly prescribed medication of any category in the United States (Kuehn 2007). In Australia, there was a 60 % increase in prescriptions for opioid analgesics and a 180 % increase prescriptions for oxycodone from 2002 to 2009 (Hollingworth et al. 2013; United Nations Office on Drugs and Crime 2011). In New Zealand, pharmaceutical opioids diverted from the medical system have been known to be a central source of opioids for injecting drug users since the regular supply of heroin was disrupted in the 1970s (Wilkins et al. 2011).

With regard to opioid abuse and addiction, this too is a global problem, with between 13 and 22 million people worldwide abusing opioids in the past year (United Nations Office on Drugs and Crime 2011). However, when we separate opioid abuse into heroin and opioid analgesic abuse, we again see substantial regional differences. In the majority of Europe, Africa, and Asia, heroin remains the most prevalent illegally consumed opioid. In the Americas, Australia, and New Zealand, illegally diverted or misused prescription opioids (e.g., codeine, hydrocodone, morphine, hydromorphone, oxycodone, meperidine, tramadol) are the primary opioids of abuse. In 2009, 1.9 million people in the United States were addicted to prescription opioid pain relievers and 359,000 addicted to heroin (United Nations Office on Drugs and Crime 2011). Morphine and methadone have become the "street" opioids of choice in New Zealand, with the number of opioid substitution treatment centers increasing from 650 in 1990 to more than 4,000 in 2011 – despite the shortage of heroin (Robinson et al. 2011). Additionally, some African and Asian nations have also reported a surge in opioid analgesic abuse in the last decade (United Nations Office on Drugs and Crime 2011; van den Brink and Haasen 2006).

In contrast to other commonly abused substances, prescription opioids are unique in that their consumption is prescribed and endorsed by healthcare professionals. Because of this, some individuals develop a false sense of safety regarding prescription opioids and erroneously believe that the severity and risk of negative side effects is lower with prescription opioids as compared to other substances. Nonmedical prescription opioid use, however, is associated with increased rates of unintentional overdose, significant physical and mental

health problems, and staggering societal cost (e.g., emergency room admissions, lost productivity) (McLellan and Turner 2008).

The purpose of this chapter is to provide a broad overview of the basic neurobiology of pain, the processes that occur naturally and pathologically when opioid analgesics are used for pain, and neurobiology specific to opioid analgesic addiction.

112.2 Neurobiology of Pain and Opioid Addiction

112.2.1 Pain

Pain can be defined as an unpleasant sensation which is localized to a part of the body. Because pain is universally understood as a signal of disease, it is the most common symptom that brings a patient to a physician's attention. The function of the pain sensory system is to detect, localize, and identify tissue-damaging processes. Whether characterized as a symptom, sign, or syndrome, the common denominator of pain is suffering. In this regard, pain is both sensation and emotion. Pain of moderate or higher intensity is often accompanied by anxiety and an urge to escape or end the feeling. When acute, pain can be associated with behavioral arousal and a stress response consisting of increased blood pressure, heart rate, pupil diameter, and plasma cortisol levels. Additionally, local muscle contraction is often present.

112.2.1.1 Types of Pain

Pain is often initially categorized as being nociceptive or neuropathic (Portenoy 1989). Nociceptive pain is perceived by a highly specialized subset of nerve fibers (nociceptors) that respond only to painful or noxious stimuli or stimuli that become painful if prolonged. These fibers are present in nerves to the skin and deep somatic and visceral structures. The most painful stimuli activate a variety of nociceptor types in the affected area, which are summed into one nociceptive input, and ultimately lead to the subjective sense of pain.

Nociceptive Pain

Nociceptive pain is generally caused by tissue damage (e.g., injury, surgery) and can be further divided into somatic and visceral pain. Somatic pain, caused by injury to body tissues, is well localized but variable in description and experience. Visceral pain, caused by injury to internal organs, is mediated by stretch receptors and generally characterized as poorly localized, deep, dull, and cramping (e.g., pain associated with pancreatitis, cholecystitis, or nephrolithiasis).

Nociceptive pain can also be divided into musculoskeletal pain, inflammatory pain (e.g., inflammatory arthritis, postoperative pain, tissue injury, infection), or mechanical/compressive pain (e.g., low back pain, neck pain, visceral pain from expanding tumor masses).

Neuropathic Pain

Neuropathic pain is caused by abnormal neural activity due to disease, injury, or dysfunction of the nervous system. It generally persists without ongoing disease (e.g., diabetic neuropathy, trigeminal neuralgia, or thalamic pain syndrome). Depending on which type of neural injury and the location of the neural injury, neuropathic pain can be further subdivided into peripheral neuropathy, sympathetically mediated pain, and central pain.

Peripheral neuropathy is caused by damage to a peripheral nerve (without associated autonomic change, e.g., postherpetic neuralgia and neuroma formation). Sympathetically mediated pain arises from injury to a peripheral nerve which does have associated autonomic changes (e.g., complex regional pain syndrome, causalgia). Central pain arises from abnormal central nervous system activity (e.g., phantom limb pain, pain from spinal cord injuries, and poststroke pain).

Mononeuropathy affects only one nerve; mononeuropathy multiplex affects several nerves in different areas of the body; and polyneuropathy describes diffuse and bilateral neuropathy.

112.2.1.2 Pathogenesis of Pain

Acute Pain

Any pain sensation begins with a noxious stimulus sensed by peripheral nociceptors. A-delta fibers are relatively fast-conducting myelinated nociceptors. They respond to thermal and mechanical stimuli and are responsible for the first (immediate) sharp pain. Unmyelinated C-fibers make up most of the peripheral nociceptors. These slow-conducting fibers respond to thermal, mechanical, and chemical stimuli, recover from fatigue more slowly than the A-delta nociceptors, and mediate delayed or longer-lasting pain, typically characterized as dull.

The pain signal is transmitted from the peripheral A-delta and C-fibers to the dorsal horn of the spinal column via primary afferent neurons. The primary ascending pathway for pain from the dorsal horn of the spinal column to the brain is the spinothalamic tract, which projects contralaterally within the spinal cord and synapses in the thalamus. Neurons from the thalamus then project to multiple brain areas in the primary and secondary somatosensory cortex, cingulate cortex, prefrontal cortex, insular cortex, amygdala, and the cerebellum. It is important to note that the spinothalamic tract axons also connect to thalamic and cortical regions linked to emotional responses, such as the cingulate gyrus and frontal lobe. This pathway is thought to mediate the unpleasant emotional aspect of pain.

In addition to ascending pain pathways, descending inhibitory and facilitatory pathways exist that modulate the experience and sensation of pain. For example, circuits from the prefrontal cortex and anterior cingulate cortex may decrease nociceptive input, indirectly augmenting analgesia. These descending fibers may also interact with the opioid system, noradrenergic system, and serotonergic system and can significantly inhibit responses to noxious stimuli. Descending facilitatory pain pathways are also present.

112.2.1.3 Mechanisms for Persistent Pain

Several mechanisms modulate the progression of acute pain to chronic pain. These include peripheral and central sensitization as well as other mechanisms (ectopic excitability, structural reorganization/phenotypic switch of neurons, primary sensory degeneration, and disinhibition).

Sensitization

Peripheral sensitization and central sensitization are the major causes of pain hypersensitivity after injury.

Peripheral Sensitization

When painful stimuli are intense, repeated, or prolonged, cells become damaged. These damaged cells can release their intracellular contents as well as synthesize substances including cytokines, chemokines, bradykinin, histamine, prostaglandins, and growth factors. As part of the inflammation process, leukotrienes are also engaged. These substances, among others, can directly activate the nociceptor terminal or sensitize the terminal so that it becomes hypersensitive to subsequent stimuli. These substances can also indirectly facilitate the sensitization process by recruiting other inflammatory substances and propagating the cycle. Therefore, in the presence of damaged tissue or inflammation, the threshold for activating nociceptors is lowered and the frequency becomes higher for all stimulus intensities. Additionally, in the presence of injury and inflammation, nociceptors themselves can begin to express new channels, further facilitating the sensitization process. A good example of peripheral sensitization is sunburn. The decreased threshold for activating the nociceptors in the damaged area serves to protect the area from further injury through avoidance of pain.

Central Sensitization

Central sensitization is caused by an increase in excitability of central nociceptor transmission neurons of the spinal cord (at the level of the synaptic transfer from the nociceptor terminal to dorsal horn neurons). Initially, strong nociceptive input, which may come from acute injury, chronic pain syndromes, or peripheral sensitization, activates the dorsal horn neurons and causes a massive release of glutamate and co-regulatory peptides. Glutamate, a major excitatory neurotransmitter, modulates synaptic transmission in the dorsal horn in several ways. First, glutamate binds alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropioninc acid (AMPA) receptors on dorsal horn neurons, which mediates fast excitatory transmission. Additionally, glutamate interacts with N-methyl-D-aspartic acid (NMDA) receptors. During a normal, physiologic pain transmission, the NMDA receptor is physically blocked by a magnesium ion so that no current flows if glutamate binds the receptor. Massive release of glutamate in the dorsal horn, which can occur with acute or persistent injury, not only activates AMPA receptors, facilitating fast excitatory transmission, but also causes strong membrane depolarization resulting in removal of the magnesium blockade to the NMDA receptor,

thereby increasing the time the channel is open. Additionally, the NMDA receptor is phosphorylated, which increases its distribution in the synaptic membrane and its responsiveness to glutamate. The increase in excitability of the dorsal horn cell means that it can be activated by normally subthreshold inputs, with increased response to suprathreshold inputs, leading to the process of central sensitization.

Other Mechanisms for Persistent Pain

In the face of injury, multiple changes in the functioning and structure of nociceptors and their pathways can lead to persistent pain. When sensory neurons are injured, they can become altered such that they begin to spontaneously initiate action potentials independent of a stimulus, similar to a pacemaker. These pacemaker-like action potentials are postulated to arise due to upregulation of voltage-gated sodium channels (or their subunits), upregulation of receptors in myelinated neurons, or downregulation of potassium channels on nociceptors. Additional alterations in the sensory neurons from nerve injury can lead to actual physical rearrangement and new growth in the circuitry of the dorsal horn and for normally quiescent glial cells in the spinal cord to become activated, producing cytokines and chemokines that alter patterns of gene transcription in neurons. Moreso, neuromodulators that are normally expressed only in C-fibers (like brain-derived neurotrophic factor and substance P) may begin to be expressed in large-diameter A fiber neurons.

Nerve injury can also decrease inhibitory pain pathways in the dorsal horn. Excessive glutamate release, failure of glutamate uptake, or TNF-alpha released from microglia can lead to selective apoptosis of GABAergic inhibitory synaptic currents. This loss in inhibitory GABA function can recruit previously absent A-beta fiber activity, effectively unmasking a previously silent pathway.

Pain Modulation: How Psychological Factors Can Contribute to Chronic Pain

In clinical work with patients experiencing pain, it is clear that the pain produced by similar injuries can be remarkably variable in different situations and in different people. Some patients with back injuries, for example, can have a full recovery, while others can become severely disabled with a seemingly minor injury. Furthermore, even the suggestion of relief can have a significant analgesic effect (placebo) in certain patients, whereas others can find even minor injuries (such as venipuncture) unbearable. It is known that the expectation of pain can induce pain without a noxious stimulus (anticipatory pain), whereas merely having perceived control over pain can decrease pain substantially.

The powerful effect of expectation and other psychological variables on the perceived intensity of pain implies the existence of brain circuits that can modulate the activity of the pain-transmission pathways.

Although there are probably several circuits that can modulate pain, one has been studied extensively. This circuit has links in the hypothalamus, midbrain, and medulla and selectively controls spinal pain-transmission neurons through a descending pathway. There is good evidence that this pain-modulating circuit also contributes to the pain-relieving effect of opioid analgesic medications.

Each of the component structures of the pathway contains opioid receptors and is sensitive to the direct application of opioid drugs. Furthermore, lesions to the system reduce the analgesic effect of systemically administered opioids such as morphine. Along with the opioid receptor, the component nuclei of this pain-modulating circuit contain endogenous opioid peptides such as enkephalins and **β**-endorphin.

The most reliable way to activate this endogenous opioid-mediated modulating system is by prolonged pain and/or fear. There is evidence that pain-relieving endogenous opioids are released following operative procedures and even in patients given a placebo for pain relief.

Pain modulation is bidirectional. Pain-modulating circuits not only produce analgesia but are also capable of increasing pain. Both pain-inhibiting and pain-facilitating neurons in the medulla project to and control spinal pain-transmission neurons. Since pain-transmission neurons can be activated by modulatory neurons, it is theoretically possible to generate a pain signal with no peripheral noxious stimulus. Such mechanisms could account for the finding that pain can be induced by suggestion alone and may provide a framework for understanding how psychological factors can contribute to chronic pain.

112.2.2 Neurobiology of Opioid Analgesia, Tolerance, and Dependence

Most of the commercially available opioid analgesics act at the mu (μ) opioid receptor, differing mainly in potency, speed of onset, duration of action, and optimal route of administration. Opioid agonists produce analgesia through direct action in brain and spinal cord regions involved in the transmission and modulation of pain. Additionally, some effects may be mediated by opioid receptors on peripheral sensory nerve endings.

112.2.2.1 Receptor Types

There are three major classes of opioid receptors: mu (μ), delta (**δ**), and kappa (**κ**). All are members of the G protein-coupled family of receptors. Multiple receptor subtypes have been proposed based on pharmacologic criteria, including μ1, μ2; **δ**1, **δ**2; and **κ**1, **κ**2, and **κ**3. Since an opioid may function with different potencies as an agonist, partial agonist, or antagonist at more than one receptor class or subtype, it is not surprising that these agents are capable of diverse pharmacologic effects.

112.2.2.2 Cellular Actions and Neural Mechanisms for Central and Peripheral Opioid Analgesia

At the molecular level, opioid receptors are physically coupled to G proteins. Opioid peptides have two well-established direct G protein-coupled actions on the opioid receptors of pain neurons: (1) they inhibit voltage-gated (N-type) calcium channels in the presynaptic membrane of primary sensory neurons,

thereby preventing the release of neurotransmitters, and (2) they hyperpolarize, and thus inhibit, postsynaptic secondary neurons by activating potassium channels, preventing the onset of action potentials. The presynaptic action – depressed transmitter release – has been demonstrated for a large number of neurotransmitters, including acetylcholine, norepinephrine, serotonin, substance P, and glutamate (the principal excitatory amino acid released from nociceptive nerve terminals).

Endogenous opioid peptides are the major inhibitory neurotransmitters in the dorsal horn of the spinal cord, and pharmaceutical opioids have been developed in order to mimic this action in order to provide pain relief. The majority of currently available opioid analgesics act primarily at the μ-opioid receptor. As μ-opioid receptors are also expressed in the medullary respiratory control center, the medullary chemoreceptor zone, and the gastrointestinal tract, opioids may also produce respiratory depression, nausea, vomiting, and constipation. Therefore, both the analgesic effects of opioid analgesics and the primary side effects and physical dependence result principally from actions at μ-receptors. The primary spinal involvement of the pain-relieving aspects of opioids has been exploited clinically by direct application of opioid agonists to the spinal cord. This can provide regional analgesic effects without causing the systemic effects of respiratory depression, nausea, vomiting, and sedation that may occur from the supraspinal actions of systemically administered opioids.

It is important to note that systemic opioid analgesic effects are complex and also include interaction with **δ** and **κ** receptors, both directly and through activation of endogenous opioid peptides. For example, when opioid analgesics are given systemically, part of the pain-relieving action involves the release of endogenous opioid peptides. All three receptor subtypes (μ, **κ**, **δ**) are present in high concentrations in the dorsal horn of the spinal cord and modulate supraspinal and spinal analgesia, but each receptor subtype responds with different affinity to endogenous opioid peptides. **δ** receptors are thought to have high affinity to the endogenous opioid class of enkephalins and are also thought to modulate hormone and neurotransmitter release. **κ-**receptors have high affinity for dynorphins and are thought to be responsible for psychotomimetic effects and slowed gastrointestinal transit of exogenous opioids. An exogenous opioid agonist (e.g., morphine) may act primarily and directly at the μ-receptor, but this action may evoke the release of endogenous opioids that additionally act at **δ**- and **κ**-receptors, causing both additional pain relief and additional side effects. Thus, even a receptor-selective ligand can initiate a complex sequence of events involving multiple synapses, transmitters, and receptor types.

In an effort to develop opioid analgesics with reduced side effect profiles, especially related to respiratory depression, tolerance, and addiction, there has been development of compounds that show preference for **κ**-opioid receptors, such as butorphanol and nalbuphine. However, these agents have been limited in their clinical success as analgesics due to dysphoric reactions and limited potency. It is interesting that butorphanol has been shown to cause significantly greater analgesia in women than in men. In fact, gender-based differences in analgesia mediated by μ- and **δ**-receptor activation have been widely reported.

Partial-agonists at the μ-opioid receptor, such as buprenorphine, have also been shown to have less propensity for tolerance than full opioid agonists.

Under most circumstances, exogenous opioid analgesics are given systemically and so act simultaneously at multiple sites. These include not only the ascending pathways of pain transmission through nociceptors detailed above but also descending (modulatory) pathways. As opioids directly inhibit pain neurons, there is a simultaneous activation of descending inhibitory neurons that send processes to the spinal cord and inhibit pain neurons. This activation has been shown to result from the inhibition of inhibitory neurons in several locations. Taken together, interactions at these sites increase the overall analgesic effect of opioid agonists.

In addition to actions in the central nervous system, animal and human clinical studies have demonstrated that endogenous and exogenous opioids can produce opioid-mediated analgesia at sites outside the central nervous system. The activation of peripheral μ-receptors on sensory terminals results in a decrease in sensory neuron activity and transmitter release and inhibition of the pain signal. Endogenously, **β**-endorphins released by immune cells within injured or inflamed tissue represent one source of physiologic peripheral μ-receptor activation. Peripheral administration of exogenous opioids, for example, into the knees of patients following arthroscopic knee surgery, has shown clinical benefit up to one day after administration.

112.2.2.3 Pharmacogenetics

There is wide interindividual variability among patients in response to opioid analgesics. The majority of exogenous opioids are metabolized by the cytochrome P450 2D6 (CYP2D6) pathway or by glucuronidation. Codeine, oxycodone, and hydrocodone undergo O-methylation to produce metabolites that have a stronger μ-receptor affinity. Therefore, they exert their analgesic properties mainly through their metabolites. The O-methylation step is controlled by CYP2D6. CYP2D6 polymorphisms have been associated with altered enzyme activity that could result in altered drug effects. For example, poor metabolizers, or individuals who do not express functional CYP2D6, can only form trace amounts of O-methylated products and may experience reduced analgesia. For example, in poor metabolizers who take codeine, a prodrug that is metabolized to morphine, only trace amounts of morphine will be detected. Conversely, drugs like morphine, oxymorphone, and hydromorphone are already O-demethylated, so they will be less effected by metabolism and have smaller interindividual variability of opioid effects.

112.2.2.4 Tolerance and Dependence

With frequently repeated therapeutic or recreational doses of morphine or its surrogates, there is a gradual loss in effectiveness which requires higher doses of the substance to get the same effect; this is termed tolerance. Along with tolerance, physical dependence develops, which is defined as a characteristic withdrawal or abstinence syndrome when a drug is stopped or an antagonist is administered.

The mechanism of development of tolerance and physical dependence is not completely understood, but persistent activation of μ-receptors, such as what occurs with the treatment of severe chronic pain, appears to play a primary role in its induction and maintenance. It is also interesting to note that tolerance develops to most side effects of opioids such as euphoria, respiratory depression, and nausea, but not to the side effect of constipation.

Withdrawal (Dependence)

The locus ceruleus, located in the upper pons, is a major source of norepinephrine for the brain and an important mediator of tolerance to opioids. There are opioid receptors in the locus ceruleus, and when activated, they suppress the release of norepinephrine, contributing to the classic symptoms of opioid intoxication, including drowsiness, slowed breathing, and low blood pressure. With repeated exposure to opioids, the locus ceruleus increases alternative paths of norepinephrine production in order to maintain a homeostatic alertness. When opioids are subsequently withdrawn, there is a relative surge of norepinephrine. This leads to subjective symptoms of withdrawal, including increased anxiety and tremor, among other symptoms. This is the site of action of clonidine when given to relieve symptoms of opioid withdrawal.

Other brain areas in addition to the locus ceruleus also contribute to the production of withdrawal symptoms, including the mesolimbic reward system. For example, opioid receptors are located in the ventral tegmental area, and when tolerance develops, there is a decrease in the release of dopamine into the nucleus accumbens. In addition to becoming tolerant to the euphoric effects of the drug, this may also prevent the patient from obtaining pleasure from normally rewarding activities such as eating. These changes in the ventral tegmental area and dopamine reward systems, though not fully understood, form an important brain system underlying craving and compulsive drug use.

Tolerance

On a molecular level, chronic opioid administration results in an upregulation of the intracellular cyclic adenosine monophosphate (cAMP) system at multiple levels in the locus ceruleus. These changes include increased levels of Gi and Go proteins (alpha subunits), adenylate cyclase, and cAMP-dependent protein kinase. Given the location of these changes in the locus ceruleus, it is postulated that the upregulation of the adenylate cyclase system may play a role in the development of tolerance. It is less clear whether the specific changes in the second-messenger function in the locus ceruleus persist beyond the period of chronic opioid administration.

Although the process of upregulation of the cAMP system is associated with tolerance, more recent theories suggest it is not sufficient to explain it. Another hypothesis for the development of opioid tolerance and dependence is based on the concept of receptor recycling. Normally, activation of μ-receptors by endogenous endorphins results in endocytosis followed by resensitization and recycling of the receptor to the plasma membrane. This process is thought to be an important component of tolerance. It is known that morphine, a drug known to be susceptible

to tolerance, fails to induce endocytosis of the μ-opioid receptor, whereas methadone, which is less susceptible to tolerance and used for the treatment of chronic pain and opioid addiction, does induce receptor endocytosis. This suggests that maintenance of normal sensitivity of μ-receptors requires reactivation by endocytosis and recycling at the plasma membrane. A related hypothesis suggests that receptor uncoupling is involved with tolerance due to a dysfunction of structural interactions between the μ-receptor and G proteins, second-messenger systems, and their target ion channels. This uncoupling and recoupling of μ-receptor function is likely linked to receptor recycling.

Another interesting theory involves the NMDA-receptor ion channel complex, which has been shown to play a central role in the development and maintenance of tolerance in that NMDA-receptor antagonists such as ketamine can block tolerance development. Although a role in endocytosis is not yet clearly defined, the development of novel NMDA-receptor antagonists or other strategies to recouple μ-receptors to their target ion channels provides hope for achieving a clinically effective means to prevent or reverse opioid analgesic tolerance. One last hypothesis suggests that the **δ**-opioid receptor is involved with tolerance and functions as an independent component in the maintenance of tolerance.

In addition to the development of tolerance, persistent administration of opioid analgesics has been observed to increase the sensation of pain leading to a state of hyperalgesia. This phenomenon has been observed with several opioid analgesics, including morphine, fentanyl, and remifentanil. Spinal dynorphin and activation of the bradykinin receptor have emerged as important candidates for the mediation of opioid-induced hyperalgesia.

112.2.3 Neurobiology of Opioid Addiction

The pleasure derived when opioids activate the brain's natural reward system promotes continued drug use during the initial stages of opioid addiction. Subsequently, repeated exposure to opioid drugs induces the brain mechanisms of dependence, which leads to daily drug use to avert the unpleasant symptoms of drug withdrawal. Further prolonged use produces more long-lasting changes in the brain that may underlie the compulsive drug-seeking behavior and related adverse consequences that are the hallmarks of addiction. Drug addiction is characterized by a pathological motivation for drug-seeking and drug-use behaviors that is associated with the inability to stop such behaviors, even despite negative consequences related to drug use (Kalivas and Volkow 2005). Recent scientific research has generated several models to explain how habitual drug use produces changes in the brain that may lead to drug addiction. In reality, the process of addiction probably involves components from each of these models, as well as other features.

The general neurobiology of addiction has been detailed in previous chapters of this text. To understand the neurobiology of addiction specific to opioids and prescription opioids, we will review animal models that most closely mimic "drug-seeking behavior" (drug reinforcement studies) and relapse and

reinstatement (conditioning homeostatic models), involving opioids. We will also review more recent literature describing structural brain changes associated with prescription opioid use and dependence.

112.2.3.1 Behavioral Neurobiology of Opioid Reinforcement ("Drug-Seeking Behavior")

Opioid tolerance, dependence, and addiction are all manifestations of brain changes resulting from chronic opioid use and abuse. It is known, however, that one does not have to be physically dependent upon opioids to experience primary reinforcing properties of opioids. Decades ago, Bozarth and Wise (1984) demonstrated the neurobiology of this phenomenon in a study on drug-naive rats that learned to press a lever in order to receive direct injections of morphine into the ventral tegmental area (mimicking drug-seeking behavior in humans). The rats were then exposed to a challenge with naloxone (a direct opioid antagonist), which did not precipitate signs of withdrawal following the morphine injections. Moreover, signs of withdrawal were not seen after long-term morphine infusion into the ventral tegmental area but were observed after chronic infusion into the periventricular gray region. The data strongly suggested that the pathways mediating opioid reinforcement (e.g., the ventral tegmental area) were independent of pathways mediating the signs of opioid withdrawal (e.g., the locus ceruleus).

The pathways for opioid reinforcement and dependence, however, are clearly overlapped in some areas of the brain where opioids can act as both reinforcers and cause dependence. In the nucleus accumbens, a brain area important for reward and pleasure, and in the locus ceruleus, an area of the pons associated with physiologic response to stress and panic (and producer of norepinephrine), opioids can acts as reinforcers. But studies have also shown that with direct placement of naloxone in the nucleus accumbens of morphine-dependent rats, withdrawal can cause the disruption of food-mediated behaviors and conditioned place aversion. The locus ceruleus is also sensitive to the acute reinforcing effects of opioids (resulting in a suppression of locus ceruleus activity), as well as to the effects of opioid withdrawal (as characterized by a large increase in locus ceruleus activity). Thus, it is clear that some neurons are affected both by the acute reinforcing effects of opioids as well as by opioid withdrawal. The data are consistent with the view that although opioids will serve as reinforcers in the absence of physical dependence, the "motivation" for opioid self-administration is enhanced during opioid withdrawal.

As with other drugs of abuse, there is evidence that opioid reinforcement involves activation of dopamine neurons, with an increase in extracellular dopamine concentrations in the nucleus accumbens. With repeated administration, more opioid is needed to stimulate the ventral tegmental area brain cells of the mesolimbic reward system to release the same amount of dopamine in the nucleus accumbens. Therefore, more opioid is needed to produce pleasure comparable to that provided in previous drug-taking episodes. Interestingly, although the lesioning of dopamine neurons in the nucleus accumbens eliminates stimulant self-administration, it fails to eliminate opioid self-administration in rats (Koob and Bloom 1988). Opioids may also indirectly increase the firing of

dopamine neurons by activating μ-opioid receptors in the ventral tegmental area and nucleus accumbens, producing local disinhibitory effects on the dopamine neurons. Not surprisingly, naloxone blocks the effects of opioids on the ventral tegmental area (Britt and Wise 1983).

It is interesting to note that with chronic administration of opioids, an increased sensitization to their reinforcing properties (reverse tolerance) can be seen. It is hypothesized that chronic opioid administration can affect gene expression of guanine-nucleotide binding proteins (G proteins) and the cyclic adenosine monophosphate (cAMP) system. These changes in the molecular biology of second-messenger function may be related to the development of sensitization to the reinforcing properties of opioids.

112.2.3.2 Models for Progression to Addiction

Theories on the neurobiologic basis of addiction are not unique to opioid addiction and have been reviewed in previous chapters. We will provide a brief review of the neurobiologic theories of addiction as they apply to opioid and prescription opioid addiction.

112.2.3.3 The "Changed Set-Point" Model in Relation to Prescription Opioid Dependence

The "changed set-point" model of drug addiction postulates that drug abuse alters a biological or physiological setting or baseline of the dopamine reward system. This model has several variants based on the altered neurobiology of the dopamine neurons in the ventral tegmental area, the nucleus accumbens, and the locus ceruleus during the early phases of withdrawal and abstinence. One variant of the changed set-point model, by Koob and LeMoal (2001), is based on the idea that neurons of the mesolimbic reward pathways are naturally "set" to release enough dopamine in the nucleus accumbens to produce a normal level of pleasure. Koob and LeMoal suggest that repeated doses of opioids initiate a vicious cycle of changing this set point which results in decreased release of dopamine during normally pleasurable activities (in the absence of opioids).

112.2.3.4 Molecular, Genetic, and Structural Changes with Acute and Chronic Opioid Exposure

On a molecular level, it is known that the dopamine receptor, which uses cAMP as its second messenger, is affected by chronic morphine administration (Beitner-Johnson and Guitart 1992). Chronic morphine treatment results in decreased levels of the G protein that inhibits adenylate cyclase, with increases in adenylate cyclase and cAMP-dependent protein kinase. Ultimately, these changes can alter the structural features of mesolimbic dopamine neurons so as to reduce the ability of these cells to transmit dopamine signals to postsynaptic cells in the nucleus accumbens. This leads to an effective resetting of the set point of the mesolimbic dopamine neurons.

Chronic morphine treatment also results in a decrease in the phosphorylation state of tyrosine hydroxylase in the nucleus accumbens (the rate-limiting enzyme in

the synthesis of dopamine) (Bietner-Johnson and Guitart 1992). This results in decreased functional activity of the enzyme in the nucleus accumbens, whereas there is upregulation (and increased phosphorylation) of the enzyme in the ventral tegmental area.

Bronstein and colleagues (1990) have reported that there is a decline in pro-opiomelanocortin (POMC) messenger ribonucleic acid (mRNA) levels with chronic morphine treatment. Because POMC yields several biologically active peptides, including **β**-endorphin, ACTH, melanocyte-stimulating hormone, and B-lipotropin, morphine may also affect the biosynthesis of the endogenous opioid, **β**-endorphin. Specifically, the authors report that chronic morphine treatment appears to result in the preferential production of **β**-endorphin 1–27 (which functions as an antagonist at the μ-opioid receptor) relative to **β**-endorphin 1–31 (which functions as an agonist at the μ-receptor). Acute stress also favors the production of **β**-endorphin 1–27 relative to **β**-endorphin 1–31. Chronic treatment with naltrexone (a narcotic antagonist) increases the mRNA for POMC and results in an increase in **β**-endorphin 1–27. The work suggests that the POMC system is quite sensitive to the effects of exogenous opioids as well as to acute stress.

Chronic opioid treatment also produces regionally specific changes in gene expression of a number of second-messenger functions in the brain that are associated with the reinforcing effects of opioids (Beitner-Johnson and Guitart 1992). Taken together, these changes result in decreased dopamine synthesis in the nucleus accumbens and changes in dopamine receptor function.

Structurally, chronic morphine treatment results in a decrease in neurofilament proteins in dopamine neurons in the ventral tegmental area. These effects are regionally specific. The neurofilament proteins form a major component of the cytoskeleton. Consistent with this result, cytoskeletal or cytoskeletal-associated elements of dopamine neurons have been shown to be altered by chronic morphine treatment resulting in selective reduction in the size of ventral tegmental area dopamine neurons (Beitner-Johnson and Guitart 1992).

As described previously, a changed set point also occurs in the locus ceruleus, but in the opposite direction, such that norepinephrine release is increased during withdrawal. Under this changed set-point model, both the positive (drug liking) and negative (drug withdrawal) aspects of drug addiction are accounted for.

It remains to be seen whether specific changes in second-messenger function in locus ceruleus (associated with tolerance and dependence) and the mesolimbic dopamine system persist beyond the period of chronic opioid administration to account for some of the signs and symptoms of protracted withdrawal/abstinence.

In 2000, researchers further specified the changed set-point model in describing additional specific ways that dopamine neurons can become dysfunctional in the face of repeated opioid exposure (Grace 2000). They postulate that the resting level of dopamine released into the nucleus accumbens is the result of two factors: cortical excitatory (glutamate) neurons that drive the dopamine neurons of the ventral tegmental area to release dopamine and autoreceptors (“brakes”) that shut down further release when dopamine concentrations become excessive.

Activation of opioid receptors by heroin and prescription opioids initially bypasses these brakes and leads to a large release of dopamine in the nucleus accumbens. With repeated use and further surges of dopamine in the reward system, the brain responds by increasing the number and strength of the autoreceptors ("brakes") on the dopaminergic neurons of the ventral tegmental area. In the absence of opioid administration, the enhanced autoreceptors lower the resting tone of dopamine in the reward system. This can trigger the dependent addict to take even more opioid to offset this lower resting tone of dopamine. Whenever he or she stops using opioids, a state of relative dopamine deficiency will result, manifesting in opioid withdrawal symptoms such as dysphoria, agitation, body pain, and malaise. This places the individual at high risk for relapse to drug use.

Thus, several mechanisms in the locus ceruleus, ventral tegmental area, and nucleus accumbens pathways are likely operating during addiction and relapse. Additionally, overactive cortical excitatory brain pathways caused by opioid addiction may also contribute to the changed set-point model, in that excitatory cortical projections may produce little activation in the ventral tegmental area during the resting state, leading to additional reductions in dopamine. However, when the addicted individual is exposed to cues that produce craving, the excitatory (glutamate) pathways may get sufficiently active to raise dopamine and stimulate desire for a greater high. This same increase in glutamate activity will raise norepinephrine release from the locus ceruleus to produce a dysphoric state during withdrawal predisposing to relapse and continued addiction.

112.2.3.5 Cognitive Deficits Model

The cognitive deficits model of drug addiction proposes that individuals who develop addictive disorders have abnormalities in the prefrontal cortex, an area important for judgment, planning, and other executive functions. The prefrontal cortex sends inhibitory signals to the dopamine neurons of the ventral tegmental area of the mesolimbic reward system and enables individuals to delay immediate gratification for the sake of longer-term goals. This model proposes that those with addictive disorders have defects in the ability of the prefrontal cortex to inhibit the mesolimbic reward system, and as a result, they have decreased ability to use higher-level judgment or restrain impulses to use drugs.

Supporting this concept, it has been shown that stimulant drugs, such as methamphetamine, can damage a specific brain circuit – the frontostriatal loop – that carries inhibitory (GABA) signals from the prefrontal cortex to the mesolimbic reward system. In contrast, heroin has been shown to damage the prefrontal cortex but not the frontostriatal loop. It may be that individuals predisposed to opioid addiction have some degree of prefrontal damage that is independent of their opioid abuse, either inherited genetically or caused by some other factor or event in their lives (Kosten 1998). Finally, the cognitive deficits model of addiction could explain the clinical finding that heroin addiction tends to be more severe in those with comorbid antisocial personality disorder – a condition that is independently associated with deficits in the prefrontal cortex (Raine et al. 2000).

112.2.3.6 Animal and Human Studies on Brain Changes Associated with Chronic Opioid Analgesic Administration

Chronic opioid exposure is known to produce neuroplastic changes in animals. However, despite theories based on animal models and literature extrapolated from research on heroin addicts, very little direct research has been done evaluating individuals with primary prescription opioid addiction. Additionally, there has been little differentiation in human data between opioid-dependent individuals and nonaddicted users of chronic prescription opioids for pain, two very different clinical populations.

In a recent small cross-sectional study of ten prescription opioid-dependent individuals and 10 age-matched controls, researchers found that the prescription opioid-dependent subjects demonstrated decreased gray matter volume in the bilateral amygdalae (Upadhyay et al. 2010). The amygdala is a key reward-modulating structure that is known to underlie opioid-related addiction, dependence, and tolerance. Morphologic abnormalities in the amygdalae of the prescription opioid-dependent individuals may explain an additional possible deficiency in the neural reward-processing network. The results of this study added to existing animal literature that showed that opioid exposure can have a broad range of effects on the amygdala, including decreased μ-opioid receptor sensitivity (Maher et al. 2005), modulated gamma-aminobutyric acid (GABA) receptor functioning (Zarrindast et al. 2004), and modified glutamate receptor targeting (Glass et al. 2005).

A subsequent pilot study (Younger et al. 2011) was the first longitudinal study to investigate prescription opioid effects on the human brain. In this study, ten nonaddicted opioid-naive individuals with chronic low back pain received structural brain MRIs before and after 1 month of daily morphine analgesic therapy. After 1 month of morphine, the investigators found significant volumetric decreases in the right amygdala and significant volumetric increases in the right hypothalamus, left inferior frontal gyrus, right caudal pons, and right ventral posterior cingulate. These changes persisted on average for 5 months after cessation of opioids. The same scanning procedure was also completed on nine patients with low back pain receiving a blinded placebo substance, and no morphologic changes were found. This study adds to a growing body of evidence that opioid exposure can cause structural and functional derangements in reward- and affect-processing circuitry and suggests that these changes can occur over a short amount of time in humans exposed to prescription opioids. Further research is needed to determine the clinical significance of this as it related to both nonaddicted and addicted individuals.

psychological strategies for pain management may serve a more central role. Despite efficacious psychosocial pain management interventions and advancing medication management for pain, there is evidence that chronic pain cannot be adequately managed and may progress in the context of substance abuse problems. For this reason, the care of patients with chronic pain and substance abuse problems must be carefully coordinated to meet the multiple needs of the patient. Pain management in the context of substance abuse problems may be best conceptualized within the biopsychosocial model of pain. The biopsychosocial model of pain emphasizes that pain is a biological, psychological, and social experience. Within this model, pain management is approached by simultaneously addressing pain through biological, psychological, and social mechanisms. Several psychosocial approaches to pain management have been developed, tested, and shown efficacious for reducing pain, pain-related disability, and psychological distress. In this chapter, we present information on pain management in patients with chronic pain and substance abuse problems from a biopsychosocial perspective, emphasizing work in psychosocial pain management strategies, behavioral strategies for substance abuse problems, and possible strategies for integrating the two.

113.1 Introduction

Managing chronic pain is challenging and further complicated in patients with substance abuse problems. There is growing evidence supporting the efficacy of psychological approaches to pain management (Williams et al. 2012). In most cases, psychological approaches for pain management are applied as an adjunct to medication management for pain. For patients with pain and substance abuse problems, psychological strategies for pain management may serve a more central role. Despite efficacious psychosocial pain management interventions and advancing medication management for pain, there is evidence that chronic pain cannot be adequately managed and may progress in the context of substance abuse problems (Savage 1993, 1996; Manchikanti et al. 2008). For this reason, the care of patients with chronic pain and substance abuse problems must be carefully coordinated to meet the multiple needs of the patient.

The management of pain in the context of substance abuse problems may be best conceptualized within the biopsychosocial model of pain. The biopsychosocial model of pain emphasizes that pain is a biological, psychological, and social experience (Keefe and France 1999; Engel 1977, 1980). Within this model, pain management is approached by simultaneously addressing pain through biological (e.g., rehabilitation, pharmacotherapy), psychological (e.g., behaviors, cognitions, affect), and social (e.g., relationships, recreation) mechanisms. The biopsychosocial model is in contrast to the biomedical model, which has the objective of explaining and eliminating pain by addressing the anatomical or pathological causes of pain.

Several psychosocial approaches to pain management have been developed, tested, and shown efficacious for reducing pain, pain-related disability, and psychological distress. In this chapter, we present information on pain management in patients with chronic pain and substance abuse problems from a biopsychosocial perspective, emphasizing work in psychosocial pain management strategies, behavioral strategies for substance abuse problems, and possible strategies for integrating the two.

113.2 Managing Pain in Patients with Substance Abuse Problems

Chronic pain is prevalent and its management can be complicated. Managing chronic pain in patients with substance abuse problems presents an even greater treatment challenge.

113.2.1 Concerns of Pain Medications

The standard of care for treating patients with chronic non-cancer-related pain is opioid medications (Portenoy 2000; Ballantyne and Mao 2003). There is empirical evidence supporting the use of opioid medication for chronic pain, and several organizations provide statements and directions for providers to follow when prescribing opioid medication for chronic pain (Manchikanti et al. 2012; Chou 2009; Chou et al. 2009; Dale et al. 2011). However, even in patients who do not have a history of substance abuse problems, there is often reluctance by many medical providers to supply long-term opioid medication due to concerns of addiction, as well as respiratory depression and decreased pain tolerance (Passik 2009). These concerns are greater in patients with a known history of substance abuse problems or patients who may be at risk for substance abuse problems.

113.2.2 Risk Factors for Substance Abuse Problems

While the actual risk for opioid addiction may be lower than perceived by both medical providers and patients, it is important to be aware of patients with chronic pain who may be at an increased risk for substance abuse problems. Risk factors have been identified that may indicate a patient with chronic pain could be vulnerable to substance abuse problems. Passik (2009) identified several factors that are listed in Table 113.1. The behaviors indentified in Table 113.1 are important for providers to keep in mind and monitor during treatment.

In addition to observable behaviors at the time of treatment, there are a number of past behaviors, patient beliefs, and emotional difficulties that can contribute to an increased risk of substance abuse problems in patients with chronic pain. A prior history of substance abuse is the most consistent predictor of medication abuse in

Table 113.1 Factors that may be related to substance abuse problems in patients with chronic pain

1.	Use of alcohol or illicit drugs
2.	Problems functioning at work or in other social roles
3.	Injecting oral medications
4.	Repeated dose increases
5.	Nonadherence to medication regimens or medical procedures
6.	Obtaining prescription drugs from nonmedical services
7.	Resistance to changes in prescription despite negative effects
8.	Repeated seeking of prescriptions from several medical sources
9.	Selling prescription drugs
10.	Stealing, borrowing, or losing drugs

persons with chronic pain (Ives et al. 2006; Portenoy 1996; Schieffer et al. 2005; Manchikanti et al. 2003, 2006). Studies have found that patients in pain management programs with a history of past alcohol or illicit drug abuse (i.e., cocaine), past misuse of pain medications, past drug or driving under the influence convictions, legal problems related to alcohol or drugs use, or a family history of substance abuse were much more likely to have problems with opioid abuse and/or urine toxicology screens that were positive for misuse of opioid medications and/or illegal drug use (Ives et al. 2006; Michna et al. 2004). One study examined differences in opioid treatments in patients with chronic pain who had a history of alcohol abuse alone versus patients who had a history of poly substance abuse or oxycodone abuse. This study found that patients with only an alcohol abuse history were successfully managed on chronic opioid treatment, but that patients with a history of poly substance or oxycodone abuse were not successful candidates for long-term opioid treatment (Dunbar and Katz 1996).

Patients' beliefs about pain medication may also contribute to their use or abuse of medication for chronic pain. In a study of 288 patients with chronic pain, patients who endorsed beliefs that narcotic mediations are effective for pain control, that medications will help with their emotions, that they would be better able to function with access to free medications, and that they needed higher amounts of narcotics to experience pain relief than other patients were more likely to abuse medications for chronic pain (Schieffer et al. 2005). Interestingly, these investigators found that patients who held these beliefs and had a substance abuse history were more vulnerable to misuse of pain medication than patients who did not hold these beliefs but still had a substance abuse history.

Current or past emotional difficulties, such as depression and anxiety disorders, have been related to problems with pain medication misuse in patients having chronic pain. A history of major depressive disorder is associated with increased opioid abuse in patients with chronic pain (Manchikanti et al. 2006; Kouyanou et al. 1997; Webster and Webster 2005). Other work has found that patients with high levels of trait

anxiety, panic attacks, or post-traumatic stress disorder were more likely to have problems abusing pain medications than patients without these problems (Wilsey et al. 2008).

The relationship between emotional difficulties and pain medication misuse is likely due to several factors. Some work has found that opioid medications are not as effective in reducing pain in patients with a history of mood or anxiety disorders (Wasan et al. 2005). Given this, patients with these disorders may experience less pain relief when taking opioid medications and thus may increase their dose or use other maladaptive strategies to control their pain. Other data has found that adults who were feeling depressed or anxious were twice as likely to initiate the use of pain medications without a prescription or to use pain medications in a way other than prescribed when compared to patients who were not experiencing these symptoms (Substance Abuse and Mental Health Services Administration 2006).

Capitalizing on the multifaceted approach of the biopsychosocial model to pain management in patients with substance abuse problems may provide particularly important guidance. In the next several pages, we present information on psychological interventions for pain management that have empirical evidence to support their benefits for reducing pain, pain disability, and distress in patients with chronic pain. We focus on cognitive-behavioral approaches that have garnered the most empirical support and are most widely applied. Given the high incidence of overlap between chronic pain and substance abuse problems, we suggest that the risk factors mentioned above be assessed (i.e., through patient medical record review or patient and family self-report) at the onset of psychosocial interventions for chronic pain.

113.2.3 Cognitive-Behavioral Approaches for Pain Management

Cognitive-behavioral approaches to the management of pain are arguably the most commonly applied psychological interventions for pain. Cognitive-behavioral approaches for pain management propose that individuals with pain often develop maladaptive thought patterns (e.g., pain catastrophizing) and behaviors (e.g., activity avoidance) that can contribute to increased pain and disability (Williams et al. 2012). These cognitive-behavioral interventions target teaching patients to reconceptualize their thoughts about pain and to increase behaviors that decrease pain and eliminate behaviors that contribute to higher pain. In a meta-analysis examining the use of CBT protocols applied to patients with cancer pain, 65 % of studies found that these protocols were effective in reducing pain and that the average effect size across studies was 0.23 (95 % confidence interval 0.07–0.39; $p = 0.004$) (Abernethy et al. 2006). Other meta-analyses in general pain samples have found that cognitive and behavioral interventions are beneficial (ES = 0.46) in decreasing pain and improving pain-related disability (Morley et al. 1999). Below, we present several common strategies used in CBT interventions for pain and highlight some empirical studies examining the efficacy of CBT interventions for pain.

113.2.4 Cognitive-Behavioral Therapy Interventions for Pain Management

Cognitive-behavioral therapy (CBT) for chronic pain management includes teaching patients a variety of skills and strategies for learning to manage their pain. CBT protocols for managing chronic pain may include one skill, a few skills, or a comprehensive program of skills and strategies. Common core skills of CBT protocols for pain management include relaxation strategies such as progressive muscle relaxation and imagery, activity pacing, pleasant activity planning, cognitive restructuring, problem solving, and goal setting.

Pain coping skill training (PCST) is a CBT-based pain management protocol that has been developed and tested by Keefe and colleagues (1987, 1990) in numerous patient samples with chronic pain. PCST was developed to (1) decrease maladaptive pain catastrophizing and (2) enhance patients' ability to cope with pain and pain-related disability. Below, we present example of CBT skills and strategies with a PCST framework, using the authors' experiences to provide illustrative points – particularly in relation to how PCST skills might be applicable to patients with chronic pain and substance abuse problems.

113.2.5 Relaxation Strategies

Progressive muscle relaxation (PMR) is a relaxation strategy that involves teaching patients to recognize tension they hold in their body and to routinely use relaxation to decrease the tension. Edmund Jacobson originally developed PMR in the early 1920s (Jacobson 1938), and it has since been used for a number of physical problems (Yoo et al. 2005; Sheu et al. 2003; Yu et al. 2007). In relation to pain, patients are taught to progressively tighten and relax several muscle groups throughout their body (e.g., feet, legs, shoulders) (Bernstein and Borkovec 1973). As patients are instructed to tighten and relax their muscles, it is suggested that tightening feels like tension and relaxing feels comforting. PMR is designed to help patients quickly recognize stress and tension in their body that will likely to lead to increased pain if not controlled and to use PMR strategies to relax any bodily tension. The goal of PMR is to have patients with pain monitor their tension levels as they go throughout their day and to habituate to relaxing tension rather than letting it increase.

PMR has been well received by patients participating in research studies in our laboratory, and it is a central component to efficacious PCST studies (Keefe et al. 1987, 1990). While the use of PMR strategies in substance abuse populations has not been well studied, research has suggested that PMR could affect physiological arousal after nicotine craving (Parker et al. 1978). In patients with substance abuse problems, PMR may serve as a strategy to decrease high pain or tension (e.g., physiological arousal) that may increase patients' risk of misusing substances.

113.2.6 Imagery

Imagery is another form of relaxation that encourages the patient to focus their attention on a safe and pleasant scene, away from pain. In practice, a therapist or coach will often help patients brainstorm several safe or pleasant scenes (e.g., beach, meadow, lake, grandmother's kitchen) and then ask the patient to select the scene they would like to use for the imagery practice. One strategy to help the patient improve the quality or vividness of their image is to take the patient through an exercise where they identify what they experience with each of their senses (i.e., see, hear, feel, taste, smell) in the scene they are imagining. Imagery often starts with a brief relaxation (e.g., getting comfortable, closing eyes, focusing on breathing) that leads into the patient using their senses to imagine their pleasant image. In patients with substance abuse problems and pain, imagery practice could be dually used to distract patients from pain and any desire/craving for medication or other drugs toward a more pleasant and safe scene. Research has demonstrated the efficacy of guided imagery in reducing levels of pain (Posadzki et al. 2012) and craving (Versland and Rosenberg 2007), supporting the use of this strategy with patients who have chronic pain and substance abuse problems.

113.2.7 Activity-Related Pain Coping Strategies

Two activity-related pain coping strategies are commonly applied in PCST, as well as several other CBT pain management protocols. The first is activity-rest cycling which teaches the patient to avoid overactivity that can lead to high levels of pain and fatigue (i.e., the overactivity cycle) (France and Krishnan 1988). Activity-rest cycling involves teaching patients to schedule activities throughout their day into cycles of moderate activity and limited rest. The goal of this strategy is to teach patients a way to remain active, but to not engage in activity that is likely to lead to pain and possibly prolonged rest, fatigue, and emotional distress. In patients with substance abuse problems, the activity-rest cycle could be presented as a strategy that can help them avoid medication overuse or misuse that can result when they engage in overactivity that leads to extreme pain.

Pleasant activity planning is another activity-related strategy commonly used in CBT protocols for pain management (Keefe et al. 1990; Somers et al. 2012a). Pleasant activity planning involves helping patients brainstorm a variety of activities they might enjoy, but are not currently doing or have never tried before. Patients are encouraged to brainstorm big activities such as a trip to another country, as well as small activities such as taking time to enjoy a cup of hot tea on the porch. The rationale for pleasant activity planning is that often when patients have chronic pain, they decrease their activities and are most likely to decrease activities they enjoy (vs. activities they are obligated to do such as work or childcare). Pleasant activity planning encourages patients to think about and engage in activities they might enjoy. Often pleasant activity planning can be combined

with the activity-rest cycle to help patients enjoy an activity without overdoing it and finding themselves in higher levels of pain.

For patients with substance abuse problems, they may find that as they decrease their maladaptive substance behaviors, they have more time on their hands and/or more energy. Pleasant activity planning may be very important in helping them engage in meaningful activities and avoid relapsing to problematic substance use behaviors (McHugh et al. 2010). This strategy has been a key component to efficacious CBT interventions for substance abuse (Dutra et al. 2008; Magill and Ray 2009), suggesting that pleasant activity scheduling could be used to jointly target pain and substance use problems.

113.2.8 Cognitive Restructuring

Chronic pain is a very challenging problem and patients with chronic pain may find that they engage in negative thinking about their chronic pain. Negative thoughts about pain, while understandable, have been shown to be related to much higher levels of pain, physical disability, and emotional distress (Somers et al. 2009, 2012b; Keefe et al. 2010). Importantly, patients who engage in negative thinking about their pain have been found to use higher levels of pain medications and/or be less adherent to using their medications as prescribed. Pain catastrophizing is a negative cognition about pain that has been widely studied and appears to result in increased pain levels as well as other negative pain-related outcomes (Keefe et al. 2004). Pain catastrophizing refers to an individual's tendency to focus on and magnify pain sensations and feel helpless when they experience pain (Sullivan et al. 2001). Cognitive restructuring within the context of pain management is a strategy that helps patients begin to notice their negative thinking patterns (e.g., I will always be in pain; there is nothing I can do to help with this pain) and to replace their negative thinking with more neutral (and at times, more positive) thinking. Helping patients change their negative pain-related thoughts can increase their ability to manage their pain. Newer CBT protocols have focused their efforts on decreasing pain catastrophizing in patients with chronic pain (Riddle et al. 2012).

Cognitive restructuring may be a particularly important skill for patients with pain and substance abuse problems (Steigerwald and Stone 1999). CBT with a focus on cognitive restructuring has been shown to be effective for patients with substance abuse problems and other comorbidities (i.e., post-traumatic stress disorder) (McGovern et al. 2009). Patients with chronic pain and substance abuse problems are likely to hold a number of negative thoughts or faulty cognitions (e.g., I need this much medication because I have pain; I don't have a problem with substance use, and I can control it; there is no other option to control my pain than to misuse this substance) around their substance use and abuse. Cognitive restructuring can help patients with substance abuse problems to recognize thoughts that maintain their substance use and work to change those thoughts to more realistic thoughts. Cognitive restructuring can be used in patients with pain and substance abuse to address both of these challenges.

113.2.9 Problem Solving and Goal Setting

CBT protocols for pain management typically include structured problem-solving skills to help patients learn to manage their pain (Somers et al. 2012a). Problem solving can help patients with pain to identify current and anticipated challenges and generate possible strategies to manage the challenge (e.g., brainstorming possible strategies to increase their use of pleasant activity scheduling during the week). Problem solving within a CBT context also includes helping patients to reflect on how well their selected solution worked and what they might change or repeat in the future. Goal setting involves having patients set short- and long-term goals in learning to manage their pain. Patients are often encouraged to break their goals into small steps and set very objective measures of progress (e.g., use the activity-rest cycle for all household activities – use activity-rest cycle while cooking dinner and assess pain levels during activity).

Problem solving and goal setting are both key skills in CBT protocols for substance use disorders, as patients with substance use problems often struggle with delaying long-term pleasure (e.g., sense of mastery that accompanies abstinence) for short-term pleasure (e.g., euphoria of drug use) (McHugh et al. 2010). Thus, these strategies could be used to simultaneously address challenges related to both pain and substance abuse.

113.2.9.1 Cognitive-Behavioral Strategies Applied to Patients with Chronic Pain: A Selected Review of Empirical Work

CBT has been widely studied as an intervention strategy for patients having chronic pain. Below we highlight results from studies using several pain populations and highlight the variability of the application of CBT.

An early study published in 1990 by Keefe et al. (1990) examined the effects of a CBT intervention designed to reduce pain, physical disability, psychological disability, and maladaptive pain behavior in patients with osteoarthritic knee pain. This CBT intervention was compared to arthritis education and standard care. The CBT protocol in this study was delivered during 10 weekly, 90 min, group sessions and taught patients the skills of relaxation, imagery, distraction, activity-rest cycling, pleasant activity planning, and cognitive restructuring. Study results showed that patients who received the CBT protocol had significantly lower levels of pain and psychological disability following treatment than patients in the other two conditions. Since this time, much work has been done applying CBT protocols to improve patients' level of pain. Subsequent research has included testing CBT protocols in patients with other types of pain conditions, involving family members in CBT pain management protocols, and increasing the reach and accessibility of such interventions (Somers et al. 2012a; van Hooff et al. 2012; Carmody et al. 2012; Radojevic et al. 1992). Below we present some studies that highlight these advances.

In a study done in the Netherlands (van Hooff et al. 2010), the investigators examined the impact of a residential, 10-day CBT program for patients with chronic low back pain. This program involved 100 h of participant contact time delivered in

a 2-week group-oriented, residential setting. The program components included a stretch and exercise program, education to explain chronic pain, and the use of CBT skills including activity planning, activity pacing, cognitive restructuring, and several relaxation techniques. In the year following the program, participants improved on measures of daily functioning and overall quality of life. A follow-up study (van Hooff et al. 2012) found that 2 years after the program, patients maintained these results and reported decreased use of pain medication and health-care services. This CBT program may be a particularly good model to consider in patients with pain and substance use problems. The inpatient nature of the pain management program may provide an intervention delivery modality that could combine CBT interventions for pain management with common inpatient interventions for substance abuse problems.

While in-person CBT interventions have long been the norm for treatment delivery, an increasing amount of work is being done examining the use of telephone and mobile health technologies (mHealth) to deliver CBT pain management interventions. Interventions delivered by telephone or mHealth technologies are enticing because the delivery reach is greater (e.g., patients can access these from their home if they are not close to a center that provides the intervention) and patient burden is reduced (e.g., travel time, rearranging schedule, physical burden of in-person sessions). Carmody et al. (2012) examined the effectiveness of a telephone-based CBT program in managing chronic in older military veterans. This study was a randomized controlled trial and compared the CBT intervention to a pain education intervention. Interestingly, results of this work found that both CBT and pain education led to improved physical and mental health and reduced pain and depressive symptoms. Pain catastrophizing mediated improvements in these outcomes (i.e., physical and mental health, pain and depressive symptoms). This study demonstrates that a telephone-based intervention can lead to improvements for patients with chronic pain.

In a recent study, published by our group (Somers et al. 2012a), we examined the utility of pairing two psychosocial interventions to benefit patients who suffered from chronic pain and obesity. In our work, we used a randomized controlled trial to examine the long-term efficacy of a combined pain coping skill training (PCST) and lifestyle behavioral weight management intervention (BWM) in overweight and obese OA patients. We found that patients who received the combined psychosocial intervention of PCST+BWM demonstrated significantly better outcomes on key variables including pain and weight compared to patients who received either treatment alone or standard care. This study should serve as model for providers who treat patients who have both chronic pain and substance abuse. When a patient experiences dual challenges, it may be necessary to address both challenges to provide patients with the optimal benefit.

In addition to CBT pain management strategies that teach skills to the patient with chronic pain, there is work that supports involving both the patient and the patient's partner in the treatment of chronic pain. Including partners in interventions for chronic pain expands the application of the biopsychosocial model of pain in psychosocial interventions, as the basis of the model is that pain is influenced by

biological, psychological, and social factors in a cyclic manner. There is evidence that suggests that when patients with chronic pain are adjusting well to their pain, their partner's biological, psychological, and social adjustment is also improved. Likewise, there is evidence that suggests that a partner's adjustment to the patient's chronic pain also impacts the patient in each of these domains. From a clinical perspective, providers often comment that the dynamics of a patient-partner relationship can have a significant impact on how the patient is adjusting to and managing chronic pain.

Intervention studies have examined the value of including partners in psychosocial interventions for treating chronic pain. One of the first studies to do this was by Radojevic et al. (1992) and examined the use of family support in teaching patients with rheumatoid arthritis to manage their pain. This study found that behavioral therapy with a family component led to improvements in joint swelling and pain compared to intervention without a family component and standard care. Other work by Keefe et al. (1996, 1999) has found that when patients with osteoarthritis pain are randomized to a pain coping skill training protocol with or without spouses, patients in the spouse intervention had the best outcomes posttreatment. Interestingly, patients in the spouse intervention showed the longest maintenance of treatment gains showing improvement up to a year following treatment.

This concept of including family members and partners in psychosocial interventions for patients with chronic pain and substance abuse problems may be particularly important and beneficial. Substance abuse programs and intervention protocols very often include partners, other family members, and even friends and other acquaintances (McHugh et al. 2010; Hunt and Azrin 1973; Epstein and McCrady 1998). In fact, there are several theoretically based substance abuse treatments with empirical support that suggest that including patients' significant others in treatment is a critical component to treatment (McCarthy 1999). Studies have found that substance abuse interventions that include a patient's partner or family are more effective than interventions that do not include others in improving substance use outcomes (Fals-Stewart and Birchler 2001; McCrady et al. 2009). While there is limited research examining the combined value of psychosocial interventions for individuals with chronic pain and substance abuse problems, work in each of these fields suggests that such treatments may result in a synergistic impact for patients struggling with these issues.

113.2.9.2 Acceptance-Based Psychosocial Approaches to Pain Management

There has been growing interest in the use of acceptance-based therapies for pain management. Acceptance and commitment therapy and mindfulness-based therapies are commonly used for patients with chronic pain and have been studied in clinical trials. Acceptance and commitment therapy (ACT) is an empirically based psychological intervention, derived from cognitive-behavioral therapy (CBT), which focuses on acceptance and mindfulness processes and commitment and behavioral change processes. ACT targets ineffective control strategies and helps

individuals learn to accept what they cannot control in life and commit to actions that are grounded in their values (Hayes 1999).

The primary therapeutic process in ACT is psychological flexibility, including processes such as acceptance, awareness, present-focused interactions, living by one's value system, and an ability to balance acceptance and change behavior (Hayes 1999). By cultivating psychological flexibility, chronic pain patients may be able to change their relationship with painful thoughts and feelings by accepting their present experience (e.g., pain sensations) and engaging in behavior grounded in their values (e.g., engage in activities that improve their day-to-day discomfort – activity pacing).

A recent review and meta-analysis concluded that acceptance-based treatments (i.e., ACT, mindfulness) have small to moderate effects on pain, depression, anxiety, physical well-being, and quality of life for patients with chronic pain (Veehof et al. 2011). Among the randomized controlled studies that assessed the efficacy of ACT interventions for chronic pain patients, results indicated that there were significant improvements in both physical (i.e., pain disability, sick days) and psychological (e.g., depression, life satisfaction) outcomes (Bruckstein 1999; Dahl et al. 2004; Wicksell et al. 2008).

To date, there has been no published research investigating the efficacy of ACT for chronic pain patients with substance abuse problems. However, ACT-based interventions have been utilized in substance abuse populations, and preliminary evidence suggests that ACT could be beneficial for individuals with substance use problems. Specifically, ACT has demonstrated positive outcomes for opiate addiction, chronic marijuana use, alcohol abuse, and nicotine dependence (Hayes et al. 2004; Twohig et al. 2007; Petersen and Zettle 2009; Gifford et al. 2004). A recent randomized clinical trial demonstrated that a group-based week-long ACT intervention led to long-term reductions in shame, fewer days of substance use, and higher treatment attendance among patients with substance use disorders (Luoma et al. 2012). The results of these studies suggest that ACT-based interventions might help individuals with substance use problems relate to difficult thoughts and emotions (e.g., shame) with acceptance and mindfulness, instead of by avoiding challenging internal experiences and engaging in conditioned responses like substance use. It appears that ACT has the potential to benefit chronic pain patients with substance abuse problems by helping them accept difficult thoughts and feelings (e.g., distress, pain), potentially reduce their substance use (e.g., pain medication-seeking behavior), and increase their commitment to values-based pain management behaviors (e.g., activity pacing).

Mindfulness-based stress reduction (MBSR) is another acceptance-based intervention for chronic pain. MBSR is a group-based intervention that originated from Eastern spiritual practices and focuses on utilizing meditation to cultivate awareness of one's moment-to-moment experience in a nonjudgmental and accepting manner (Kabat-Zinn 1990). Through the practice of mindfulness meditation techniques (i.e., body scan, sitting meditation, hatha yoga) and group dialogue related to meditation practice and stress management, individuals learn how to accept the present moment, not react in a conditioned way, and utilize effective coping skills

when facing physical states, emotions, or thoughts, such as those related to chronic pain.

Systematic reviews have demonstrated the feasibility and efficacy of MBSR and mindfulness-based interventions on psychological and physical outcomes among healthy and clinical populations (e.g., lower anxiety, improved immune markers) (Bohlmeijer et al. 2010; Matousek et al. 2010; Chiesa and Serretti 2009). Interestingly, there has been growing evidence for the use of MBSR interventions among patients with chronic pain. A recent review indicated that mindfulness-based interventions can lead to nonspecific effects related to the expectation of pain reduction and an improvement of depressive symptoms among patients with chronic pain (Chiesa and Serretti 2011). Additionally, mindfulness-based interventions have been shown to lead to greater pain acceptance and tolerance, compared to control conditions. This research suggests MBSR and mindfulness-based interventions can help chronic pain patients relate differently to their thoughts and feelings (e.g., increased awareness and acceptance of distress and pain).

Preliminary research has also indicated that MBSR and mindfulness-based interventions can lead to improvements in substance use-related outcomes (e.g., decreased substance use and psychological distress) (Zgierska et al. 2009). Conceptually, MBSR would be posited to increase an individual's awareness of their thoughts and feelings (e.g., distress, cravings) and help them mindfully respond to such sensations, instead of automatically reacting and engaging in substance use behaviors. In light of this research, it is possible that mindfulness-based interventions could offer psychological and physical relief to chronic pain patients suffering from substance use problems.

113.2.10 Substance Abuse Treatment Strategies to Use Within the Context of Psychological Pain Management

Psychological approaches, particularly CBT-based protocols, to pain management have been shown to be efficacious. Psychological approaches largely target patients' behaviors (e.g., activity avoidance), cognitions (e.g., pain catastrophizing), and affect (e.g., depression). Behavioral techniques are also commonly used within the context of pharmacotherapy for patients with pain who are prescribed certain medications (e.g., opioid) and/or have a history of substance abuse problems. Behavioral techniques include strategies such as an opioid agreement contract, frequent brief visits to monitor adherence, prescription of a limited number of pills at a time, and toxicology screens. There are also several self-report questionnaires and interviews that are used to assess patients' risk for opioid abuse and their adherence (vs. nonadherence) to pain medication. These behavioral techniques and self-report assessments could effectively be integrated or used conjunctively with psychological approaches to pain management. Perhaps most important in monitoring and attending to substance abuse problems in patients with chronic pain is capitalizing on collaborative treatment planning between all providers and the patient.

113.2.10.1 Opioid or Other Medication Agreement or Contract

Medication agreements or contracts are a common approach to reducing the risk of substance abuse problems in patients with chronic pain who are at risk for substance abuse (Manchikanti et al. 2008). These contracts include objective and specific details of medication treatment, lay out the responsibility of the patient and the provider, and outline the consequences the patient will face if they do not meet their responsibilities (Fishman et al. 1999). Medication agreements or contracts may also include educational information about medications, emergency issues, and legal considerations. This type of document and exercise could easily be integrated into the psychosocial treatment protocols described above. For instance, part of the educational information could include a list of pain coping skill strategies (e.g., relaxation, pleasant activity) that the patient could engage in instead of misusing a substance. There is evidence that medication agreements or contracts reduce abuse of pain medications (Fishman et al. 1999; Fagan et al. 2008). Medical providers have reported that initiating a medication contract with patients is a useful tool for discussing potential problems related to medication misuse. They also have reported that medication contracts decreased many of the problematic behaviors often noted in these patients (e.g., reducing patients' use of multiple providers, decreasing request for early refills, identification of patients likely misusing pain medications) (Fagan et al. 2008).

113.2.10.2 Frequent Brief Visits to Monitor Adherence and Limited Prescriptions

Another strategy that some providers have reported to be helpful in decreasing substance abuse and misuse in patients with chronic pain is frequent monitoring of adherence by having patients see a provider often. Psychosocial intervention protocols provide a good platform to increase patient contact with providers. Psychosocial pain interventions are often delivered in weekly sessions. Patients who are attending weekly sessions to learn new strategies for pain management have frequent contact with a provider. In this way, monitoring patients' adherence may be integrated into the psychosocial intervention, or patients may visit their medical provider at the beginning or end of the psychosocial protocol to monitor adherence.

This close and scheduled contact with providers in the context of a psychosocial intervention protocol may improve adherence in several ways. First, it may increase the patients' sense of accountability and thus decrease their likelihood in engaging in problematic substance abuse behaviors. Second, problematic behaviors are more likely to be identified early by providers, and problem solving can be implemented before the substance misuse becomes chronic and/or out of control. Third, the patient will learn strategies to manage their pain in the context of the psychosocial intervention, and new treatment strategies can be implemented for patients whose pain is not being adequately managed. Many health-care providers who prescribe pain medications find it helpful to give patients a limited prescription amount, forcing patients to stay engaged in regular contact with the provider to receive additional medications.

113.2.10.3 Toxicology Screenings

There is evidence that using toxicological screenings to gather objective information about medication intake and other substance use can reduce substance misuse (Riddle et al. 2012). Patients with chronic pain who are using opioid medications may be tested at the start of treatment and at regular intervals during treatment to determine the presence of opioids and/or the presence of other substances related to problematic behavior (Hammett-Stabler et al. 2002). Urine testing for the presence of absence of substances is common, is fairly non-burdensome for patients, is reliable, and has a low cost (Manchikanti et al. 2008). Toxicology screenings are a strategy that could easily be incorporated into psychosocial pain management intervention protocols for patients who are at risk for substance abuse problems. We suggest that if this monitoring strategy is deemed important for particular patients that patients agree at the initiation of the psychosocial intervention to provide a urine sample at each session. It is important that the patient understand the purpose of the screen, what substances are being considered, and the outcome if substance levels indicate negative substance use behaviors. For instance, it is necessary to alert the providers who prescribe the patients their medications of any problems and that the patient understands that their provider will have access to the information yielded from the screen. Careful communication is critical in psychosocial interventions for patients with pain and substance abuse; missteps in communication by providers or misunderstanding by patients have the potential to undermine intervention benefits.

113.2.10.4 Monitoring with Questionnaires or Interviews

There are several self-report questionnaires and interviews that have been developed that assist in identifying patients' medication abuse (or problematic behavior) and adherence to pain medication over the course of treatment. These assessment techniques are often standard practice for patients who are receiving opioid medications for chronic pain and could be used within the context of psychosocial pain management intervention protocols. These assessments may be used at the initiation of a psychosocial pain management intervention to gather important information about a patient and tailor the intervention to their needs. Assessments may also be used at regular intervals during the course of the intervention to monitor for problematic substance use behaviors and to document improvements that patients participating in psychosocial interventions may be making.

One reliable and valid assessment instrument that may be helpful in this context is the Addiction Behaviors Checklist (ABC) (Wu et al. 2006). The ABC is a 20-item instrument that was designed to help providers monitor ongoing and current behaviors characteristic of prescription opioid medication addiction in patients with chronic pain. The ABC consists of a checklist of observable behaviors that are noted during an interaction with a provider and heard about between clinic visits. A provider completes this checklist. Within a psychosocial intervention, the provider (e.g., psychologist, social worker) who provides the intervention could be trained to complete this instrument and keep track at regular intervals of the patients' medication use. Another valid and reliable assessment tool is the Pain

Assessment and Documentation Tool (PADT), (Passik et al. 2004) which is an interview-based measure that can be included in the patient's medical record. This simple charting device takes approximately 5 min to complete and focuses on four key areas: analgesia, activities of daily living, adverse events, and potential aberrant drug-related behaviors (e.g., requests frequent early refills, changes in route of administration). Within a psychosocial intervention, this tool could be completed by the provider delivering the psychosocial intervention and shared with the prescribing provider if any problems are noted. Other assessment tools such as the Prescription Drug Use Questionnaire (PDUQ) (Compton et al. 1998) are also available. Providers are always encouraged to consider the needs of their patient population and determine a good fit with a validated and reliable assessment tool.

A challenge of formal assessment tools in any context is incorporating them into busy clinic settings with limited staff resources. While incorporating them into psychosocial pain management interventions may eliminate some of this challenge, repeated and consistent formal assessment can still be difficult. All providers (e.g., prescribing physicians, psychosocial interventionist, support staff) working with patients with chronic pain should be taught to be aware and monitor key high-risk behaviors that can reflect substance abuse problems (Manchikanti et al. 2008). Chabal and colleagues (1997) recommend consistently assessing and documenting the following high-risk behaviors: (a) an overwhelming and persisting focus on drug-related issues during pain clinic visits; (b) a pattern of early refills or problems associated with their prescription; (c) multiple telephone calls or visits with requests for more medication; (d) reports of lost, spilled, or stolen medications; (e) obtaining opioids from multiple providers, emergency rooms, or illegal sources; and (f) escalating medication use in the absence of an acute change in the medical condition.

113.2.10.5 Collaborative Treatment Planning

There is evidence that to successfully manage chronic pain, particularly in the context of substance abuse problems, a collaborative treatment planning model between health-care provider and patient is critical. While psychosocial pain intervention protocols can provide patients with many benefits, it is necessary that the psychosocial interventionist works closely and collaboratively with the medical providers and patient to provide the best care. Within this model, the patient is encouraged to participate in treatment planning – their knowledge about their pain, support network, resources, daily life, and values and beliefs are capitalized on in designing a treatment plan. This model also allows the psychosocial interventionist to introduce pain management skills being learned by the patient to the prescribing provider. In this way, the prescribing provider can use language similar to that used by the psychosocial interventionist and encourage the patient to engage in pain management skills they have found particularly helpful. Collaborative treatment planning includes providing patients with the potential benefits and risk of certain pain medications and agreement upon treatment goals between all parties involved. Involving patients in treatment planning may increase the patients' investment or commitment to a treatment (Rains et al. 2006). Increased

investment and commitment is likely to improve patients' adherence to pain medication adherence, increase their use of adaptive pain management skills, and ultimately lead to decreased pain and distress (Rains et al. 2006).

113.2.11 Recommendations and Future Directions

Patients with chronic pain often face a challenging course that is complicated when they have problems with substance use or abuse. Using a biopsychosocial approach to treat patients with these common, comorbid problems may provide the greatest benefit to patients. As mentioned above, the biopsychosocial model suggests that pain management is best approached by simultaneously addressing pain through biological (e.g., rehabilitation, pharmacotherapy), psychological (e.g., behaviors, cognitions, affect), and social (e.g., relationships, recreation) mechanisms. Throughout this chapter, we have presented information on how behavioral and cognitive strategies, with a focus on CBT, are used or could be used to address patients with pain who have substance abuse problems. There is surprisingly limited literature, to date, on psychosocial interventions designed to address both chronic pain and substance abuse problems. There is evidence that CBT for substance use problems is efficacious, (McHugh et al. 2010), yet despite the high prevalence of substance abuse problems in patients with chronic pain, little work has been done examining a psychosocial intervention designed to address both of these challenges.

There have been numerous investigations conducted to examine strategies for using psychosocial strategies to help patients manage chronic pain as well as substance use problems. Separately, these interventions have been shown to be efficacious for the target problem. Perhaps the most obvious area for future work is to examine how CBT and other psychosocial strategies that have been applied to either chronic pain or substance abuse might be combined into an intervention to address both chronic pain and substance use problems.

The sampling of CBT programs for pain management presented above provides a number of treatment delivery modalities that might be used and/or combined to provide a CBT-based intervention that can address comorbid pain and substance abuse problems. CBT pain management programs have been successfully delivered in brief interventions and intensive interventions, as well as been applied to the patient alone or to the patient and a significant other in their life. Past work has also shown that two challenging areas (e.g., pain and obesity) can be intervened on with one synergistic CBT program.

There are several possible combinations of intervention modalities that may be successfully applied to this patient population. Some patients may benefit from the application of simultaneous intervention for both chronic pain and substance abuse problems. Others, however, may need to learn CBT and other psychosocial strategies for either pain or substance use problems first, followed by a subsequent intervention for the secondary challenge. There is also the option to combine treatment modalities such that one component of an intervention (i.e., substance

use treatment) may be delivered in person, while another component of the intervention (i.e., CBT for pain management) is delivered by telephone or an mHealth modality. One challenge of psychosocial interventions has been the maintenance of treatment effects without booster or maintenance sessions. Combining delivery modalities such that the core part of the intervention is delivered in person and the booster is delivered through mHealth technologies may provide the most benefit to patients with chronic pain and substance use problems.

Patients with chronic pain and substance abuse problems may face difficulties in accessing psychosocial intervention programs that can help them manage these challenges. Difficulties accessing interventions may be due to practical barriers such as distance from the medical center, time away from work or family, cost and availability of transportation, or physical/emotional barriers such as the difficulty of travel, the hassle of parking/walking to an appointment, and physical challenges such as pain or other problems. Health-care providers who treat patients with these comorbid challenges should consider these challenges and focus on helping patients to access psychosocial interventions for pain and substance use problems. Mobile health (mHealth) technologies are increasingly being used to manage patients' medical care at all levels and may provide the infrastructure necessary to provide support for patients suffering from chronic pain and substance abuse problems.

Given the prevalence of comorbid chronic pain and substance use problems and the promise provided by a biopsychosocial approach to these challenges, it seems timely that both clinical practice and research would begin to focus on (1) the integration of psychosocial interventions that can address pain and substance use problems and (2) ways to help patients access these interventions. There is an increasing focus on designing intervention trials that are patient centered and adaptive (Schneeweiss et al. 2013). This type of intervention trial applied to psychosocial interventions may be well suited to begin to answer questions such as (1) should both chronic pain and substance abuse problems be intervened on simultaneously or should one be addressed first and another subsequently, (2) what duration of intervention is most effective (i.e., is ten weekly sessions more beneficial than two intensive weeks?), (3) what format is most effective and/or what format do patients prefer (i.e., group, individual, or a combination), and (4) what delivery modality is most effective while also being highly accessible to patients (e.g., is face-to-face, phone, mHealth, or a combination best?).

113.2.12 International Perspectives

There is a strong evidence base for chronic pain programs that are interdisciplinary and adhere to a biopsychosocial model of intervention (Turk 2002; Hoffman et al. 2007). Treatment in interdisciplinary programs typically includes cognitive and behavioral strategies for pain management integrated with medication management and graded physical exercise. In the United States, there has been a rapid decline in pain programs that approach programs from a biopsychosocial model

(Jeffery et al. 2011) (i.e., multidisciplinary pain programs), while there is some evidence that such programs are increasing in other countries. Detailed reasoning for the rapid decline in this promising treatment modality is beyond the scope of this chapter, but it is largely agreed that the main reason for the dramatic drop is due to the US health-care system and insurance reimbursement. Schatman (2012) presents data from a number of countries, including the United States, and details that multidisciplinary pain programs in countries besides the United States are increasing their programs. Of the 12 countries surveyed, only the United States demonstrates a decline in such multidisciplinary programs. Given the complexity of treating patients with pain and substance abuse problems, interdisciplinary programs are likely promising for providing benefits.

113.3 Conclusion

Chronic pain is common and difficult to manage, and it is a major public health and health-care problem (Gallagher 1999). There is evidence that using a biopsychosocial model provides the most comprehensive care and improved outcomes to patients with chronic pain. This approach may be critical for patients with chronic pain who have a history of and/or are at risk for substance abuse problems. We have presented information on cognitive-behavioral and other psychosocial approaches to pain management in the context of substance abuse problems. There are a number of promising approaches that would likely benefit patients with chronic pain and substance abuse problems, yet there is limited work detailing these types of interventions. Future work, from both a clinical and research standpoint, should strive to move this area of knowledge forward by systematically studying approaches to treating patients who struggle with the dual challenge of chronic pain and substance use problems.

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment: International Perspectives*, DOI 10.1007/978-88-470-5322-9_86,

addiction has become a particularly challenging issue and area of rapid growth. This development has particularly affected prescription opioids in North America, as they are prescribed there in greater amounts to more patients than anywhere else in the world, particularly for nonmalignant pain conditions. The increase in the number and dosage of opioid prescriptions here has been dramatic and widespread in all aspects of medicine (Boudreau et al. 2009).

The practice of pain treatment has been significantly complicated and degraded by this growing problem in multiple ways, including the significant population of pain patients who have comorbid addiction issues, but also the structural effects that this growing illicit use of prescription opioids has had on pain practices. There are regular reports of pain clinics being shut down by regulatory agencies for illegal or incautious prescribing practices. Some of these are so-called pill mills which primarily exist to provide opioid prescriptions for profit, but others are well-meaning providers who are manipulated or taken advantage of. Some pain patients are known to continue to seek regular refills of their medications despite no longer needing them in order to resell them; this is said to be particularly prevalent in patients on fixed incomes. Other patients who divert may be actual addicts who engage in doctor shopping and seek out physicians willing to prescribe drugs in large amounts and in high doses. Alongside these frankly abusive pseudo-patients, there are a much greater number of pain patients who have developed aberrant use of their opioids or actual opioid addiction after being prescribed opioids chronically for a pain condition. These patients are complex and challenging and are at high risk for bad outcomes in multiple respects – their pain is unlikely to improve, and they are more likely to experience increased morbidity and mortality associated with opioid use. Prescription opioids are now causing more deaths than either heroin or traffic accidents in some states (Maxwell 2011). This rise in mortality appears to parallel the rise in the availability and strength of prescription opioids for noncancer pain.

The interaction between pain treatment and addiction can be complex and hazardous. Treatment of pain with opioids raises iatrogenic addiction risk (Ballantyne and LaForge 2007). In the United States, illicit drug use was estimated by government survey to be almost 9 % (Substance Abuse and Mental Health Services Administration 2011). The prevalence rate of addiction in patients with chronic nonmalignant pain is estimated to be as high as 48 % in some populations (Morasco et al. 2011a). While some subgroups of prescription opioid abusers, such as youth, are clinically similar to other substance abusers (Catalano et al. 2011), there is a wide spectrum of illness, and many of the older pain patients who develop problems with opioids have significant physical and psychiatric comorbidities, particularly females (Cicero et al. 2012). A large population-based study of opioid use in the general US population found that over half the surveyed population was using prescription opioids that are either not prescribed for them or using prescribed opioids in an inappropriate manner (Green et al. 2011).

114.2 Addiction in the Context of Pain

114.2.1 Addiction Complicates the Treatment of Pain

Worldwide, the case of opioids as treatment for cancer pain remains strong, and there are many areas which suffer from a significant lack of access to these powerful analgesics. However, the initial promising picture of opioids for chronic pain has appeared more and more troubled as evidence of the riskiness of this treatment has become apparent (Ahlbeck 2011). In addition to the addiction issues, the risk of mortality also rises as the dose and duration of chronic opioid treatment increases (Paulozzi et al. 2012).

Patients with addiction are more challenging and risky to treat for pain for multiple reasons. For patients who are actively using, there is naturally a high risk that the opioids will simply add into the mix of drugs that are being abused, with potentially lethal results, particularly if the patient is also using sedative/hypnotics or alcohol. Active substance use also decreases adherence to treatments and can make patients less able to attend follow-up appointments or physical therapy appointments reliably. Active substance abuse is also considered a contraindication for some pain-relieving procedures due to increased risks.

For patients with addiction in remission, treatment with opioids may be a trigger for relapse in their drug of choice, and they are also at increased risk of developing addiction problems with their prescribed opioids.

114.2.2 Diagnosis and Assessment of Addiction in the Pain Treatment Setting

The diagnosis of addiction in psychiatry has been complicated by a distinction between substance abuse and substance dependence. This has always been a poor fit for the particulars of opioids, which cause a withdrawal syndrome in everyone who takes them chronically, regardless of addiction issues. This will be resolved in the forthcoming DSM-V which should have only the diagnosis of substance dependence (O'Brien 2011). While all long-term opioid patients will develop withdrawal with sudden discontinuation, not all will develop the ASAM-APS-AAPM criteria for addiction or impaired control over use or compulsive use, continued use despite harm, and preoccupation with use or cravings (Heit 2003). It should be said, however, that some patients on chronic opioid therapy will go on to develop these addiction symptoms, even without past histories of substance problems or other clear risk factors.

Addiction can be challenging to recognize in many settings, but is particularly difficult in pain clinics, where the majority of patients are in some degree of emotional distress, there is high psychiatric comorbidity with depression and anxiety and frequent occupational and interpersonal problems, and many patients are seeking or are already prescribed habit-forming medications. Studies suggest

Table 114.1 Opioid aberrancies

Escalation of medication dosage
Requesting early refills
Doctor shopping
Losing prescription medications
Tampering with prescriptions

that clinicians may overestimate their ability to recognize substance abusers "by feel" and that they are prone to fall into prejudicial misapprehension, overestimating the prevalence of substance abuse in minority patients and failing to detect it in other population groups.

However, clinicians can reliably observe two important sets of clues to addiction: risk factors and aberrancies. Aberrancies cover a wide spectrum of undesirable, unsafe, or boundary-transgressing patient behavior (see Table 114.1). The use of prescription monitoring programs and urine drug screenings can also be very helpful in identifying aberrant behavior. Once identified, whether by a physician, support staff, or lab, it is important to consider the anomalies in the context of the clinical picture. The differential for addiction includes major mental disorders, delirium, misunderstanding, and interference by family members, roommates, or romantic partners.

Risk factors can be obtained from the patient, his or her other providers, and family. Several standardized questionnaires, such as the SOAPP and ORT, allow providers to identify known risk factors for addiction by self-report at time of intake.

It is important not only to make an accurate pain diagnosis and detect substance abuse in patients but also identify any other psychiatric comorbidities they may have. Once a patient has been identified as having a complex pain problem with addiction or dual diagnosis issues, they need to be evaluated more thoroughly to develop a good understanding of their psychosocial situation, their social and other resources, and significantly their limitations and challenges, including limited resources, legal issues, and family problems (Clark and Treisman 2011).

114.2.3 Acute Pain in Addicted Patients

The evidence suggests that nonaddicted patients in acute pain who have not had opioids before are at low risk for developing addiction during a short course of treatment with low-potency opioids (Skurtveit et al. 2011). However, brain changes of unclear significance are observable after as little as a month of treatment with opioids (Younger et al. 2011). Clinical observations suggest that it is quite difficult for patients to discontinue opioids after 90 days of continuous treatment, which is also the threshold for pain conditions to be considered chronic. It is not unusual in academic pain centers to encounter patients who have undergone procedures and been prescribed pain medication for one, two, or even 3 months before they are referred to the pain service for a subacute problem

which is rapidly becoming a chronic condition. Particularly when a hospitalized patient is nearing discharge, this can be problematic if they continue to require high doses of opioids for pain management but would not be safe to be given prescriptions for large amounts of these.

This situation requires close monitoring to determine what is happening, as the same clinical picture may represent reactivation of addiction and medication overuse, an inadequately treated pain condition, or diversion. Ideally, in the case of elective procedures, these issues can be identified beforehand and incorporated into treatment planning; however, a significant proportion of acute pain patients, particularly those with substance abuse issues, will present with pain secondary to trauma occurring due to assault, injury, or motor vehicle collision with no advance warning. When these issues are identified, they should be incorporated into treatment planning for their care of that acute pain episode and beyond. This can also be an excellent time for substance abuse interventions, particularly if the patient's injury was related in some way to their addiction, as this provides a clear adverse consequence to use as a platform for motivational interviewing or other interventional techniques. Motivational interviewing has been beneficial for preventing alcohol-related reinjury (Gentilello et al. 1999) and for increasing exercise in fibromyalgia patients (Ang et al. 2007), but there is no evidence for MI-based interventions for opioid dependence at this time. At the same time, further psychiatric assessment may be indicated, particularly if there is concern for suicidality prior to hospitalization or during the hospital stay. Some hospitals will have a 12-step-based program meeting on their grounds, and this may also be an option for interested patients to attend if they are healthy and mobile enough.

For pain providers, one challenge of treating the addicted patient for acute pain consists of finding safe and adequate treatments in a population who may have elevated tolerance and decreased ability to manage stress and handle discomfort. In fact, substance abusers have been found to have increased pain perceptions in the emergency department (Neighbor et al. 2011). Perioperative management must take into account patients' use of prescribed opioids, illicit opioids such as heroin, and potentially patients on chronic buprenorphine or methadone for opioid dependence who will have high tolerance and, in the case of the buprenorphine patient, some initial difficulty in getting adequate analgesia due to the partial antagonism of the buprenorphine (Mitra and Sinatra 2004). The provider must also be watchful for signs of other substance toxicity or withdrawal, such as stimulant-inducted psychosis or benzodiazepine withdrawal.

For the pain relief provider, it is important to determine, or at least estimate, their baseline opioid dosage, and then maintain them on a regimen of opioids close to this in potency, with additional opioids available as needed for the acute pain. This may require conversion to parenteral opioids, and frequently, the use of IV PCA analgesia is the safest and most effective strategy for managing their acute pain needs. In cases of thoracic or abdominal surgery or trauma, neuraxial anesthesia using epidural catheters to deliver local anesthetics or opioids can be very effective. Epidural morphine, for example, is ten times more potent than systemic morphine.

Where the pain has a focal source, particularly in an extremity, regional anesthesia, such as using nerve catheters, can block much of the nociception from the injury and thus reduce the need for opioids overall, as well as improve perfusion and recovery time. When patients with extremely high opioid tolerance require systemic opioids, a switch to methadone can often allow a decrease of overall dose. Very high doses of opioids raise the risk of respiratory depression and opioid-induced hyperalgesia, a condition characterized by whole-body pain that only worsens with increased opioid dosing.

114.2.4 Treating Chronic Pain in Addiction

Chronic pain is a highly significant and growing problem as the world's population gets older and more people are surviving significant illness or injury. Addicts are more likely to have all kinds of comorbidities, psychiatric and physical, and have a higher rate of physical injury and chronic pain as well (Karasz et al. 2004). The phenomenon of so-called self-medication for chronic pain is another mechanism by which patients may be exposed to these medications and develop addiction (Rosenblum et al. 2003). Chronic pain has been defined variously as pain lasting more than three or more than 6 months; for our purposes, the ASA description of chronic pain as pain lasting longer than "the expected temporal boundary of tissue injury and normal healing and adversely affecting the function or well-being of the individual" is most germane (American Society of Anesthesiologists Task Force on Chronic Pain Management and American Society of Regional Anesthesia and Pain Medicine 2010). Perhaps the most important fact about chronic pain is that it is chronic; in other words, it should be managed without the expectation of complete resolution, a quick return to premorbid function, or a short horizon for treatment. The effectiveness of chronic pain treatments is also less than those for acute pain, with an average effect size of 40–50 %. Any treatments offered for chronic pain should be safe and able to be provided longer term.

The most vexing question in the treatment of chronic pain, particularly chronic pain in addicts, is that of chronic opioid therapy. Patients prescribed opioids for pain are also likely to use opioids nonmedically. This finding has been seen in military veterans and in the general population (Barry et al. 2011; Edlund et al. 2010). A history of substance use disorder makes it less likely that primary care patients will have good relief after 12 months of treatment for musculoskeletal pain including opioids (Morasco et al. 2011b). When one considers that systematic reviews of chronic opioid therapy for noncancer pain have failed to present strong evidence for the effectiveness of this treatment, the balance of risks and benefits seems fairly unfavorable for this treatment approach, despite its popularity in modern medicine (Chan et al. 2011).

"Adverse selection" is the phenomenon of the sickest and highest-risk patients receiving more opioids for longer and often receiving the bulk of opioid prescriptions in any given population. This phenomenon has been demonstrated in multiple settings including private insurance and public, rural and urban (Morasco

et al. 2011a; Sullivan et al. 2010). Similar findings have also been reported among US military veterans and HIV patients (Morasco et al. 2010; Silverberg et al. 2012). Even in the condition of fibromyalgia, in which there is no real indication for opioid therapy, this pattern of increased dosing among patients with more psychiatric illness, substance abuse, and lower function is seen (Fitzcharles et al. 2011).

The APS-AAPM guidelines published in 2009 for the treatment of noncancer chronic pain may be helpful in guiding treatment, although they are not specifically focused on substance abuse patients (Chou et al. 2009). These patients are often more complex, with layered conditions including substance use disorders, one or more primary pain conditions, and frequently psychiatric comorbidities as well. Although these complex pain patients have been shown to respond better to intensive treatment, the health-care system rarely allows them to receive it (Morasco et al. 2011c). Interdisciplinary pain care, which includes treatment by allied professionals and mental health, has become less and less available in the United States, due largely to coverage and access issues.

In this patient population, then, opioids should be prescribed cautiously, in the knowledge that this is intrinsically risky, and not as a first step in pain management. If the patient is enrolled in substance treatment, or about to be referred, opioids may be incompatible with treatment and should be avoided when possible. These patients should first have the benefit of alternative treatment methods to the greatest extent possible, including non-opioid pain medications, nerve medications that are not addictive, behavioral interventions, and physical interventions such as physical therapy, TENS units, and injections where appropriate.

If opioids are felt to be a necessary part of pain treatment, they should be prescribed at the lowest dose possible. Many experts recommend short-acting opioids used on a schedule. If the patient is converted to a longer-acting opioid, it is recommended that they are not also prescribed short-acting opioids on an as-needed basis. This practice of treating "breakthrough pain," while very helpful in cancer pain, often results in patients taking both their scheduled and as-needed medications daily to the maximum extent possible, increasing risks and total opioid dosage (Manchikanti et al. 2011). It is predictable that some patients will overuse or misuse their medications. Many patients, after an initial good response, will quickly develop tolerance to at least part of the analgesic effect of the opioids and will escalate use on their own or request dosage increases. When opioid therapy is discontinued in these patients with comorbid depression and pain, they are likely to relapse on opioid abuse (Heiwe et al. 2011).

One manualized approach that has been developed for veterans with these comorbidities places heavy emphasis on cognitive behavioral therapy (CBT) and acceptance therapy to address many aspects of recovery, including stress management, increased function, and appropriate use of pain medication. This treatment approach is notable for its embrace of the harm reduction approach, enabling it to be used in patients who continue substance abuse (Ilgen et al. 2011).

Patients in underserved groups with severe psychosocial needs, such as the homeless and refugees, have a high risk of untreated or undertreated chronic pain (Hwang et al. 2011).

114.2.5 Palliative Care in Addicted Patients

Palliative care was defined by the WHO as an approach to treatment which improves the quality of life of patients and their families facing the problems associated with life-threatening illness (Sepulveda et al. 2002). In this specialized arena of health care, the mandate to provide comfort may take precedence over concerns about addiction. While it is rare for patients in this clinical context to develop new addiction issues, preexisting psychiatric and addiction issues may be reactivated or worsen under the stresses of serious illness and may go unrecognized by providers. Untreated alcohol dependence, for example, is linked to other substance misuse and worse outcomes in pain patients (Dev et al. 2011). Some cancer patients are provided with pain medications in larger quantities and dosages towards the end of life than any other type of patient. In addition to addiction, misuse or simple incorrect use due to misunderstanding can put patients at risk. These patients, who may be dependent on others for the management and administration of their medications, are also more vulnerable to diversion of medications by people near them. At the same time, many cancer patients do not receive adequate pain treatment due to access to care issues and also due to patient reluctance to use these medications for fear of addiction (Simone et al. 2012).

Following best practices in these patients can help track their medication use and identify aberrancies earlier. Close monitoring of symptoms and more frequent dispensing of opioids can be useful harm reduction approaches. In larger, well-staffed cancer care centers, even daily dispensation of pain medications may be a useful intervention for selected patients. Pill safes and enlisting family members to dispense daily dosages can also improve safety and reduce the risk of misuse/overuse/diversion. In many cases, the medication misuse is also being driven by complex physical and emotional distress, with combined factors of depression, anxiety, worry about the future, impending death, being a burden on family, how family will fare after the patient's death, and non-pain forms of suffering such as dyspnea, fatigue, constipation, or immobility (Kircher et al. 2011).

114.2.6 Pain Treatment in the Setting of Addiction

The initial assessment should include risk assessment. Once risk factors such as past history of addiction have been identified, or current aberrancies suggestive of substance misuse or dependence are seen, the decision must be made how to respond. Treatment should be individualized; however, there are many best practices that should be routinely followed in pain treatment, particularly as these risk factors and aberrancies may not be identified initially. Patients with fewer risk factors and less severe aberrancy may not require specific changes in treatment beyond closer monitoring. For high-risk patients or those whose aberrancy is more concerning, practices including a written, explicit treatment agreement, compliance checklists, and randomized urine drug screens may be helpful in reducing aberrancy in high-risk

pain patients. Early substance abuse intervention, such as SBIRT or motivational interviewing, may also be helpful (Jamison et al. 2010). For patients with severe ongoing addiction issues or serious aberrancies, such as obtaining opioids from multiple prescribers for routine care or diversion, it is often safest to discontinue opioids with a taper or avoid them if they are not taking them already. Some patients in this position will complain that they are being driven to seek illicit drugs. For ethical and professional reasons, it is recommended to continue to offer these patients the full panoply of non-opioid pain treatments to the extent that they are appropriate. In less severe cases, treatment in collaboration with substance abuse treatment providers may be helpful, along with a highly structured treatment plan.

114.2.7 Best Practices for Risk Management

All patients may be potentially at risk for addiction, and current approaches to risk stratification are very limited. For example, there is consensus that there is a large genetic component in predisposition to addiction, with abnormalities of the endogenous opioid system in particular being linked to increased risk of opioid abuse. However, no standard, evidence-based genetic testing protocol has been introduced. While family history may provide some clues to genetic predisposition, addiction is well known to "skip generations" and is often not openly discussed within families so that the patient may not be aware of relevant history.

Therefore, the concept of universal screening in pain medicine, similar to the use of universal precautions for infection control, is becoming more popular (Gourlay et al. 2005). This universal approach may also serve to reduce stigma and improve the detection of addiction in patients who might not fit the stereotypical image that clinicians hold. For example, opioid dependence is often missed in older adults and in Whites, presumably because the index of suspicion is lower in patients who look more like the typical White male physician (Becker et al. 2011; Vijayaraghavan et al. 2011). This screening and risk stratification may also help use scarce community mental health, pain management, and substance abuse treatment resources more effectively, as low-risk patients remain in the primary care setting as long as they are doing well, while riskier patients are able to access more specialized and interdisciplinary care. Patients with serious psychiatric issues, substance dependence, or both should generally be seen in a setting with the availability of mental health consultation. This model tends to apply most to large cities and areas near academic medical centers; however, telemedicine applications may extend the reach of these specialties into rural areas and isolated regions (McGeary et al. 2012).

Several useful screening tools for determining risk factors for patients include the COMM, SOAPP, and ORT. These are all brief, self-administered tests. The COMM has 17 items; the ORT 8 and the SOAPP come in a full 24-item version and briefer versions (Meltzer et al. 2011). The full version of the SOAPP may be the most effective at predicting future aberrancy (Moore et al. 2009). Note that even if a high score does not automatically translate into "do not prescribe opioids," these tests must always be interpreted using clinical judgment. Since they are self-reported screens

and do not attempt to conceal the nature of the assessment, they may underestimate risks in patients who are unreliable historians or deliberately deceitful.

The use of an opioid treatment agreement is also widespread, although there is very little evidence to support its efficacy. The greatest usefulness of this measure is to provide a transparent means of disclosing treatment policy to patients in advance. It is important to discuss the agreement with patients, along with obtaining fully informed consent for any treatments and documenting it. Since the risks of opioid therapy are much better appreciated now than they were even a decade ago, it is not safe to assume that a patient who is seen already on chronic opioids has full understanding of the implications and risks of this treatment. Any specific policies regarding prescription monitoring, pill counts, and urine drug screens should also be discussed at this time.

Urine drug testing (UDT), also known as urine toxicology or "UTox", offers the promise of letting the prescriber know what the patient is exactly taking. In practice, given the multiple metabolites that may be observed even with monotherapy, it is important that an expert reviews these results, whether pain specialist, pharmacist, or lab medicine specialist. UDT is most helpful in demonstrating that patients are not taking prescribed medications or are taking additional, non-prescribed medications or illicit drugs. A policy should be developed to guide providers consistently on what actions to take in the event of an unexpected UDT result. Some studies have shown that even when UDT is obtained and shows unexpected results, prescribers continue to prescribe opioids (Gupta et al. 2011). In some states, where the state law recognizes a role for medical marijuana, providers may choose to obtain UDT without checking routinely for THC. UDT is not able to reliably determine whether a patient is taking the full dose of their prescribed medication. These limitations aside, UDT helps providers recognize aberrancy that would not be identified by behavioral monitoring (Katz et al. 2003). In the United States, many health insurances will not cover the cost of UDT, so providers must make smart choices about when and how often to order them. Systematic reviews suggest that the benefit for patients of standard UDT policies is modest (Starrels et al. 2010).

114.2.8 Cooperation with Allied Providers

Pain providers cannot be expected to master the fields of psychiatry and addiction, but must understand enough to recognize patients with these issues, make appropriate referrals, and collaborate with the appropriate allied providers. It is important to provide solid information to colleagues about the nature of the patient's pain diagnoses and their treatment. For patients with addiction issues, some medications such as benzodiazepines and opioids may be both inadvisable and incompatible with their addiction treatment. In this case, prescribing these medications for the patient may unknowingly sabotage their addiction treatment or provoke relapse.

In patients who have been diagnosed with opioid dependence, a possible option for them may be opioid agonist therapy, namely, methadone or buprenorphine. In the United States, methadone may be prescribed freely for pain, but only

prescribed for the treatment of addiction by federally recognized methadone clinics. In addition, methadone clinics provide patients with a single larger daily dose of methadone, rather than dosing three times a day as is done for pain. Buprenorphine, in the form of Suboxone, may be prescribed for opioid dependence and (off-label) for pain. Buprenorphine is also available without the combination of naloxone, and as a long-acting transdermal patch, Butrans. Both of these forms are more prone to abuse. Since buprenorphine is a partial opioid agonist, it may be less prone to abuse than other opioids, and it is also not suitable for combining with other opioids and may precipitate withdrawal in a patient who has been taking other opioids chronically. Buprenorphine treatment has been shown to be an effective treatment of opioid dependence and also reduces the rush experienced by patients who do relapse and use other opioids on top of the buprenorphine (Jones et al. 2011).

114.3 Conclusion

Substance dependence is a large and growing problem in developed countries. The growth of prescription drug abuse has been particularly concerning. Pain treatment is intimately involved with this explosion in prescription drug abuse, as many of the drugs involved are being ostensibly prescribed for pain and pain patients may be at higher risk for addiction. Many pain patients have comorbid conditions including depression, anxiety, and addiction which complicate their treatment and worsen their prognosis. These patients should be offered the full range of pain management services, with particular emphasis on behavioral interventions; opioids should only be considered, if at all, after reasonable trials of other, safer treatment approaches. Early recognition of the patients by identifying their high-risk status and detecting aberrancies can help with early referrals to mental health and substance abuse providers and cautious, closely monitored prescribing practices.

114.3.1 International Perspectives

The international picture of pain treatment is diverse but can be summed up by region. The Americas have had the greatest increase in opioid consumption over the past 30 years, largely driven by the United States and Canada. Central and South America make some use of oral and injectable morphine for intractable pain.

At the opposite end of the spectrum, Africa has had very little growth in opioid consumption. In general, a small number of developed countries consume most of the world's morphine, and the rest of the world, with most of the world's population, consumes very little (Gilson et al. 2012). These low- and middle-income countries (LMICs) in one study were found to have 83 % of the population but only 9 % of opioid consumption, in part due to fears of addiction and regulatory

barriers (International Narcotics Control Board 2010). For example, a study of opioid prescribing in India followed 1,723 pain patients in Kolkata and did not identify any misuse; most of these patients appear to have been receiving palliative treatment for cancer pain (Karasz et al. 2004; Rosenblum et al. 2003; Gilson et al. 2012; Rajagopal et al. 2001). The Middle East and North Africa are very diverse, but are commonly restrictive in their use of opioid pain relievers except for the wealthy gulf states. Likewise, in the Asian Pacific region, Australia and New Zealand follow the pattern of Western Europe, while other Asian nations use significantly less opioids, and the large, poor, and populous nations of India and China have significant pain undertreatment issues. Japan uses significantly more opioids than other East Asian nations, but much less than Australia and New Zealand, and Japanese physicians have been shown in polls to have very high levels of concern about addiction resulting from opioid treatment of pain (Miyashita et al. 2010).

Africa has the lowest opioid use of any region, and the health providers in sub-Saharan Africa in particular appear to make very little use of opioids even for cancer pain and palliative care (Human Rights 2011).

In many LMICs, opioids are not widely available, even for cancer pain, and there is a significant issue of undertreatment of severe pain (Human Rights 2011). In parts of Eastern Europe and the former Soviet Union, the traditional medical practice was to restrict opioid use to inpatient use for postoperative care, with little or no outpatient opioid use. In the last decade, this has changed, particularly in the treatment of cancer pain; however, acetaminophen and NSAIDs continue to be the mainstay of pain treatment. The EU agency ATOME has promoted a balance between improved pain control and abuse prevention, and much of their efforts have focused on education and legal reform (AtOMiE).

Western European practice tended to avoid chronic opioid therapy in noncancer pain again until the last 10–15 years, when new guidelines came out for responsible opioid use in this population in the early 2000s. At the same time that the use of opioids was being extended in this population, European pain specialists were already noting the same issues that were seen elsewhere: “Chronic pain patients demonstrate a wide range of biological, psychological and social symptoms and complications, and patients referred to specialised pain units usually belong to the most stigmatized groups. Higher prevalence rates of opioid usage among these patients are therefore not surprising. About 70% of patients in our Pain Centre are treated with opioids already at referral in a mean daily dose of about 70 mgs of morphine. High prevalence rates of opioid users have increasingly been reported from other multidisciplinary pain centres” (Eriksen 2003). These fears, expressed by a Danish expert, appear to have been borne out. A more recent study of 253 patients at a Danish tertiary care center found that 14.4 % were considered addicted by ICD-10 criteria and 19.3 by criteria derived from the publications of Russell Portnoy (the DSM-IV is not used widely in Denmark) (Hojsted et al. 2010). As has been demonstrated previously in so many other populations, the addicted population of pain patients was more likely to drink alcohol, smoke tobacco, use benzodiazepines, and be clinically anxious and depressed.

Psychiatric Comorbidities and Complications of Alcohol and Other Drugs: An Introduction

115

Kathleen T. Brady and Giuseppe Carrà

Abstract

The co-occurrence of substance use disorders with other psychiatric disorders has been an area of increasing focus over the past 20 years. This more intensive focus has increased the knowledge base with regard to the prevalence of co-occurring disorders, the neurobiological interface between substance use and other psychiatric disorders, and both pharmacologic and psychotherapeutic treatment options. In addition, a critical focus on workforce training and designing systems of care that can optimally address the treatment needs of individuals with co-occurring disorders is needed. In these efforts, sharing knowledge across cultural and national boundaries is essential.

An international perspective on co-occurring disorders is particularly important for a number of reasons. Just as there are cultural influences in definitions, recognition, diagnosis, and treatment approaches to substance use disorders, there are important cultural influences in other psychiatric disorders and in the approaches to comorbidity. As Drs. Ruiz and Salloum point out in their overview, while different countries experience varying levels of recognition of the importance of co-occurrence of substance use and substance use disorders in the mental health-care systems, the concept of "dual diagnosis" is becoming increasingly well accepted, and recognition of the importance of co-occurring disorders is rapidly expanding around the globe. In this context, they emphasize the importance of

recognizing that "ethnic, racial and cultural groups manifest their medical illnesses, including psychiatric illnesses, within the context of their culture, tradition, beliefs and heritage." The chapters that follow are written by clinicians and scientists from a wide range of countries in an attempt to give the reader a broad and international perspective on the topic of co-occurring disorders.

The chapter on psychotic disorders by Dr. Carretta and colleagues provides an excellent overview of the epidemiology of co-occurring psychotic disorders and substance use disorders as well as a scholarly discussion of potential etiologic connections (▶ Chap. 122, "Psychotic Disorders and Substance Use Disorders"). The area of cannabis and psychotic disorders is particularly well covered as this has been a topic of intense investigation and discussion at an international level for the past 25 years. Drs. Nunes and colleagues have written a comprehensive chapter covering the topic of co-occurring mood and substance use disorders. In particular, their discussion of the approach to differential diagnosis and treatment of individuals with these comorbidities is detailed and useful across global boundaries. Dr. Roncero and colleagues have provided an excellent chapter focused specifically on bipolar disorder and co-occurring addictions. They emphasize the high risk for comorbidity between these disorders and discuss possible reasons for this etiologic interface. Their discussion of subtypes of bipolar disorder often seen with substance use disorders, such as rapid-cycling disorders, is particularly useful for clinicians.

Dr. Bartoli and colleagues have extensively reviewed epidemiological and clinical issues with regard to the comorbidity between anxiety and alcohol or substance use disorders whose etiologic links and temporal relationships are still unclear and, probably, heterogeneous and multifactorial. Alcohol and substances may be misused to self-medicate anxiety, avoidant, and phobic symptoms, but also anxiety disorders may be consequences of alcohol and/or substance misuse. Dr. Levin and colleagues have also provided a scholarly and comprehensive chapter addressing the issue of co-occurring ADHD and substance use disorders. This comorbidity is an issue of particularly concern in the United States where the diagnosis of ADHD has increased dramatically in prevalence over the past 20 years. In this regard, other nations and health-care systems may be able to learn from experiences of the United States concerning potential problems stemming from both under- and overdiagnosis of ADHD. The chapter on substance-induced disorders by Baldacchino and colleagues provides an excellent overview of general concepts in the dual diagnosis and comorbidity literature from an international perspective before an in-depth and comprehensive discussion of specific substance-induced psychiatric syndromes (▶ Chap. 116, "Substance-Induced Mental Disorders"). A "sidebar" in this chapter by Drs. Bonny-Noach and Mell addresses a specific substance-induced syndrome that has been seen with increasing frequency in young Israeli military veterans and is particularly fascinating (▶ Chap. 121, "A Drug Treatment Program for Young Israeli-Military Veterans").

The chapter by Drs. Szerman and Peris addressing the co-occurrence of personality disorders and addictive disorders is of particular interest with regard to providing international perspectives (▶ Chap. 124, "Personality Disorders and Addiction Disorders"). The authors address substantial criticism of the Diagnostic

and Statistical Manual of Mental Disorders (DSM) system of psychiatric diagnosis which may not provide the best approach to co-occurring disorders, particularly when it comes to personality disorders. In particular, the dimensional approach to psychiatric diagnosis and the overlap between Axis I and Axis II disorders which has been recognized and developed more in the European psychiatric literature is relevant to this chapter. Their more positive review of the DSM-5 trait system for the diagnosis of personality disorders is of interest in helping to understand the rationale for the new approach proposed.

In sum, this section provides a thorough and comprehensive review of the co-occurrence of psychiatric and substance use disorders from multiple perspectives. We have much to learn from sharing evidence and observations across cultural and national boundaries in order to develop the most sophisticated understanding of this complex patient population. This improved understanding is essential to expanding treatment options and improving treatment outcomes worldwide.

Substance-Induced Mental Disorders 116

Alex Baldacchino, V. Arvapalli, Anthony Oshun, and Serenella Tolomeo

Contents

Abstract

Comorbidity is a condition describing the presence of two or more diagnosable conditions happening, either at the same time or having a close temporal relationship, to the same individual. This is usually more focused on the presence of psychological/psychiatric problems and associated polydrug use and misuse. This chapter will try to identify and clarify the nature and relationship of the different avenues of clinical presentations presenting as substance-induced mental disorders.

They include:

- Substance use and withdrawal from substances may lead to psychiatric syndromes or symptoms.
- Intoxication and dependence may produce psychological symptoms.
- Substance use exacerbating or altering the course of preexisting mental disorder.

- A primary mental disorder precipitated by a substance use disorder, which may lead to psychiatric syndromes.

  Although there are several different classification schemes for psychoactive drugs (pharmacological, legal, medical), the most common organization is based on their effect on behavior and cognition. According to this scheme, psychoactive drugs will be classified into three broad categories: (1) sedatives, (2) stimulants, and (3) hallucinogens. Substance-induced mental disorders will be described on the basis of this classification in this chapter.

116.1 Introduction

Four categories of dual diagnosis involving substance misuse have been suggested by Krausz (1996):

- A primary diagnosis of a mental disorder, with a subsequent (dual) diagnosis of substance misuse that adversely affects mental health
- A primary diagnosis of drug dependence with psychiatric complications leading to mental disorder
- Concurrent diagnosis of substance misuse and mental disorders
- A dual diagnosis of substance misuse and mood disorder, both resulting from an underlying traumatic experience, for example, posttraumatic stress disorder

Central to these explanations is the distinction between "primary" and "secondary" in terms of cause and effect. However, the distinction has also been made in terms of temporal appearance or age at lifetime onset (Feighner et al. 1972). While such a distinction has face validity in suggesting that the first temporal disorder is independent of subsequent disorders, it does not clarify whether the secondary disorder is independent of the first or how the disorders may be interrelated (Samet et al. 2004). However, it is widely recognized that certain mental disorders have characteristic ages of onset and can thus be distinguished temporally as primary or secondary. For example, attention deficit disorder (ADD) and conduct disorder begin in childhood; alcohol and drug abuse in early to mid-adolescence; and anxiety, mood, and psychotic disorders in late adolescence and adulthood.

However, the operational use of concepts of substance use and misuse relies heavily on etiology, clinical practice, particular cultures, and ideology (Todd et al. 2004) as well as the purpose(s) behind their use. Berridge points out that "definitions of alcoholism and drug addiction are historically constructed, are the products of particular historic sets of circumstances and interrelationships (Berridge and Edwards 1987; Scull 1981). Disease concepts, for example, may have been common in the 1890s and 1950s, but the components of the theoretical basis were very different in those decades" (Berridge 1993).

Many terms have been used over the last century or more to describe or define problems related to the use of alcohol, drugs, and other substances. Some of these terms are, to say the least, very ambiguous and fluid. It is important to appreciate the latter point since these terms are in turn employed in some of the descriptions or definitions of dual diagnosis, comorbidity, etc. The definition of addiction,

dependence, etc., is key to intervention with substance abusers as it classifies abusive drug/drinking behaviors and impacts on the type(s) of treatment that is given.

116.2 Dimensions of Substance-Induced Mental Disorders

The difficulty of making a diagnosis of a substance-induced mental disorder is because of the different points of view from mental health and addiction services that tend to confuse the situation. Furthermore, Abdulrahim (2001) suggests that the nature and relationship of comorbidity is complex and is so for the following reasons:

- Substance use and withdrawal from substances may lead to psychiatric syndromes or symptoms.
- Intoxication and dependence may produce psychological symptoms.
- Substance use may exacerbate or alter the course of preexisting mental disorder.
- A primary mental disorder may precipitate a substance use disorder, which may lead to psychiatric syndromes.

116.2.1 Examples

116.2.1.1 Cannabis-Induced Mental Disorders

An issue which has caused considerable debate in this area is the precise mechanism of the link between cannabis and psychosis. Specifically, cannabis use may alter the onset, course, and clinical expression of the psychotic episode.

There are several theories including:

(A) Cannabis use occurs as a means of self-medicating for the effects of a prodromal or florid psychosis episode/illness (Khantzian 1985).

(B) Latent form of schizophrenia. Cannabis use interacts synergistically with a predisposition to psychosis to result in the emergence of psychotic symptoms earlier. It assumes that cannabis is just one of many confounding factors, including a genetic predisposition, which precipitates psychosis. According to this theory, the psychosis will not necessarily reduce or cease with a withdrawal from cannabis use and will not present with a distinctive psychopathology (Henquet et al. 2004; Miller et al. 2001).

(C) Cannabis worsens or ameliorates an established psychosis (Caspi et al. 2005).

(D) Cannabis use directly causes toxic effect causing specific psychosis. Psychosis would not occur in the absence of cannabis use, and the fact that cannabis is the cause of the psychosis can be inferred from the symptoms or psychopathology of the psychosis (Ghodse 1986).

(E) Coincidental presentation of two prevalent disorders which peak in a young age group. Understanding how clusters of disorders through either concurrent or sequential links may promote a specific type of psychopathology (Cerda et al. 2008).

Another possibility is that cannabis and associated psychosis are not different from psychotic symptoms in the presence of other substances such as amphetamine, cocaine, and alcohol use. For example, Jordaan et al. (2009) concludes that since patients with alcohol-induced psychotic disorder have fewer negative and disorganized symptoms, better insight and judgment, and less functional impairment compared to patients with schizophrenia, this alcohol-induced psychotic disorder is a distinct entity. This resonates with the conclusions that alcoholic hallucinosis was not a variant of schizophrenia but a distinct condition (Glass 1989).

116.2.1.2 MDMA-Induced Neurotoxic Damage and Mental Disorders

That substance use could cause mental disorders or at least can intensify such problems is supported by both psychological and neurobiological data. For example, it is known that the effect mechanism of MDMA significantly concerns the serotonin system (Battaglia and De Souza 1989; Kankaanpaa et al. 1998; Kovar 1998; Piercey et al. 1990) and chronic MDMA use is supposed to have a neurotoxic effect on the serotonin system (McCann et al. 1994). Since the use of MDMA is linked to decreased sensitivity of serotonin receptors, it is a well-supported assumption that this bodily change could have a significant role in the often experienced symptoms of depression of MDMA users. This view seems to be strong, although it has been often stated that emotional instability might precede substance use, and it may have a role in the development of substance use, thus a circular causality might be assumed.

116.2.1.3 Chronic Opioid Use and Neuropsychological/Cognitive Impairment

Given the current emphasis on patients suffering from co-occurring substance use disorders (SUD) and other Axis I or Axis II mental disorders, one may forget that dual diagnosis can also include patients displaying both SUD and cognitive impairment. For example, chronic exposure to opioids has been reported to be associated with a number of neuropsychological impairments both during active use and after a period of abstinence. A wealth of studies have examined the acute, subacute, and chronic effects of opioids on neuropsychological performance using a broad variety of measures sensitive to component aspects of attention, memory, learning, and executive functioning (Fernandez-Serrano et al. 2011; Ersche and Sahakian 2007).

However, for methodological reasons, defining the nature and extent of opioid-related impairments remains elusive. For instance, research on memory functions has resulted in a number of studies showing impairments in word/pattern recognition, learning and recall of words/figures, paired associate learning, and retrieval (Ersche et al. 2006; Fishbein et al. 2007; Ornstein et al. 2000; Prosser et al. 2006). However, other studies failed to replicate these findings of memory deficits in chronic, opioid-dependent individuals (Davis et al. 2002; Mintzer et al. 2005). In addition to memory function, studies on attention also suggest inconsistent findings. Studies have shown either no impairments in attention (Davis et al. 2002; Soyka et al. 2005) or a significant reduction in attention span (Schindler et al. 2004; Soyka et al. 2008) in chronic, opioid-dependent individuals.

Neuropsychological studies of chronic opioid users have identified similarly inconsistent deficits in executive function measures. These have included impairments in cognitive flexibility (Pirastu et al. 2006), strategic planning (Fishbein et al. 2007), decision making (Brand et al. 2008; Verdejo-Garcia and Perez-Garcia 2007), and risk taking (Prosser et al. 2006; Verdejo-Garcia et al. 2007). However, other studies found no clear deficits when comparing the performance of healthy controls, with that of opioid abstinent, polysubstance users, head injury patients, or patients with chronic pain (Rotherham-Fuller et al. 2004; Gruber et al. 2006).

A meta-analysis by Baldacchino et al. (2012b) suggests that chronic opioid exposure is associated with deficits across a range of different neuropsychological domains. However, the only domains where meta-analysis suggests robust impairment were those of verbal working memory, risk taking, and cognitive flexibility (verbal fluency).

116.2.2 Presentations

Although there are several different classification schemes for psychoactive drugs (pharmacological, legal, medical), the most common organization is based on their effect on behavior and cognition. According to this scheme, psychoactive drugs can be classified into three broad categories: (1) sedatives, (2) stimulants, and (3) hallucinogens. Substance-induced mental disorders will be described on the basis of this classification (Table 116.1).

116.2.3 Sedative-Induced Mental Disorders

Sedatives depress or inhibit brain activity and produce drowsiness, sedation, or sleep, relieve anxiety, and lower inhibition. Although the depressant compounds do not share a common neural mechanism of action, most of them either decrease the metabolic activity in the brain or increase the transmission of the principal inhibitory neurotransmitter of the brain, gamma-aminobutyric acid (GABA). Common depressants include barbiturates, benzodiazepines, opioids, and alcohol (Eşel et al. 2003).

There are several mental disorders presenting as a direct consequence to excessive consumption of alcohol. The conditions presented with benzodiazepine and other sedatives tend to have the same quality but not necessarily severity of the psychopathology arising.

116.2.3.1 Alcohol-Induced Amnesia (Blackout)

Loss of memory is related to periods when intoxicated with alcohol. The anterograde memory loss tends to be as a result of lack of recall rather than registration (Jennison and Johnson 1994). Two types have been identified:

(a) "En bloc" – Discrete start and finish points with complete loss of memory for interim events
(b) Fragmentary – Partial amnesia with islands of recollection still intact

Table 116.1 Substance-induced mental disorders

	Sedatives	Stimulants	Hallucinogens
Acute effects	Relaxation, sedation, disinhibition and impaired judgment, slurred speech, ataxia, nystagmus, auditory hallucinations with delusions, labile mood, stupor and coma. Impairment of motor coordination and cognition	Increased alertness, energy, and confidence; reduced hunger and sleep; euphoria, anxiety, and paranoia	Relaxation, sedation, disorientation, euphoria and increased sensory awareness with hallucinations and delusions. Sometimes dysphoria, an overwhelming sense of fear often leading to panic attacks. Synesthesia
Withdrawal effects	Anxiety, agitation, disorientation, hallucinations (tactile, visual, auditory), and insomnia	Fatigue, anxiety and depression ("crash")	Emotional and behavioral disturbance, anxiety, depression, insomnia, and loss of appetite
Chronic effects	Depressive and anxiety symptoms including guilt and hopelessness confusion, ataxia, ophthalmoplegia, nystagmus, anterograde memory loss, and confabulation. Others include deficits in abstract thinking, perceptual motor skills, and visuospatial and verbal learning	Depressive and psychotic symptoms. Cognitive impairments	Cognitive impairment and possible long-term, anxiety, depressive, and psychotic symptoms. Suicidal ideations. Cognitive impairments

116.2.3.2 Alcohol-Induced Psychosis/Hallucinosis

This mental disorder presents with a sudden onset of auditory hallucinations and delusions in the presence of clear "sensorium" in individuals with a history of alcohol abuse. The auditory hallucinations are usually derogatory in nature or portray negative connotations (Jordaan et al. 2009). These symptoms usually improve quickly (usually within a week) although they can become chronic due to ongoing alcohol misuse they tend to persist. Patients with alcohol-induced psychosis can present with later onset of psychosis, lower educational level, more anxiety and depressive symptoms, fewer negative and disorganized symptoms, and less functional impairment compared with patients with schizophrenia (Jordaan et al. 2009).

116.2.3.3 Alcohol Withdrawal Syndrome (AWS)

This arises in alcohol-dependent patients, usually within 24–48 h of stopping alcohol consumption (McKeon et al. 2008). AWS can occur unexpectedly in an alcohol-dependent patient following hospital admission and intentionally in those seeking abstinence. Alcohol withdrawal is common and usually mild but can also lead to withdrawal seizures and delirium tremens, both of which may be fatal (McKeon et al. 2008). The definition of alcohol withdrawal encapsulates the key

clinical findings of AWS including anxiety, agitation, tremor, delirium, disorientation, hallucinations (tactile, visual, auditory), and insomnia.

116.2.3.4 Delirium Tremens

This is characterized by an acute confusional state with fluctuating levels of cognition and consciousness over the day following alcohol withdrawal in a patient with alcohol dependence. It usually occurs 2–4 days after last alcohol consumption unlike simple alcohol withdrawals which occur within a few hours of stopping alcohol. Autonomic symptoms including sweating, nausea, palpitations and tremor, hypertension, and tachycardia are invariably present. It occurs in about 5 % of withdrawal episodes in admitted patients (Mayo-Smith 1997). Important clinical features include visual hallucinations and severe tremors. Other symptoms include fear, paranoid delusions, and psychomotor agitation.

116.2.3.5 Wernicke's Encephalopathy and Korsakoff Psychosis

Chronic alcohol consumption can result in thiamine deficiency via inadequate dietary intake, malabsorption of thiamine from the gastrointestinal tract, and impaired utilization of thiamine in the cells. Thiamine is an essential cofactor for several enzymes involved in brain cell metabolism that are required for the production of precursors for several important cell components as well as for the generation of the energy-supplying molecule ATP. Accordingly, thiamine deficiency can cause a number of processes that are toxic to brain cells (Martin et al. 2003).

Wernicke's encephalopathy is a relatively common and potentially dangerous neuropsychiatric condition caused by thiamine (vitamin B1) deficiency (Boileau et al. 2006). If not treated it can result in a chronic form of the disease known as Korsakoff psychosis. As a result of the close relationship between Wernicke's encephalopathy and Korsakoff psychosis, reference is often made to the Wernicke–Korsakoff syndrome (Thomson et al. 2002).

The symptoms of Wernicke's encephalopathy include mental confusion, oculomotor disturbances, and gait ataxia (an impaired ability to coordinate movements, particularly of the lower extremities). Patients will also manifest deficits in memory function, abstract problem solving, perceptual motor skills, visuospatial, verbal learning, and motor function.

Korsakoff syndrome consists of memory impairments (preserved primary memory, impaired recent memory, and extensive retrograde amnesia) occurring in clear sensorium. Other psychopathology includes poor insight into the memory deficit with resulting confabulation, absence of impairment of consciousness, and absence of global cognitive impairment (Kopelman et al. 2009).

116.2.4 Stimulant-Induced Mental Disorders

Stimulants produce behavioral arousal. As with the sedatives, there are a variety of substances each with a different neural mechanism of action. These drugs act by increasing the activity of three neurotransmitters in the brain: serotonin, dopamine,

and norepinephrine (Taylor et al. 2013). Examples of stimulants are cocaine, caffeine, and nicotine. Other examples of stimulants are amphetamines and amphetamines-like substances such as methamphetamine. Smoking, sniffing, ingesting, inhaling, and injecting are the most common methods in which these drugs are used.

Stimulant-induced mental disorder presents in the acute stage with euphoria and in vulnerable groups severe anxiety, paranoia, and manic type (increased energy, mental alertness, increased sexuality, and extended periods of wakefulness) psychopathology (McKetin et al. 2013; Harris and Batki 2010). This is associated with improved attention and suppressed appetite (Tang et al. 2009). It can also cause perceptual disturbances especially "formication." This is described as a sensation that resembles that of insects crawling (tactile hallucination) on (or under) the skin. It is one specific form of a set of sensations known as paresthesia, which also include the more common prickling, tingling sensation of "pins and needles." As the effects of the drugs subside, the user feels dysphoric, tired, irritable, and mildly depressed, which may lead to subsequent drug use to regain the previous experience (Shoptaw et al. 2009; Sofuoglu and Kosten 2005).

Chronic use of excessive amounts of stimulants can intensify symptoms or precipitate a psychotic episode similar to schizophrenia in vulnerable individuals (Ujike 2002; Yui et al. 1999).

116.2.5 Hallucinogen-Induced Mental Disorders

Hallucinogens and psychedelics do not share a common mechanism of action, but all induce hallucinations. These drugs can be either natural such as mescaline, which is derived from the peyote cactus, or synthetic such as lysergic acid diethylamide (LSD), but they are typically classified pharmacologically according to the affected neurotransmitter system. Cholinergic psychedelics (drugs altering acetylcholine transmission) include physostigmine, scopolamine, and atropine. Drugs that alter norepinephrine transmission include mescaline and ecstasy. Drugs that alter serotonin transmission include LSD and psilocin. Other drugs in this category include the psychedelic anesthetics phencyclidine (PCP) and ketamine (Nichols 2004; Van Jan et al. 2011; Seivewright and Lagundoye 2000).

Cannabinoids, psychoactive substances derived from the hemp plant Cannabis sativa, are often classified as hallucinogens. There are two types of acute effects on mental function – euphoric and calming. Besides dramatic impact on emotional functions, acute cannabis intoxication can induce cognitive impairments, sometimes persisting for weeks or months following abstinence. This usually presents as fragmentation of thought process, major disruption of temporal understanding, distortion of perceptual stimuli, and poor attention and concentration. "Cannabis psychosis" may not be qualitatively any different from other forms of psychosis (Baldacchino et al. 2012a). Some specific psychopathologies stated include confusion, disorientation, amnesia, depersonalization, delusions, hallucinations, paranoid, ideation, psychomotor agitation, labile affect, and hostility (Amar and Potvin 2007).

Chronic exposure to cannabis leads to a cannabis withdrawal syndrome (Budney et al. 2008) characterized by the frequently reported symptoms of emotional and behavioral disturbance which includes depression, anxiety and irritability, nausea, abdominal discomfort, decreased appetite, weight loss, physical discomfort, and insomnia with strange dreams (Budney et al. 2008). A chronic buildup of cannabinoids produces both short-term and long-term cognitive impairments. There is insufficient knowledge to determine the level of risk associated with cannabis use in relation to long-term psychotic symptom (Minozzi et al. 2010).

116.3 Conclusion

Substance-induced mental disorders are important conditions that need to be contextualized within the substance use history but also need to be well managed to prevent further deterioration. Substance-induced mental disorders also need to be understood within the context of the overall lack of defined and strict operational definitions used in the field of comorbidity/dual diagnosis.

Abstract

Mood disorders, which include the depressive disorders and bipolar disorders, are prevalent in the general population and are among the most common disorders observed to co-occur with substance use disorders. Mood disorders have been associated with worse prognosis among substance-dependent patients. Further, treatment of co-occurring mood disorders has been shown to improve treatment outcome among substance-dependent patients with improvement in both mood and substance use. At the same time, mood symptoms and syndromes among substance-dependent patients frequently remit when the patient enters treatment for substance dependence and reduces substance use or achieves abstinence – no specific mood disorder treatment required. Thus, it is important for clinicians working with substance-abusing patients to be able to recognize mood disorders in the clinical history, distinguish mood disorders that require specific treatment, recommend appropriate treatment options, and monitor clinical course. This chapter reviews the evidence on the diagnosis and treatment of co-occurring substance and mood disorders, with emphasis on depressive disorders.

117.1 Introduction

The co-occurrence of mood and substance use disorders has been a source of considerable controversy, sparked by the complexity of potential relationships between mood syndromes and substance use. For example, in an alcoholic, do depressive symptoms represent side effects of chronic alcohol exposure that will resolve if the patient achieves abstinence? Or do they represent an independent mood disorder that requires specific treatment, either with behavioral therapy, medication, or a combination of the two? In any given patient, either of these explanations may be correct. Effective management of co-occurring mood symptoms in substance-abusing patients requires a nuanced awareness of the differential diagnosis of the mood symptoms. This chapter will attempt to provide a guideline for clinicians to the differential diagnosis and therapeutics of mood syndromes among substance-dependent patients, based on the current evidence.

The co-occurrence of bipolar disorders and substance use disorders is covered in detail in a separate chapter of this text. However, when conducting a diagnostic evaluation and treatment planning for patient with a substance use disorder and mood symptoms, it is very important to consider bipolar disorders in the differential diagnosis, since the treatment implications are quite different. This chapter therefore provides an overview of the diagnosis of bipolar disorders.

117.2 Prevalence and Co-occurrence

117.2.1 DSM-IV and DSM-5

The publication of this textbook coincides with the recent (May 2013) release of the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) (American Psychiatric Association 2013). However, virtually all the empirical evidence that will be cited in this chapter, bearing on co-occurrence of mood and substance use disorders, derives from investigations that used DSM-IV (American Psychiatric Association 1994) or earlier criteria sets. The criteria for depressive disorders (major depression, persistent depressive disorder (dysthymia)) and bipolar disorders (bipolar I, bipolar II, cyclothymia) have changed little between DSM-IV and DSM-5. Dysthymia, which in DSM-IV described chronic low-grade depression, has been renamed persistent depressive disorder in DSM-5 and now encompasses both chronic low-grade depression and chronic major depression. DSM-5 added a new category of disruptive mood dysregulation disorder (DMDD) to the group of depressive disorders. DMDD is intended to distinguish children with predominantly irritable mood, but without other features of bipolar disorder, from children in the bipolar spectrum. The substance-induced diagnoses (substance-induced depressive disorder, substance-induced bipolar disorder) are similar conceptually in DSM-5 and DSM-IV with some subtle differences reviewed below.

A thorough review of the diagnostic criteria for depressive and bipolar disorders is beyond the scope of this chapter. Readers who are not familiar with these diagnostic criteria should review the DSM-5 (American Psychiatric Association 2013), which provides detailed descriptions.

The substance use disorders were changed in DSM-5, in that substance dependence (DSM-IV) and substance abuse (DSM-IV) have been combined into one category, named substance use disorder (DSM-5). This was done because the weight of the evidence indicated the criteria for DSM-IV substance abuse, which involved hazardous use (e.g., driving while intoxicated), social or interpersonal problems related to use, or failure to perform in major role responsibilities, were intermixed across the severity spectrum with substance dependence criteria, representing part of a chronic pattern of substance use with loss of control, tolerance, dependence, and adverse consequences (Hasin et al. 2013). Another difference between DSM-IV and DSM-5 is the addition of "craving" as a criterion for substance use disorder in DSM-5. In terms of the evidence on the co-occurrence of mood and substance use disorders, these change should make little difference, since the three retained abuse criteria and craving are unidimensional with the seven dependence criteria (all therefore indicating the same underlying condition) and most epidemiological and treatment research on the comorbidity of depression and substance disorders concerned co-occurrence with substance dependence. Further, substance dependence (DSM-IV) and substance use disorder

(DSM-5) are conceptually similar, representing a chronic pattern of substance use with loss of control, tolerance, dependence, and adverse consequences.

In summary, the DSM-5 criteria sets for mood and substance use disorders are similar enough to DSM-IV, and prior criteria that the evidence on co-occurrence described in this chapter can be expected to generalize to the DSM-5 framework. Future research examining co-occurrence of substance and other mental disorders in the DSM-5 framework is needed. Meanwhile in this chapter, evidence described on prevalence and treatment will be derived from studies based on DSM-IV or earlier criteria sets.

117.2.2 Depressive Disorders

117.2.2.1 Major Depressive Disorder

Major depressive disorder represents an episode, lasting 2 weeks or more, of relatively severe depression, characterized by a persistent state, "most of the day, nearly every day" (American Psychiatric Association 2013), of either depressed mood or markedly diminished interest or pleasure in usual activities, or both, along with at least three or four associated symptoms, again occurring nearly every day (anorexia and weight loss, insomnia or hypersomnia, psychomotor agitation or retardation, fatigue or low energy, feelings of worthlessness or guilt, trouble concentrating or making decisions, recurrent thoughts of death or suicide). Major depression may occur as a single episode, but in patients, a chronic course is not uncommon, in which there are recurrent major depressive episodes, followed by partial remissions during which some of the depressive symptoms persist.

117.2.2.2 Persistent Depressive Disorder

Persistent depressive disorder (DSM-5), which was called *dysthymia* in DSM-IV, represents a chronic syndrome of depressed mood "more days than not... for at least 2 years" (American Psychiatric Association 2013), along with at least 2 of the following associated symptoms – either low appetite or overeating, insomnia or hypersomnia, fatigue or low energy, low self-esteem, poor concentration or difficulty making decisions, and feelings of hopelessness. Persistent depressive disorder may be specified "with persistent major depression" or "with intermittent major depressive episodes" to indicate the confluence of major depressive episodes with the chronic low-grade symptoms.

117.2.2.3 Prevalence and Co-occurrence of Depressive Disorders with Substance Use Disorders

Like substance use disorders, depressive disorders are among the most commonly occurring mental disorders. Community surveys indicate 10 % or more of individuals have experienced a depressive disorder during their lifetime (Hasin et al. 2005). Depressive disorders are responsible for substantial suffering, functional impairment, lost productivity, and suicide risk. Large community surveys, such as the Epidemiological Catchment Area study (ECA) (Regier et al. 1990), the National Comorbidity

Survey (NCS) (Kessler et al. 1994; Kessler 1995), and the National Epidemiologic Survey on Alcoholism and Related Conditions (NESARC) (Hasin et al. 2005; Grant et al. 2005), consistently show that the presence of a depressive disorder significantly increases the risk of alcohol or drug dependence (or vice versa) by a factor of 2 or more. Treatment-seeking samples tend to display even greater comorbidity due to the relatively greater severity of illness of treatment seekers. Across numerous studies of such samples, the prevalence of major depression has ranged from 15 % to 50 %, making it probably the most common co-occurring psychiatric disorder encountered among drug- or alcohol-dependent patients in treatment (Hasin et al. 2004).

117.2.2.4 Prognostic Effects of Depressive Disorders on Substance Use Disorders

Many longitudinal studies have found that the presence of depression in drug- or alcohol-dependent patients is associated with worse treatment outcome and prognosis. These findings suggest the importance of identifying and treating depression among substance-dependent patients, since the implication is that treatment of the depression has the potential to improve prognosis. Importantly, the findings of the adverse prognosis of depression are most consistent among studies where a depressive disorder (mainly major depression) is diagnosed by clinical history and structured diagnostic assessment. Findings on the association between depression and prognosis of substance use are less consistent when depression is measured only with cross-sectional scales (Hasin et al. 2004). For example, one study that followed alcohol-dependent patients for a year after an index hospitalization found that a diagnosis of major depression was associated with poor drinking outcome over the coming year, while the Hamilton Depression Rating Scale score at baseline was not (Greenfield et al. 1998).

117.2.3 Bipolar Disorders

Bipolar disorders are more rare in the general population, but are more strongly associated with co-occurring substance use disorders. Large community surveys yield estimates of the lifetime prevalence of bipolar I disorder ranging from 1 % to 3 %, another 1 % for bipolar II disorder, and 2 % or more having subthreshold disorders in the bipolar spectrum (Grant et al. 2005; Merikangas et al. 2007). Although bipolar disorders are characterized by the presence of manic or hypomanic episodes during the lifetime, these episodes alternate with episodes of major depression or chronic depression, and the depressed periods typically predominate, particularly later in the course of the illness. Thus, bipolar patients are most likely to present clinically as depressed. When evaluating a depressed, substance-using patient, it is therefore very important to search the history for evidence of past manic or hypomanic episodes because the treatment of bipolar disorders differs significantly from the treatment of depressive disorders. The cornerstone of the treatment of bipolar disorder is mood stabilizer medications – lithium, anticonvulsants, or neuroleptics. Treating bipolar depression with antidepressant medications alone can be ineffective or even cause worsening of mood instability.

117.2.3.1 Bipolar I Disorder

Bipolar I disorder is characterized by the presence of one or more manic episodes over course of the lifetime. Manic episodes are characterized by a week or more of persistently elevated, expansive, or irritable mood, accompanied by at least three associated symptoms, including grandiose thinking, decreased need for sleep, increased talkativeness, racing thoughts, distractibility, increased activity level, and risky or foolish behavior that the person would not usually engage in. The syndrome is severe and causes marked impairment in functioning. Mania may become psychotic with paranoid or grandiose delusions (e.g., a patient becomes convinced that he/she is a messiah or on a special mission from God). Typically, the course of bipolar I includes episodes of major depression, may also include hypomanic episodes, and typically runs a course that is predominated by depressive symptoms.

117.2.3.2 Bipolar II Disorder

Bipolar II disorder is characterized by one or more hypomanic (as opposed to manic) episodes, along with one or more episodes of major depression over the lifetime. A hypomanic episode resembles a manic episode, except that hypomania may be shorter, and is less severe. There must be a change in functioning to meet criteria for hypomania, but hypomania does not cause marked impairment or psychosis. Again, bipolar II frequently runs a predominantly depressive course.

117.2.3.3 Co-occurrence of Bipolar and Substance Use Disorders and Prognostic Effects

Large-scale community surveys indicate that the presence of a bipolar disorder increases the odds of having an alcohol use disorder by a factor of 5 or more and a drug use disorder by a factor of 8 or more (Regier et al. 1990; Kessler et al. 1994; Kessler 1995; Hasin et al. 2005; Grant et al. 2005). In outpatients seeking treatment for substance use disorders, bipolar disorder is less commonly encountered than depressive disorders because bipolar is less frequent in the general population. However, patients with co-occurring bipolar and substance use disorders are particularly likely to be encountered in inpatient settings dealing with more severe dually diagnosed patients.

The co-occurrence of bipolar and substance use disorders is associated with worse outcome for both disorders. Patients with bipolar disorders can be very difficult to manage until the disorder is recognized and successfully treated with mood stabilizers. Conversely, finding the right mood stabilizer regimen for a given patient can be dramatically effective. This, again, suggests the importance, when evaluating substance-dependent patients, of taking a careful past history for past episodes of mania or hypomania.

117.2.4 Co-occurring Depression and Substance Use as a Signal for Other Disorders

A recent analysis of the NESARC data on co-occurrence of mood and substance use disorders yielded an interesting finding (Hasin et al. 2007). When the

association between major depression and substance use disorders is analyzed in such a way as to control for the presence of other disorders (bipolar disorder, anxiety disorders, etc.), the odds ratio of association between depression and substance use disorders is substantially reduced. This suggests that the apparent association between depression and substance use disorders may be explained, at least in part by the presence of the other co-occurring disorders, including anxiety disorders, since anxiety is a commonly occurring symptom among those with depression. In contrast, the association between bipolar disorder and substance use disorders remained significant after controlling for the other disorders. Substance use disorders have high rates of co-occurrence with anxiety disorders, such as panic disorder, social anxiety disorder, and post-traumatic stress disorder (PTSD); attention deficit hyperactivity disorder (ADHD); and personality disorders, including antisocial personality and borderline personality. Each of these disorders, in turn, has high co-occurrence with depressive disorders or symptoms or has symptoms that resemble depression. Thus, in substance-dependent patients, depressive symptoms may be a signal that other disorders are also present. It is therefore important to take a careful history looking, not only for bipolar disorder but also for anxiety disorders, ADHD, or personality disorders. These disorders also have distinct behavioral and pharmacological treatment indications, and instituting appropriate treatment will be important to securing the best clinical outcome.

117.3 Diagnosis of Co-occurring Mood Disorders with Substance Use Disorders

In approaching the differential diagnosis of a patient with a substance use disorder and mood symptoms, it is important to recognize that there are multiple potential relationships between mood symptoms and a substance use disorder. There may be an independent mood disorder (e.g., major depressive disorder or bipolar disorder), or the depressive symptoms may be a manifestation of another co-occurring disorder such as PTSD or ADHD. Mood and substance use disorders may be related by common genetic or environmental risk factors. Stress is the most obvious example of this, as stress is a causal risk factor for both mood disorders and substance use disorders.

Perhaps most commonly, substance use causes mood symptoms, either as part of substance intoxication or withdrawal or as a result of the toxic effects of chronic exposure to substances. Moreover, individuals with substance use disorders often experience negative consequences and losses (e.g., medical problems, loss of employment or family), which may trigger depressive symptoms. Some of these substance-related or substance-induced mood symptoms will resolve if the patient is able to achieve abstinence. Hence, it is almost always appropriate to initiate treatment for a substance use disorder, while sorting out the co-occurring mood disorder. If the patient's substance use is substantially reduced or resolved, the mood symptoms may resolve with it. A number of studies across alcohol- and

drug-dependent samples have shown that initiation of treatment for substance use disorders and achievement of abstinence are associated with marked improvement in mood symptoms (Brown and Schuckit 1988; Weddington et al. 1990; Strain et al. 1991; Satel et al. 1991; Brown et al. 1995; Liappas et al. 2002).

It is also important to bear in mind that resolution of a depressive syndrome with treatment of the substance abuse alone is not pathognomonic of a substance-induced depression. Depressive disorders, particularly in the mild to moderate range of severity, respond well to psychotherapy, such as cognitive behavioral therapy (CBT) or interpersonal therapy (IPT). Treatment for substance use disorders generally includes nonspecific psychotherapeutic elements, such as development of a supportive clinician-patient relationship and treatment alliance, which are likely to be helpful with treating depression. Further, many treatments for substance use disorders include components on coping with stress and with dysphoric moods that are quite similar to cognitive behavioral techniques for treating mood and anxiety disorders. Further, reductions in substance abuse and related problems in response to treatment are likely to reduce stress and improve self-efficacy, also likely to help depression. In summary, good treatment for substance use disorders may also be effective for treatment of an independent depressive disorder.

117.3.1 DSM-IV/DSM-5 Approach to Co-occurring Mood and Substance Use Disorders

Before the advent of DSM-IV, there was not a clear consensus on how to diagnose co-occurring mood disorders in the setting of substance use disorders. There was recognition that some co-occurring mood disorders were independent of substance use and some mood syndromes were caused by substance use, which would resolve once abstinence was achieved. However, determining the optimal way to handle the large proportion of cases, in which the history is not so clear with respect to relative onset and offset, is less obvious, especially when the patient does not quickly achieve abstinence. DSM-IV advanced the field by distinguishing between independent mood disorders, substance-induced mood disorders, and mood symptoms that are usual effects of substances and for providing some criteria to make the distinctions. DSM-5 has retained this system. Substance-induced mood disorder provides a category in which to place the unclear cases, in which a mood disorder syndrome exceeds the symptoms that would be expected from intoxication and withdrawal, but the syndrome has not occurred in the absence of regular substance use. It has generated meaningful research as to its prognosis and course, as reviewed below.

117.3.1.1 Independent Mood Disorder

An independent mood disorder is diagnosed if the patient meets full criteria for the mood disorder (e.g., major depression, persistent depressive disorder, bipolar I) and the symptoms can be established by history to be temporally independent of substance abuse (prior onset or emergence or persistence during periods of

abstinence). DSM-IV also suggested that an independent disorder could be diagnosed if its symptoms were substantially in excess of effects expected to be caused by the substance(s) the patient was taking. DSM-5 deals with this by specifying that a substance-induced disorder is only diagnosed if the mood syndrome and symptoms are consistent with symptoms known to be caused by the substance(s). The clinical implications are similar. In the criteria sets for substance-induced mood disorders, DSM-5 suggests that a mood syndrome co-occurring with substance use may be considered an independent disorder (and thus distinguished from substance-induced disorder) if the mood syndrome had its onset prior to the onset of substance abuse, or persists for about 1 month or more after abstinence is achieved, or there is a clear past history of independent mood disorder episodes. An example might be a current major depression syndrome that had its onset concurrent with substance abuse in the current episode, but there is a clear history of one or more major depressive episodes during past abstinent periods.

117.3.1.2 Substance-Induced Mood Disorder

A substance-induced mood disorder is diagnosed if there is a "persistent disturbance in mood," which (a) develops at or soon after substance intoxication or withdrawal and (b) the substance(s) in question is "capable of producing the symptoms," and the syndrome is not better explained by a diagnosis of an independent mood disorder. There must be significant distress or impairment. Further, with respect to distinguishing a substance-induced mood disorder from usual effects of substances, the DSM-5 criteria state that a substance-induced mood disorder should be diagnosed, instead of a diagnosis of substance intoxication or withdrawal, only if "the mood symptoms predominate and are sufficiently severe to warrant clinical attention." DSM-IV worded this slightly differently, indicating that substance-induced mood disorder should be diagnosed when the mood and related symptoms (e.g., insomnia) exceed what would be the expected effects of intoxication or withdrawal and warrant clinical attention. Again, the clinical implications are similar.

117.3.1.3 Usual Effects of Substances

Mood symptoms, such as depressed mood, insomnia, and weight loss, can also be usual effects of substance intoxication or withdrawal. DSM-IV and DSM-V contain detailed criteria sets for the intoxication and withdrawal syndromes of alcohol, nicotine, and each of the other commonly abused drugs. Clinicians should be mindful of these lists of symptoms when evaluating patients with co-occurring mood symptoms and substance use. These symptoms have various time frames, but generally, symptoms of intoxication last only for the few hours during and after substance ingestion while blood levels are peaking and before they substantially decrease. Symptoms of withdrawal usually evolve and resolve over a period of a few days. Subacute withdrawal syndromes (also called protracted withdrawal), sometimes lasting a few weeks, have been described, particularly for alcohol and opioid dependence, although boundaries between this phenomenon and substance-induced disorders can be difficult to define.

Depressed mood and related symptoms (e.g., anxiety, fatigue, hypersomnia, insomnia, difficulty concentrating, irritability) occur variously as part of the withdrawal syndromes of most of the common addictive substances. In summary, when conducting a diagnostic evaluation on a substance-using patient, familiarity with the intoxication and withdrawal effects of the substance(s) involved is important in order to distinguish mood symptoms that are best explained as components of intoxication or withdrawal from symptoms that are better explained as a substance-induced disorder.

117.3.1.4 Co-occurring Bipolar and Substance Use Disorder

Episodes of frank mania are generally too persistent (1 week or more) and too severe to be explained as substance induced. For example, cocaine or methamphetamine intoxication may produce a syndrome closely resembling mania (increased activity, hyper-loquaciousness, grandiosity, lack of need for sleep, and psychosis with paranoid or grandiose delusions), but this typically only lasts for the duration of the drug binge, a day at most, after which there will be a crash with the typical depressive withdrawal symptoms (fatigue, hypersomnia, depressed mood, etc.). Hence, a history of one or more episodes of frank mania in a patient presenting with co-occurring mood symptoms and substance problems is clear evidence of co-occurring independent bipolar disorder that requires appropriate mood stabilizer medication.

Hypomania can be more difficult to identify both in the present and historically. Hypomania is milder, and patients may not report it because they do not remember it or did not experience it as a departure from normal functioning. Moreover, periods of elevated mood, and increased energy and activity, may be difficult to distinguish from periods of normal mood – for example, when a chronically depressed patient becomes euthymic or when a patient has an exciting life event such as a new job or another major success. Periods of hypomania can be difficult to distinguish in a patient with heavy stimulant use, given the shorter duration of hypomania and the overlap in symptoms between hypomania and cocaine or stimulant intoxication (e.g., euphoria, increased sociability). As with depressive disorders, to confirm an independent bipolar II disorder, it becomes important to seek episodes in the history in which syndromes of hypomania occurred in the absence of stimulant-like substances.

117.3.2 Course and Prognosis of DSM-IV Independent and Substance-Induced Depression

Prior to DSM-IV, considerable evidence existed that independent depressive disorders could be identified with distinct prognostic and treatment implications. Brown and Schuckit showed among hospitalized alcoholics that a history of major depression prior to the onset of alcohol problems over the patient's lifetime (primary depression) was associated with depressive symptoms that persisted despite 3–4 weeks of abstinence (Brown and Schuckit 1988; Brown et al. 1995).

Rounsaville and colleagues, using the Schedule for Affective Disorder and Schizophrenia, a structured diagnostic instrument, found major depression to be associated with worse prognosis among drug-dependent patients (Rounsaville et al. 1982, 1986; Carroll et al. 1993). We and others found that depression with evidence of temporal independence from substance use either by history (Nunes et al. 1993, 1998; McGrath et al. 1996) or through observed persistence of depression symptoms during abstinence (Mason et al. 1996; Cornelius et al. 1997; Roy 1998) responded to antidepressant medication.

117.3.2.1 Structured Diagnostic Assessment

With the advent of DSM-IV, the Structured Clinical Interview for DSM-IV (SCID) incorporated a module for substance-induced mood disorder and logic for diagnosing a mood syndrome as independent or substance induced. However, the determinations were left largely up to clinical judgment with little guidance in the interview as to how to make the distinction. The Psychiatric Research Interview for Substance and Mental Disorders (PRISM) (Hasin et al. 2006) was developed to operationalize the diagnosis of co-occurring substance and other mental disorders within the DSM-IV framework. For a given syndrome, such as major depression, the interviewer is asked, for each criterion symptom, to judge whether that symptom appears attributable to usual effects of substances. The substances that might cause that symptom, either as intoxication or withdrawal effects, are listed. For example, when a depressed patient reports insomnia, the interviewer is asked to determine whether substances that might cause insomnia (stimulant intoxication or alcohol, sedative, or opioid withdrawal) could explain the insomnia. The insomnia is only scored as positive, and allowed to contribute to a diagnosis of a depressive disorder, if it can be determined either not related to or exceeding the expected effects of the substances the patient is taking. If sufficient criteria are endorsed to allow diagnosis of a depressive syndrome, then the interviewer is asked to determine whether the depressive syndrome is temporally independent of current substance use in terms of its onset and persistence during abstinence. If the history indicates that the depressive episode started prior to the onset of substance use or persists during a substantial abstinent period (e.g., a month or more), then it is diagnosed as independent. Otherwise, it is diagnosed as substance induced.

Thus, the PRISM provides an operationalized definition of substance-induced depression that is quite stringent. It requires criteria for a full depressive syndrome (e.g., for major depression) to be met, and it requires that the symptoms contributing to that syndrome not be better explained as toxic or withdrawal effects. In contrast, DSM-IV criteria for substance-induced depression refer only to a syndrome of depression without specifying how many or which symptoms of depression need to be present. DSM-5 criteria for substance-induced depression similarly require that there be a persistent disturbance in mood or loss of interest (much like the essential two criteria for major depression) but no specific associated features (such as insomnia, fatigue, suicidal ideation). This highlights an area of vagueness in the DSM-IV and DSM-5 definitions of substance-induced disorders, which the PRISM sought to correct by being more definitive. The PRISM yields

a diagnosis of substance-induced major depression, rather than the more broad and vague category of substance-induced depression.

117.3.2.2 Prognostic Effects

Subsequent research with the PRISM established good to excellent reliability of diagnoses of independent and substance-induced major depression (Hasin et al. 2006). Further, there were clear prognostic effects. In a longitudinal study, substance-dependent patients entering an inpatient treatment facility were diagnosed with the PRISM while hospitalized, then followed for 1 year after discharge. Substance-induced major depression was found to predict failure to achieve abstinence after discharge from hospital, while independent major depression was found to predict relapse to substance use after periods of abstinence (Hasin et al. 2002; Samet et al. 2013). Both independent and substance-induced depression were associated with suicidal ideation (Aharonovich et al. 2002). Further, over half of cases diagnosed as substance-induced depression at baseline converted into an independent depression over the year's follow-up, based on the major depression persisting during a period of at least a month of abstinence (Nunes et al. 2006). Predictors of conversion to independent depression included a past history of an independent major depression and either PTSD or borderline personality disorder (Nunes et al. 2006), again suggesting the importance of identifying other disorders that commonly co-occur with both mood and substance use disorders. Studies with other samples and diagnostic methods have similarly suggested the validity and prognostic significance of independent and substance-induced depressive disorders as conceptualized by DSM-IV/DSM-5 (Schuckit et al. 1997; Ries et al. 2001, 2008) and the finding that a substantial proportion of substance-induced depression will convert to an independent depressive disorder over time (Ramsey et al. 2004).

117.3.2.3 A Note About Terminology

The term "substance-induced depression" carries a causal implication, namely, that the substances are definitely causing the observed depression syndrome. This can cause clinicians to underestimate the potential clinical significance of a substance-induced depression, both because intoxication and withdrawal effects are also induced by substances and also because, as reviewed above, some depressions diagnosed as "substance induced" will turn out to be independent depressions if followed into a period of abstinence. Substance induced is to some extent a holding category for depressions for which the status as independent is uncertain at the time of diagnosis. It might be useful for clinicians to think of this as "substance induced until proven otherwise," to emphasize that continued clinical attention is warranted and that the depression may turn out to be independent or to warrant specific treatment.

In summary, these studies suggest that in diagnosing a substance-induced depression, it is important to determine what depressive syndrome is being observed – e.g., substance-induced major depression. The findings suggest that substance-induced depression is a valid and useful category. It represents a diagnostic entity that lies between usual toxic effects of substances and an

independent mood disorder. As the DSM-IV and DSM-5 criteria suggest, substance-induced depression "warrants clinical attention" because it carries adverse prognostic effects (suicidal ideation, lower likelihood of achieving abstinence) and is likely to convert to an independent depression over time. Further, as the DSM-5 criteria suggest, a past history of independent depression may be considered sufficient evidence to diagnose a current depression as independent, rather than substance induced. Other co-occurring disorders such as PTSD should also be suspected.

117.3.3 Summary and Recommendations for Diagnostic Assessment

117.3.3.1 Screening Instruments

Instruments that assess cross-sectional mood symptoms (e.g., Beck Depression Inventory, Hamilton Depression Rating Scale, Brief Symptom Inventory, or Quick Inventory of Depressive Symptomatology – Self-Report (QIDS-SR)) are useful for screening. However, by themselves they do not indicate the presence of any specific mood disorder and have unclear prognostic or treatment implications.

117.3.3.2 Clinical History and DSM-IV/DSM-5 Criteria

A substance-dependent patient with mood symptoms should be evaluated by taking a careful lifetime clinical history. The history should seek to establish the onset of substance use disorders over the lifetime and substantial periods of abstinence lasting a month or more. The history should then establish the onset and course of mood syndromes (major depressive episodes, persistent depressive disorder, mania, hypomania), in the context of the lifetime course of substance use, and apply the DSM-5 criteria for independent or substance-induced disorders. Among other things, this means establishing that symptoms of a mood disorder are not better explained as usual effects of substances or exceed what would be expected from the usual effects of substances. A mood disorder that cannot be established to be temporally independent of substance abuse, but exceeds the expected effects of substances, is diagnosed as substance induced. For substance-induced syndromes, we also recommend noting the full syndrome that is in evidence, for example, "substance-induced major depression" if the full criteria for major depression are met (i.e., five or more criteria are met), as some of the stronger prognostic data pertain to substance-induced depression defined in this way (Hasin et al. 2002; Aharonovich et al. 2002; Nunes et al. 2006; Samet et al. 2013).

117.3.3.3 Search the History for Mania or Hypomania

The presence of one or more episodes of mania and hypomania indicates a bipolar disorder, which carries prognostic and treatment implications distinct from depression. Mania and hypomania may be difficult to elicit in the history. It is often helpful to interview family members, who may recall such episodes when the patient does not.

117.3.3.4 Look for Other Co-occurring Disorders

We also recommend a thorough review of the history for other disorders that commonly co-occur with mood disorders, including PTSD, social anxiety disorder, and other anxiety disorders; ADHD; and borderline personality. The presence of mood symptoms may signal the presence of one of these disorders. Such disorders have symptom patterns that are distinct from typical substance effects – substance use does not cause phobias, social anxiety, or reexperiencing symptoms of PTSD. Some have clear childhood onset (e.g., ADHD, social anxiety disorder), well prior to the onset of substance problems. And they have distinct treatment indications for both behavioral therapy and medications.

117.4 Treatment of Co-occurring Mood Disorders

117.4.1 Depressive Disorders

117.4.1.1 Antidepressant Medications

A number of placebo-controlled trials have examined the effect of antidepressant medication on mood and substance use outcome among substance-dependent patients with diagnosed mood disorders. Two meta-analyses (Nunes and Levin 2004; Torrens et al. 2005), published 10 years ago, reached similar conclusions, namely, that antidepressant medications are useful in improving both mood outcome and substance use outcome; these findings are more clear among alcohol-dependent patients. Among drug-dependent patients, there are fewer studies with less clear results. More recent studies have been mixed, with some negative trials (Gual et al. 2003; Kranzler et al. 2006; Cornelius et al. 2009; Raby et al. 2014). These include a large trial among alcohol-dependent outpatients that showed a high placebo response rate and no medication effect on mood or substance use outcome, despite patients being diagnosed with independent major depression using the PRISM. Other more recent trials have also been positive, at least in showing a beneficial effect of antidepressant medication on mood outcome (Hernandez-Avila et al. 2004; McDowell et al. 2005; Riggs et al. 2007).

117.4.1.2 Placebo Response and Other Factors Associated with Response to Antidepressants

A striking finding from the antidepressant trials is the wide variation in placebo response among studies, which varies from 20 % to more than 70 %, and the strong relationship between placebo response and study outcome. Studies with low placebo response tended to show beneficial effects of antidepressant medication on mood and substance use outcome, while studies with high placebo response showed no benefits of medication, a pattern observed in the original meta-analysis (Nunes and Levin 2004) and evident in the more recent studies (Gual et al. 2003; Kranzler et al. 2006; Cornelius et al. 2009; Raby et al. 2014; Hernandez-Avila et al. 2004; McDowell et al. 2005; Riggs et al. 2007). Several other study features were also found to be related to low placebo response and to benefit of medication, including

Table 117.1 Factors associated with low placebo response and beneficial effect of antidepressant medication in placebo-controlled trials among depressed, substance-dependent patients

Factor associated with low placebo response and medication efficacy	Potential mechanism	Implications for clinical management
Abstinence established before diagnosing depression	Withdrawal effects and substance-induced depression resolve with abstinence, leaving independent depressions more likely to benefit from medication	Initiate treatment with hospitalization for severely ill patients or evidence-based psychosocial treatment (e.g., cognitive behavioral relapse prevention). Some depression will resolve. Depression that persists should be considered for antidepressant medication
Diagnosis of a depressive disorder, rather than merely depressive symptoms	Depressive symptoms are more likely to represent withdrawal effects or be substance induced	Base diagnosis of depression on careful clinical history and application of DSM-IV/DSM-5 criteria for independent or substance-induced depression
Noradrenergic or mixed-mechanism antidepressants	Less evidence of efficacy for serotonin reuptake inhibitors (SRI) among substance-dependent patients may relate to the study samples (high placebo response) rather than lack of efficacy. However, several trials suggest SRI makes drinking worse among early onset alcoholics	SRIs may still be considered the first-line treatment based on their good safety and tolerability, but consider switching to a noradrenergic or mixed-mechanism medication (e.g., venlafaxine, duloxetine, mirtazapine, nefazodone) if non-responsive to SRI
Concurrent manual-guided behavioral intervention	Behavioral interventions for substance use disorders (e.g., cognitive behavioral relapse prevention) typically contain elements likely to help with depression (e.g., support, coping skills)	Initiate psychosocial treatment for the substance use disorder as a first step

(a) diagnosis of depression after abstinence has been established, particularly enforced abstinence on an inpatient unit; (b) diagnosis of a depressive disorder, as opposed to merely depressive symptoms; (c) noradrenergic or mixed-mechanism antidepressants (serotonin reuptake inhibitors have shown little evidence of efficacy); and (d) concurrent manual-guided psychosocial intervention (psychosocial interventions were associated with high placebo response and absence of benefit of medication). These are described further in Table 117.1 along with their possible mechanisms and implications for clinical practice.

The phenomenon of high placebo response is not surprising, given the evidence from the wider literature on treatment of depression, which shows cognitive

behavioral and other psychosocial interventions to be effective and shows high placebo response, particularly among patients with only mild to moderate depressive symptoms. Generally, the level of severity of depression in clinical trials needs to be high (severe) before there is consistent evidence that antidepressant medication is superior to placebo (Fournier et al. 2010). For the treatment of substance-dependent patients with depression, then, a reasonable first step is to initiate treatment for the substance use disorder. For more severely depressed or substance-dependent patients, hospitalization may be needed to induce abstinence. Or, on an outpatient basis, evidence-based behavioral treatment for the addiction can be offered. If the depression fails to respond once addiction treatment is initiated, then specific antidepressant treatment should be considered.

117.4.1.3 Behavioral Treatments

As noted above, manual-guided psychosocial treatments for substance use disorders are associated with high placebo response rates in the antidepressant medication trials, suggesting these interventions have some efficacy at treating depression in this population. Some controlled trials have examined cognitive behavioral treatments for depression among substance-dependent patients, with some evidence of efficacy (Brown et al. 1997, 2001; Patten et al. 1998; Carpenter et al. 2006, 2008; Daughters et al. 2008; Hides et al. 2010). Psychosocial and behavioral treatments have solid evidence of efficacy for treatment of mood and anxiety disorders, and their use avoids risks of drug interactions that may be of concern when prescribing antidepressant medications to substance-dependent patients. Thus, such behavioral interventions may be considered as a first step, prior to medication, particularly when the severity of depression is in the mild to moderate range.

117.4.1.4 Treatment of the Substance Use Disorder

Again, it bears emphasizing that when a patient presents with combined substance use and mood disorders, treatment should begin by identifying the substance as problem and initiating treatment for the substance use disorder. This could range from brief motivational intervention to a more formal treatment regimen. Successful treatment of the substance use disorder, with resultant reduction in substance use or abstinence, eliminates the toxic effects the substance may likely be having on the nervous system and is likely to improve or even eliminate symptoms of depression (Brown and Schuckit 1988; Weddington et al. 1990; Strain et al. 1991; Satel et al. 1991; Brown et al. 1995; Liappas et al. 2002). That said, when a depressive disorder persists after initiation of treatment for the addiction, specific antidepressant treatment, either behavioral, medication, or a combination of the two, should be initiated.

117.4.1.5 Combined Medications for Depression and Substance Use

There have been a few studies of medications for treatment of addictions, such as disulfiram and naltrexone (Petrakis et al. 2005, 2007), buprenorphine, or methadone (Strain et al. 1991; Nunes et al. 1998), among patients with substance and mood or

anxiety disorders or symptoms. These studies suggest such medications are at least well tolerated and potentially effective at improving mood symptoms, probably because they are effective in reducing or eliminating substance use.

One innovative study examined the combination of sertraline and naltrexone for alcohol-dependent patients with depression, finding the combination superior to either medication alone or placebo (Pettinati et al. 2010). Medications for treating substance use disorders are generally underutilized and should be always considered as part of treatment planning generally, as well as specific treatment planning for patients with combined mood and substance use disorders.

117.4.2 Bipolar Disorders

Thorough reviews of medication treatments of bipolar disorder can be found in published reviews elsewhere (Suppes et al. 2005; Thase 2007), and treatment of bipolar disorders in the setting of substance use disorders is covered in detail in a separate chapter of this text. Briefly, lithium, anticonvulsants (e.g., valproate, carbamazepine, lamotrigine), and neuroleptics (particularly second-generation agents such as quetiapine, risperidone, and aripiprazole) are the mainstays of treatment for bipolar disorder. Among these, lithium (Geller et al. 1998) and valproate (Salloum et al. 2005) have been tested in controlled trials and found effective for patients with co-occurring bipolar and substance use disorders. Despite the typical predominance of depressive symptoms and syndromes among bipolar patients, antidepressant medications are often ineffective or even counterproductive among bipolar patients. This again highlights the importance of making the differential diagnosis between bipolar and depressive disorders with the clinical history.

Behavioral treatments can also be helpful as adjuncts to medication treatment for bipolar disorder by building treatment alliance, medication adherence, and coping skills (Craighead and Miklowitz 2000; Scott and Gutierrez 2004). Weiss and colleagues have developed a group behavioral treatment for patients with combined bipolar and substance use disorders, integrated group therapy (IGT), which has shown evidence of efficacy in a series of controlled trials (Weiss 2004; Weiss et al. 2007, 2009; Weiss and Connery 2011). Interestingly, among its key features, IGT encourages patients to think of their combined mood and substance problems as a single disorder ("bipolar substance abuse"). This stands in contrast to the DSM approach, reviewed above, which involves establishing separate mood and substance use disorder diagnoses. It suggests that a co-occurring mood and substance use disorder may be more than the sum of the separate diagnoses and best treated in an integrated fashion.

117.5 Conclusion

As we hope this chapter has illustrated, considerable evidence has accumulated that mood disorders can be distinguished from substance-related syndromes and

effectively treated, through a careful clinical history, and longitudinal observation of the response of mood symptoms and substance use as treatment is implemented. A guideline exists for the differential diagnosis of independent versus substance-induced mood disorders versus intoxication or withdrawal effects of substances, based on DSM-IV/DSM-5 criteria. In all cases, it makes sense to initiate treatment of the substance use disorder as a first step. Substance-induced depression, and even cases that meet criteria for an independent depressive disorder, may respond to behavioral treatment for the substance use disorder. However, for cases that do not respond, specific antidepressant treatment should be considered – either medication or behavioral treatment or both. It has been shown that many cases of substance-induced depression, particularly if a full major depressive syndrome is present, will be observed to persist during abstinence over follow-up, thus converting to independent depression. For clear-cut or severe cases of major depression, initiation of antidepressant treatment may be considered concurrent with substance abuse treatment from the outset. A careful search of the history should be conducted for episodes of mania or hypomania, indicating the presence of bipolar disorder. Bipolar disorder should generally be treated with mood-stabilizing medications concurrent with the initiation of treatment for the substance use disorder.

In the treatment of mood disorders, the variety of treatment options has led to the development of and testing of treatment algorithms that outline potential sequences of treatments to be followed depending on the response to prior treatments (Crismon et al. 1999; Trivedi et al. 2004; Davis et al. 2007). The various treatment options for co-occurring substance and mood disorders (behavioral and medication treatments for substance use disorders, medication and behavioral treatments for mood disorders) suggest that similar algorithms might be developed and tested.

Abstract

Several studies have provided evidence that patients with bipolar disorder (BD) show high prevalence of a comorbid substance use disorder (47–60 %) (SUD). The cause of the high comorbidity rate between BD and SUD has not been clearly established; the relationship is probably bidirectional. This combination of entities is characterized by frequent relapses, suicide attempts, elevated impulsivity, and greater frequency of rapid cycles, more severe picture, complicated diagnosis, poor adherence, and poor response to treatment. Patients who suffer this dual diagnosis have worse clinical course. The substances that were most frequently associated to SUD were alcohol, nicotine, and cocaine. Patients with BD should be warned about the risk of developing an SUD and about the importance of its early detection. Different pharmacotherapies have been studied in open and non-blind studies and in small groups and in same well-controlled trials in which patients whose mood disorder had been stabilized were treated with a double-blind medication. In these studies, adding a medication to reduce substance use to a pharmacotherapy for treating bipolar disorder did not consistently reduce substance use in this patient group. Antiseizure agents are profiled as the most promising treatments. In addition, there is an increase in the use of atypical antipsychotics, although there are few double-blind, controlled studies and the role of the adjuvant therapy for SUD must still be evaluated.

118.1 Introduction

Psychiatric disorders and substance use disorders (SUD) commonly co-occur. The term dual diagnosis or dual pathology is commonly used to refer to the concomitant presentation of a SUD and another mental disorder (Szerman et al. 2013). There is a high prevalence of dual disorders in drug-dependent patients seeking treatment, (Szerman Bolotner et al. 2011; Roncero et al. 2011; Szerman et al. 2012).

The prevalence of bipolar disorders (BD), using the most extensive definition of this disease (bipolar spectrum), would be between 5 % and 7 % of the general population (Akiskal et al. 2000). In relationship with the dual diagnosis associated to this disorder, it has already been described in several studies. Population-based studies have provided documentation that patients with bipolar disorder show the highest prevalence of comorbid SUD. Bipolar I subjects appear to have higher rates of these comorbid conditions than bipolar II subjects (Chengappa et al. 2000).

In the Epidemiologic Catchment Area Survey (ECA), 60.7 % of the subjects with type I bipolar disorder had a comorbid SUD. This percentage exceeds that of any other psychiatric disorder, including type II bipolar disorder that also has an equally high comorbidity (Regier et al. 1990), and is only exceeded by antisocial personality disorder. These comorbidity rates significantly increase if the most benign and mild cases of BD or cyclothymic disorder that often occur subclinically or with subthreshold symptoms are taken into account.

In the National Epidemiologic Survey on Alcoholism and Related Conditions, which surveyed 43,093 people in 2001 and 2002 (Hasin et al. 2007), and in and the National Comorbidity Survey Replication, which surveyed 9,282 people in 2001 and 2003 (Kessler et al. 2005; Merikangas et al. 2007), comorbidity of mental disorders and SUD was evaluated. The lifetime prevalence of bipolar spectrum disorders (bipolar I and II disorders and subthreshold bipolar disorder) is estimated to be approximately 4.4 %. Based on distributions of age at onset, the projected lifetime risk at age 75 is higher, with estimates of 5.1 % for bipolar I and II disorders. Comorbidity of these disorders with SUD is substantially greater. The lifetime prevalence rate of any BD and any substance use disorder is 47.3 % and for bipolar I disorder and any substance use disorder is 60.3 %.

118.2 Clinical Features

The cause of the high comorbidity rate between BD and SUD has not been clearly established; the relationship is probably bidirectional (Tohen et al. 1998) and based on neurobiological facts (Szerman et al. 2013). A different hypothesis has been proposed, among which impulsivity, considered by different authors as an underlying psychopathology dimension in all the periods of bipolar disease (Swann et al. 2001), is one of the most relevant. Impulsivity is also identified as a primordial factor in SUD. Furthermore, both disorders, BD and SUD, could represent manifestations of a single genetic diathesis (Winokur et al. 1995). Other explanation for this dual disorder is the "self-medication hypothesis", which states that some patients experience improvement in psychiatric symptoms as a result of substance use (Weiss et al. 2004).

BD may occur, and in fact often do, comorbidly with SUD and are generally, in the clinical practice, considered, diagnosed, and treated exclusively as substance abuse or dependence, overlooking the presence of the affective disorder, which reduces diagnostic and therapeutic possibilities (Merikangas et al. 2007). This indicates why it has clinical and health care importance.

Clinical management of this patient has been described as a highly complicated process (Roncero et al. 2009) (Table 118.1). Patients who suffer this dual diagnosis have worse clinical course; tend to have greater chronicity of both comorbid disorders (Kranzler et al. 1996; Goldberg et al. 1999); have symptoms that are

Table 118.1 Clinical features in dual-bipolar patients

Clinical	Greater chronicity
	Risk suicide
	Greater frequency of rapid cycles
	More severe picture
Treatment	Complicated diagnosis
	Poor adherence
	Difficult managing
	Greater frequency of hospitalization

more difficult to treat, such as those of the mixed affective type; and finally have greater frequency of rapid cycles and hospitalization (Casas et al. 2008). On the other hand, these patients have an increased risk of suicide during their lifetime in comparison with BD patients without substance abuse or dependence (39.5 % versus 23.8 %, respectively) (Dalton et al. 2003).

The presence of comorbid SUD makes it difficult to achieve clinical stabilization of the bipolar patient and also significantly worsens their global functioning (Weiss et al. 2005). Patients who present BD and SUD comorbidly develop a more severe picture (with anxiety, mixed or dysphoric mania, and rapid cycles) than patients who only have BD (Feinman and Dunner 1996). Regarding the severity of the symptoms, BD is less severe in patients who begin with alcohol abuse or dependence and then develop BD than in those who begin with BD. In addition, the former tend to recover faster (Winokur et al. 1995; Strakowski et al. 2005).

Patients with BD should be warned about the risk of developing an SUD and about the importance of its early detection (Brady and Sonne 1995; Casas et al. 2008). Prevention and treatment of the substance use disorder is especially indicated for patients with an early age at onset of a BD (Pettinati et al. 2013).

Gender differences have been studied in dual-bipolar disorders. More symptoms and episodes of depression have been reported among women; however, there is no conclusive evidence for gender differences. Further studies should be made (Miquel et al. 2011).

The substances that were most frequently associated to SUD were alcohol, nicotine, and cocaine (Casas et al. 2008). Drug use in depressed or manic episode was studied by Maremmani and cols. who described that stimulant use was more prevalent during the "up" rather than the "down" phase of the illness. As well, patients with a depressive episode more frequently used nonprescribed anxiolytic-hypnotics. Bipolar patients were found to use cocaine-amphetamines more frequently during a hypomanic episode, whereas the use of cannabis and cocaine-amphetamines occurred more frequently during a manic episode. The associated use of alcohol, cocaine-amphetamines and cannabinoids was more frequently encountered during a mixed episode (Maremmani et al. 2012).

118.2.1 Diagnosis

Diagnosis of dual-bipolar patients is a very complex process. As it is known, use of certain stimulant substances may cause symptoms that are not differentiated from mania or hypomania during the time that the drug has a pharmacological effect. All the aforementioned facts underscore the importance of an accurate and complete diagnostic evaluation of this dual diagnosis and of performing an individualized treatment, considering all the comorbid disorders, their interrelationships, and prognostic implications (Krishnan 2005) with the final objective of achieving a treatment in these patients that would provide.

Self-administered questionnaires may be a valid instrument for the detection of substance abuse in BD patients (Weiss et al. 1998a). However, BD questionnaires should be used with caution in patients being treated for SUD (Nallet et al. 2013).

For the diagnosis of dual-bipolar patients, the following are recommended (Casas et al. 2008):

- Two weeks may be necessary to rule out the chance of a manic episode in a patient with SUD (with or without background of BD) being induced or provoked by the effect of the drugs, and the evaluation of such episode in patients with BD and SUD should be done using the usual instruments aimed at patients with BD for mania.
- In patients with SUD without a background of BD and who have episodes of depression/mania, the possible previous symptoms of hypomania should be reevaluated since these may have been interpreted as secondary to the SUD.
- Special care must be taken when examining patients with alcohol abuse since this may often mask a diagnosis of concomitant BD.

118.2.2 Treatment

Patients with co-occurring bipolar and SUD are a difficult-to-treat population, and conducting research with this group can be particularly challenging. Integral treatment of the dual patient requires both a psychopharmacological and psychotherapeutic approach. Typically, these patients are treated for either their mood disorder or their SUD before receiving treatment for the other disorder (Nunes et al. 2010). However, the experts recommend that if a concomitant SUD is detected in the common clinical practice, both treatments are administered simultaneously, without giving priority of one over the other (Casas et al. 2008).

In patients with uncontrolled SUD and personal background of BD, hospital admission is frequently required. As well, more frequent visits have been proposed (one every 2 week), and when there is a suicide attempt, admission of the patient is especially recommended (Casas et al. 2008).

118.2.3 Drug Treatment

Overall, findings from the relatively small amount of available data indicate that pharmacotherapy for managing mood symptoms can be effective in patients with SUD, although results have not been consistent across all studies (Pettinati et al. 2013).

There is a paucity of pharmacotherapy research focused exclusively on patients with dual-bipolar disorder. Medication trials have typically excluded individuals with BD with comorbid SUD. In regard to treatment with drug agents, there is abundant bibliography regarding the use of lithium and valproate in dual diagnosis, especially with alcohol abuse. However, patients who were prescribed both lithium

Table 118.2 Double-blind clinical placebo-controlled trials in dual-bipolar patients

Author	Dependence	Add-on treatment	Mood	SUD result
Salloum et al. 2005	Alcohol	Valproate	None	Reduce drinking
Brown et al. 2008	Alcohol	Quetiapine	None	None
Brown et al. 2009	Alcohol	Naltrexone	None	None
Stedman et al. 2010	Alcohol	Quetiapine	Reduction of depressive symptoms	None
Tolliver et al. 2012	Alcohol	Acamprosate	None	None
Brown et al. 2007	Cocaine	Citicoline	None	Reduce cocaine use

and valproate were more likely to report full compliance with valproate than with lithium (Weiss et al. 1998b). Furthermore, in dual-bipolar patients, lithium administration has been reported as a high risk of interactions with opiate agonists and/or treatments for concurrent medical conditions (Roncero et al. 2009). On the other hand, antiepileptics do not induce counter-polar states (depressed patients abruptly turning manic or hypomanic or patients currently hypomanic or manic abruptly turning depressed), so their use among these patients has been proposed (Maremmani et al. 2010). Equally, a literature and series of studies, although with unequal results, are found in relationship to the use of carbamazepine, gabapentin, topiramate, lamotrigine, and atypical antipsychotics, among others. Antidepressant should be prescribed with caution in order to avoid inducing a manic episode. SSRI (always associated with mood stabilizer) could be the more adequate treatment for a depressive episode (Casas et al. 2008).

However, in the last years, at least six principal double-blind placebo-controlled trials published have targeted dual-bipolar adults. Alcohol was the primary substance in five of the six trials, and the remaining study focused on cocaine use. The typical research paradigm for studying pharmacotherapy in these trials was to give a double-blind medication, primarily to treat the SUD after the patient was stabilized on a medication for the BD (Pettinati et al. 2013). Thus, the few published double-blind placebo-controlled trials have "added on" other medications that sometimes were a treatment for BD, valproate (Salloum et al. 2005) or quetiapine (Brown et al. 2008; Stedman et al. 2010) or a medication for treating alcohol dependence (naltrexone (Brown et al. 2009) or acamprosate (Tolliver et al. 2012)) or a nutritional supplement (citicoline (Brown et al. 2007)) (Table 118.2).

Typically, the double-blind clinical trials not only evaluated the medication's efficacy compared with placebo in reducing substance use but also assessed any further reduction in mood symptoms that the double-blind medication might provide beyond any medication patients were taking for their mood disorder. This type of design has its limitations, and it does not allow the flexibility needed to evaluate investigative medications for mood and addiction outcomes independently of other medications the patient is already taking to treat the mood disorder (Pettinati et al. 2013).

Results of the majority of the trials revealed that no additional benefit was achieved in reducing either depressive or manic symptoms. However, failure to show a differential response to depression in bipolar patients should not be surprising given the study design that is being used. Two trials showed a significant reduction in substance use: one using valproate to reduce drinking (Salloum et al. 2008) and the other using citicoline to reduce cocaine use (Brown et al. 2007). There are other trials in which bipolar patients were a minority in the study group or in which outcomes were indistinguishable from those of other types of patients. Although there are few studies of BD with opiate dependence, it has been described that the combination of opiate agonists and mood stabilizers often produces results which are difficult to obtain with the use of the two types of drugs separately (Maremmani et al. 2010).

When only the mood disorder responds to treatment, it is important to determine the effect the SUD may have on the recovery of the mood disorder. Some studies have demonstrated the ill effects on recovery from BD when the SUD goes untreated, while others have not found this to be the case (Pettinati et al. 2013). It is known that BD is less severe in patients who begin with alcohol abuse or dependence and then develop BD than in those who begin with BD (Winokur et al. 1995; Strakowski et al. 2005). The sequence of syndrome emergence and the age at onset of BD may offer some explanation. Age at onset of BD may be the most salient factor in understanding whether or not there will be a negative relationship between mood and substance use symptoms in patients treated for BD (Pettinati et al. 2013).

To summarize, different pharmacotherapies have been studied in open and non-blind studies and in small groups (Casas et al. 2008) and in the same well-controlled trials in which patients whose mood disorder had been stabilized were treated with a double-blind medication. In these studies, adding a medication to reduce substance use to a pharmacotherapy for treating bipolar disorder did not consistently reduce substance use in this patient group.

However, because of the low number of studies conducted and the small sample size of some of these, there is need for extensive controlled studies that include sufficiently large samples of patients of this complex condition.

118.2.4 Rapid Cycling

Rapid cycling is a very frequent situation among dual-bipolar patients, for this reason, some special recommendations should be taken into account (Casas et al. 2008):

- The obligations of adapting the rapid cycling treatment if the SUD presents itself as acute intoxication or abstinence syndrome.
- The best treatment of rapid cycling associated or not to acute intoxication or abstinence syndrome, regardless of the SUD-causing drug, is the atypical antipsychotics and/or antiseizure drugs.

- Regardless of the SUD causing rapid cycling, tricyclic antidepressants are inadequate treatments against a rapid cycling episode associated or not to an acute intoxication or abstinence syndrome.

118.2.5 Psychoeducational or Psychotherapeutics Approach

Psychotherapy with a psychoeducative approach is recommended to achieve better understanding of BD. As well, psychotherapy is considered adequate for the maintenance of abstinence, prevention of relapses, and improvement of drug treatment compliance (Casas et al. 2008). In BD group psychoeducation significantly reduced the number of relapsed patients and the number of recurrences per patient and increased the time to depressive, manic, hypomanic, and mixed recurrences. The number and length of hospitalizations per patient were also lower in patients who received psychoeducation (Colom et al. 2003). Even psychoeducation for caregivers of bipolar patients may improve long-term outcome in terms of time to recurrence. It has been showed the need to introduce psychological interventions early in the course of the illness as some treatments may be more useful in patients at earlier stages of BD (Reinares et al. 2010). In dual-bipolar patients, use/abuse of substances may worsen the BD. If the patient continues using drugs, above all, it should be attempted that he or she continues with the treatment. In this sense, the educative approach and reduction of harm from the SUD are very important (Casas et al. 2008).

Different forms of psychotherapy have been studied. Integrated Group Therapy to patients with BD and SUD has been found to be efficacious in reducing substance use. This was put forward after a pilot study was conducted in patients with this dual diagnosis, in which specific Integral Group Therapy was carried out with significant success in regard to the percentage of patients in abstinence versus those who had not followed an integrated therapy. Consequently, it seems to be a viable alternative to reduce substance abuse in patients with BD (Weiss et al. 2007). However, Integrated Group Therapy's length (20 sessions) and need for highly trained therapists may limit its adoption in substance use disorder community treatment programs. So a briefer (12-session) version of Integrated Group Therapy was compared, led by substance use disorder counselors without previous cognitive-behavioral training or BD experience, to group drug counseling. Analyses of primary outcomes showed trends favoring Integrated Group Therapy, with greater reduction in substance use during follow-up and diminished risk of mood episodes during treatment. Secondary analyses favored Integrated Group Therapy, with a significantly greater likelihood of achieving total abstinence, making it to the first abstinent month quickly and making for a "good clinical outcome" (a composite measure encompassing both substance use and mood simultaneously described by Weiss and cols.). Thus, a shortened version of Integrated Group Therapy can be delivered successfully by substance use disorder counselors, with better overall outcomes than those achieved with group drug counseling (Weiss et al. 2009).

118.3 Conclusion

It is known that BD and comorbid SUDs (dual diagnosis/disorders) are frequently found in the common psychiatric practice. Considering the comorbidity of BD associated to SUD and the few publications existing on it (with reduced sample sizes), efforts should be done to define some action guidelines in the management of this dual diagnosis. However, given the importance and incidence of this dual disorder, it is necessary to continue to study its nosological description in greater depth and also that of the action of its clinical-therapeutic approach (Casas et al. 2008).

This combination of entities is characterized by frequent relapses, suicide attempts, elevated impulsivity, poor adherence, and poor response to treatment. The substances that were most frequently used in BD were alcohol, nicotine, and cocaine. It is important to warm patients with BD about the risk of developing SUD and to stress the importance of early detection and treatment.

Some practical recommendations could be suggested: a visit every 2 weeks and hospital admission for patients with uncontrolled SUD and BD, as well as those with a risk of suicide and that Integral Group Therapy was carried out.

In regard to treatment with drug agents, there is a bibliography regarding the use of lithium and valproate in dual-bipolar patients, especially with alcohol abuse. Equally, a literature and series of studies, although with unequal results, are found in relationship to the use of carbamazepine, gabapentin, topiramate, lamotrigine, and atypical antipsychotics, among others. At least, six published double-blind placebo-controlled trials have targeted dual-bipolar adults, including valproate, quetiapine, acamprosate, naltrexone, and citicoline. However, antiseizure agents are profiled as the most promising treatments. In addition, there is an increase in the use of atypical antipsychotics, although there are few double-blind, controlled studies and the role of the adjuvant therapy for SUD must still be evaluated.

The existence of so many treatment alternatives may be due to the lack of conclusive studies in this disorder. Thus, it is recommendable to conduct prolonged controlled studies that include sufficiently large patient samples in this complex condition. However, it is unlikely that a single therapy will be developed in the near future due to the heterogeneity of patients with BD and SUD. Although it will be possible to identify the most appropriate therapies based on scientific evidence, until then the recommendations including heroin should be updated in future reviews.

Comorbid Anxiety and Alcohol or Substance Use Disorders: An Overview

119

Francesco Bartoli, Daniele Carretta, Massimo Clerici, and Giuseppe Carrà

Contents

Abstract

The comorbidity between anxiety and alcohol or substance use disorders represents a common and serious clinical challenge, characterized by a high worldwide prevalence. The co-occurrence of these disorders complicates treatment, management, and prognosis of both disorders, but it remains often unrecognized and untreated. Mental health professionals should accurately assess and evaluate the comorbidity, although related etiological links and temporal relationships are still unclear and, probably, heterogeneous and multifactorial. Alcohol and substances may be misused by individuals to self-medicate their anxiety, avoidant, and phobic symptoms, but also anxiety disorders may be consequences of alcohol and/or substance misuse. Integrated treatment appears the most promising approach, but there is paucity of evidence on pharmacological and

non-pharmacological treatments addressed to both anxiety and substance use disorders. This chapter provides a comprehensive overview of main epidemiological and clinical issues, etiological/temporal links hypotheses, and treatment options for the comorbidity between anxiety and addictive behaviors.

119.1 Introduction

Comorbid anxiety and alcohol or substance use disorders represent a serious clinical challenge, influencing both treatment and prognosis (Smith and Randall 2012). Clinical evidence demonstrates that people with anxiety disorders, such as social phobia, generalized anxiety, panic, agoraphobia without history of panic, and specific phobia disorders, often misuse alcohol and prescription (e.g., benzodiazepines) and/or illicit drugs (e.g., stimulants or cannabinoids), developing substance abuse or dependence. At the same time, individuals primarily treated for an alcohol or drug use disorder are more likely to suffer from a comorbid anxiety disorder, due to the effect of substances in inducing anxiety symptoms (Pasche 2012).

All clinicians and mental health professionals who care for people with anxiety and substance use disorders should have a comprehensive knowledge of main relevant clinical and epidemiological issues such as:

- Prevalence and correlates of substance use disorders among subjects suffering from anxiety disorders
- Etiological hypotheses and temporal relationships underlying this comorbidity
- Methods to assess this comorbidity and to classify comorbid anxiety and alcohol/substance use disorders, taking mainly into account important changes introduced by the recently released fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) (American Psychiatric Association 2013)
- Specific clinical features, course, and prognosis of people suffering from this comorbidity
- Main evidence on preventive and treatment strategies

In this chapter, we aimed to present a comprehensive overview on these issues, highlighting data derived from research which may be useful to the clinical routine.

119.2 Epidemiological and Clinical Issues

119.2.1 Epidemiology

Comorbid anxiety and alcohol or substance use disorders are highly prevalent both in general and clinical populations (Pasche 2012). Data from the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) on 43,093 adults shows that the 12-month prevalence of any DSM-IV substance use disorder among respondents with a 12 month DSM-IV independent anxiety disorder is 15.0 % (Grant et al. 2004). As regards specific drug use disorders involved, cannabis use was the most common (15.1 %), followed by cocaine (5.4 %), amphetamine (4.8 %),

hallucinogen (3.7 %), opioid (3.2 %), sedative (2.6 %), tranquilizer (2.5 %), and inhalant/solvent (0.6 %) use disorders (Conway et al. 2006). People suffering from any anxiety disorder had an odds ratio (OR) of 1.9 (1.7–2.1) for any substance use disorder and of 1.7 (1.5–2.0) for any alcohol use disorder. The likelihood to develop a dependence syndrome was high with ORs of 2.8 (2.4–3.2) and 2.6 (2.2–3.0) for substance and alcohol dependence, respectively (Grant et al. 2004). Panic disorder with agoraphobia seems to show the strongest association with a co-occurring substance use disorder.

Other relevant data from North American samples are provided by the Mental Health Supplement to the Ontario Health Survey (Gratzer et al. 2004), a Canadian study on 7,195 individuals aged 15–64 years, and interviewed using the World Mental Health Composite International Diagnostic Interview (CIDI). A lifetime alcohol abuse or dependence by diagnostic subgroup was found in 8.7 % of people with any anxiety disorder (OR vs. healthy controls: 3.4; 95 % CI: 1.6–7.1) and in 18.0 % of people with comorbid anxiety and depressive disorders (OR vs. healthy controls: 7.6; 95 % CI: 3.5–16.7).

Relevant epidemiological data are available also from European populations. Data from the French representative sample of the Mental Health in General Population (MHGP) survey (Leray et al. 2011) on 36,105 adults showed a prevalence for alcohol abuse of 7.1 %, 6.5 %, 4.9 %, and 3.6 % among subjects suffering from agoraphobia, panic disorder, social phobia, generalized anxiety disorder, respectively. The results highlighted an OR of 1.7 (1.4–2.0) for alcohol abuse among people with any anxiety disorder. Similar results were found for drug addiction, with a prevalence of 6.5 %, 4.4 %, 3.7 %, and 2.8 % among individuals suffering from panic disorder, social phobia, agoraphobia, and panic disorder, respectively. Drug addiction was significantly associated with the diagnosis of any anxiety disorder, with an overall OR of 2.1 (1.8–2.5).

Baseline data from the Netherlands Study of Depression and Anxiety (NESDA), including 2,329 subjects with lifetime DSM-IV anxiety (social phobia, generalized anxiety disorder, panic disorder, agoraphobia) or depressive disorders and 652 controls, showed a significant association between alcohol dependence and comorbid anxiety disorder (OR: 2.4; 95 % CI: 1.5–3.8) or for an anxiety disorder associated to a depressive disorder (OR: 4.3; 95 % CI: 3.0–6.2) (Boschloo et al. 2011).

Epidemiological data are available also from the National Survey of Mental Health and Well-Being (NSMH&WB) conducted in Australia. This study, involving more than 10,000 adults, showed that the respondents with an alcohol use disorder (abuse or dependence) were three times more likely to suffer from a 12-month anxiety disorder. On the other hand, people suffering from any anxiety disorder had a prevalence of 16.0 % for any past-year alcohol use disorder (Burns and Teesson 2002).

Finally, some relevant epidemiological information is available also from Latin America. For example, a cross-sectional household survey in a sample of 2,302 Brazilian adults from Bahia, Brazil (Almeida-Filho et al. 2007), highlighted a prevalence of comorbid anxiety disorders and alcoholism of 14.4 %, with an OR of 2.7 (1.7–4.2).

Generally, the comorbidity between anxiety and alcohol or substance use disorders appears a worldwide phenomenon, with similar prevalence rates and high and significant risk of co-occurrence as compared with general population.

119.2.2 Etiological Hypotheses and Temporal Relationships

The underlying mechanisms influencing the association between anxiety and alcohol/substance use disorders are unclear because of relevant clinical heterogeneity as different drugs and alcohol may not share identical relationships with different anxiety disorders (Kushner et al. 2000). Three main etiological hypotheses are worth to be mentioned.

First, an anxiety disorder may be a direct predictor of addictive behaviors. This direction of the association is supported by evidence suggesting that some individuals may use alcohol and/or illicit substances to self-medicate their anxiety or depressive symptoms (the "self-medication" hypothesis) (Mueser et al. 1998). For example, alcohol shares many pharmacological effects with sedatives, anxiolytic agents, hypnotics, or anticonvulsants drugs (Lingford-Hughes et al. 2002). Further scientific support for the "self-medication" hypothesis comes from longitudinal studies. Data from the NESARC on 34,653 US adults showed that those who had used alcohol or other drugs for the purpose of reducing their fear, anxiety, or avoidance had a significant risk of incident alcohol or substance dependence, with adjusted ORs of 2.6 (1.0–6.7) and 5.0 (1.7–14.2), respectively (Robinson et al. 2011). However, further findings from NESARC (Martins and Gorelick 2011) did not support the self-medication hypothesis, highlighting that both mood and anxiety disorders may influence the transition from substance use to abuse and/or dependence rather than from abstinence to use. The representative National Comorbidity Survey (NCS) showed that a self-medication intent was present in 21.9 % of individuals with any anxiety disorder, with the highest prevalence (35.6 %) among people with a generalized anxiety disorder (Bolton et al. 2006). More generally, social phobia has been predominantly identified as a primary disorder preceding substance use, though the temporality of other anxiety and substance use disorders is less clear (Pasche 2012).

The second etiological hypothesis posits that alcohol and other substances directly promote the development of anxiety syndromes, in terms of consequences of chronic alcohol/substance use and/or related withdrawal syndromes (Kushner et al. 2000). For example, although alcohol is a fast-acting and effective anxiolytic agent, it can also increase the levels of anxiety, when the consumption is excessive and the subjects develop withdrawal symptoms, which determine a vicious cycle between anxiety and alcohol use (Lingford-Hughes et al. 2002). Another relevant example involves early cannabis exposure that may be related to the subsequent development of an anxiety disorder. A recent study (Degenhardt et al. 2013) on a cohort of 1,756 young Australians recruited in secondary schools showed that the continuity of cannabis use from adolescence to the age of 29 was associated to a risk 3–4 times higher of having a comorbid anxiety disorder. Data from the Netherlands

Mental Health Survey and Incidence Study (NEMESIS), a prospective study on 3,854 adults who had no lifetime anxiety disorders at baseline, highlighted a significant association between baseline cannabis use and 3-year incidence of any anxiety disorder (especially generalized anxiety and panic disorders), after adjusting for age, gender, education, urbanicity, employment, and partner status (van Laar et al. 2007).

Furthermore, the existence of anxiety disorders induced by specific classes of substances, such as alcohol, cannabis, cocaine/other stimulants, opioids, is supported by different neurobiological findings. Recent advances on the complex relationships between stress, anxiety, and alcohol use disorders show that synaptic communication in brain regions regulating stress and anxiety-related behaviors, such as amygdala and bed nucleus of the stria terminalis, is modulated by endogenous factors like dopamine and corticotropin-releasing factor (CRF) as well as by acute and chronic use of alcohol (Silberman et al. 2009). The CRF, a stress-related neuropeptide, has been implicated also in the anxiogenic effects of cocaine withdrawal, as well as in some of long-term effects of cocaine (Erb et al. 2006). Cannabis, mainly through the cannabinoid type 1 (CB1) receptors, can induce biphasic responses on anxiety- and fear-related behaviors. Generally, low doses of cannabis tend to induce anxiolytic-like effects, whereas high doses often cause an increase of anxiety symptoms (Moreira and Wotjak 2010). Finally, as regards heroine, morphine, or other opioids, it should be highlighted that the opioid system seems to play a key role in the neural modulation of anxiety. The activation of opioid system leads to anxiolytic effects both in healthy subjects and in individuals suffering from anxiety disorders since the opioid neurotransmission may serve as an adaptive mechanism addressed to blunt acute negative and distressing affective responses (Colasanti et al. 2011). At the same time, blockade or downregulation of opioid systems and second messengers is associated with the occurrence of severe anxiety, similar to opiate withdrawal (Colasanti et al. 2011).

Finally, there may be an independent mediator explaining the relationship between anxiety and alcohol/substance use disorders rather than a direct causal association. Generally, studies on the common-factor models for anxiety and substance use disorders are limited, and publications directly addressing this topic are sparse (Smith and Randall 2012) and focused on alcohol use disorders. Anxiety and alcohol or substance use disorders may share genetic and environmental factors, such as a disruptive family environment and parental abuse or neglect (Kushner et al. 2000). Especially among women, a childhood traumatic event might be at least partially responsible for the association between these two disorders (Marquenie et al. 2007). Mediators of the relationship between anxiety disorders and addictive behaviors may be also some personality traits characterized by a high level of anxiety sensitivity (Smith and Randall 2012). Individuals with increased levels of sensitivity to anxiety, and who do not have a diagnosable anxiety disorder, may be more likely to develop both anxiety and alcohol or substance use disorders. Furthermore, it has been investigated whether some molecular mechanisms could represent the common factor between anxiety and alcohol/substance use disorders. For example, it has been hypothesized that a decreased function of cAMP response

element-binding protein (CREB) in the central nucleus of the amygdala might regulate both anxiety and alcohol intake via the reduced expression of neuropeptide Y (NPY) and, therefore, might provide a common link between anxiety and alcohol use disorders (Pandey 2003).

119.2.3 Diagnosis and Classification

Anxiety disorders among people suffering from substance use disorders, as well as alcohol or drug addictive behaviors among people with an anxiety disorder, remain often unrecognized and, consequently, untreated. Despite scientific background of this comorbidity is mainly based on DSM-IV-TR criteria (American Psychiatric Association 2000), future diagnostic issues should necessarily take into account modifications approved by the recently released DSM-5 (American Psychiatric Association 2013). As regards anxiety disorders, these no longer include neither obsessive-compulsive disorder (now in the "obsessive-compulsive and related disorders" chapter) nor posttraumatic and acute stress disorders (included in the "trauma- and stressor-related disorders" chapter). At the same time, DSM-5 includes several changes in criteria of the new chapter "Substance-Related and Addictive Disorders," such as the exclusion of the abuse/dependence dichotomy, the introduction of craving as a diagnostic criterion, and the dimensional classification of alcohol and substance use disorders. However, no studies on vulnerable populations, such as those suffering from psychiatric disorders, are still available.

Actually, all subjects suffering from any anxiety disorders should be screened for alcohol or substance use disorders at the initial assessment. Early diagnosis and treatment can improve consistently course, prognosis, and treatment outcomes of both disorders. However, often it is difficult to ascertain the diagnosis and to assess whether anxiety symptoms are alcohol or substance induced or represent signs of an independent anxiety disorder (Smith and Randall 2012). Because of the overlapping of symptoms, a detailed interview is often a step needed to fully differentiate symptoms, which should resolve with abstinence, from anxiety and alcohol/substances use disorders. Therefore, it is important to carefully assess not only symptoms but also distinct diagnoses and clinical syndromes using structured diagnostic interviews, such as SCID (Structured Clinical Interview for DSM Disorders) (First et al. 2002), CIDI (Composite International Diagnostic Interview) (Robins et al. 1988), or MINI (Mini-International Neuropsychiatric Interview) (Sheehan et al. 1998). The Psychiatric Research Interview for Substance and Mental Disorders (PRISM) is a semistructured diagnostic interview, designed to maximize reliability and validity in alcohol, drug, and co-occurring disorders, individuals with a good reliability for many psychiatric diagnoses, including substance use and some anxiety disorders (Hasin et al. 1996).

Observing symptoms over a sustained period of abstinence may represent the best way to differentiate substance-induced from independent anxiety disorders. Anxiety may return to baseline levels after the period of withdrawal, so clinicians

should always reevaluate and reassess clinical features after 2–3 weeks of abstinence (Lingford-Hughes et al. 2002). The minimum duration of abstinence to establish the presence of an independent or substance-induced anxiety disorder is heterogeneous and based on half-life of involved drugs. For example, some benzodiazepines or methadone may require several weeks of abstinence to exclude a secondary anxiety disorder, whereas alcohol or cocaine necessitates shorter periods of abstinence to make valid diagnoses (Back and Brady 2008).

In order to diagnose a primary, and not substance-induced, psychiatric disorder, clinicians should verify whether (a) the onset of symptoms occurred before the substance use disorder, (b) the symptoms persist after a period of abstinence according to the characteristics of withdrawal course of each substance, and (c) symptoms exceed those produced by the specific misused substance. On the other hand, clinicians should suspect a secondary anxiety disorder if (a) the anxiety syndrome develops only during periods of active alcohol or substance misuse, (b) the symptoms are well-matched with specific symptoms of intoxication or withdrawal of the involved substance, and (c) the age at onset is atypical for a primary anxiety disorder.

A significant amount of alcohol and substance use screening tools are available and may be helpful to detect potential disorders. For example, the ASSIST (Alcohol, Smoking and Substance Involvement Screening Test), developed for the World Health Organization (WHO), is used to detect substance use and related problems in primary and general medical care settings (Humeniuk et al. 2008). As regards alcohol use disorders, AUDIT (Alcohol Use Disorders Identification Test) (Saunders et al. 1993) is probably the most widely used screening tool. Relatively recent data from the NESDA (Boschloo et al. 2010), including 1,756 individuals suffering from a past-year depressive and/or anxiety disorder, showed that AUDIT accurately detected alcohol dependence in depressed and/or anxious men and women, as compared to the gold standard of a CIDI-based diagnosis. However, the overall accuracy in detecting alcohol abuse was limited, without appropriate and identifiable cutoff scores for sensitivity and specificity.

The Addiction Severity Index (ASI) is a multidimensional and semistructured interview used to measure substance use severity, health-related outcomes, and social problems in individuals suffering from alcohol and other drug use disorders, both at admission to treatment and at follow-up (McLellan et al. 2006). The ASI can be used appropriately for screening of anxiety disorders, since the clusters of psychological composite scores are significantly related to a current psychiatric diagnosis, especially depressive and anxiety disorders (Dixon et al. 1996). Therefore, this instrument may be useful for both evaluation of the substance use severity and screening of patients who need an additional evaluation or treatment for their comorbid psychiatric disorder.

However, psychometric scales and diagnostic interviews need to be always integrated with all other information sources useful to assess and differentiate primary and secondary anxiety disorders. Laboratory data, age of onset of anxiety and substance disorders, collateral information, and a family history for anxiety and/or substance use disorder should be accurately collected.

119.2.4 Clinical Features, Course, and Prognosis

According to a recently published systematic review (Whiteford et al. 2013), anxiety, illicit drug, and alcohol use disorders accounted, respectively, for 14.6 %, 10.9 %, and 9.6 % of overall disability-adjusted life years (DALYs) caused by mental and substance use disorders.

The comorbidity between anxiety and substance use disorders makes difficult treatment and management of both disorders, with mutual negative effects. Individuals with an alcohol use and co-occurring anxiety disorders are significantly more disabled and use health services more than individuals without this comorbidity (Burns and Teesson 2002). Furthermore, subjects with comorbid generalized anxiety and substance use disorders are more likely than those with a generalized anxiety disorder only to have a lifetime history of any psychiatric disorder, pathological gambling, and an antisocial personality disorder (Alegría et al. 2010). A severe current alcohol dependence represents an important risk factor for unfavorable course of depressive and/or anxiety disorders, with persistent and unremitted symptoms (Boschloo et al. 2012a). The relationship is bidirectional, since the severity of depressive/anxiety symptoms is an additional independent predictor of the recurrence of an alcohol dependence (Boschloo et al. 2012b). A recent study (Magidson et al. 2012) compares substance users with and without a comorbid generalized anxiety disorder. The results showed that the co-occurring generalized anxiety disorder had a significant impact for what concerns a worse health-related quality of life, higher rates of treatment seeking, and greater self-reported drug use at follow up, supporting the need to define specific treatment options for this clinical population. Similar results were found from the National Comorbidity Survey (NCS) in a variety of clinical domains, such as rates of health-care utilization, additional psychiatric diagnoses, physical health problems, and interpersonal stress. Among most of comorbid individuals, social anxiety disorder onset predated that of alcohol dependence, with the former increasing the vulnerability for misusing alcohol (Buckner et al. 2008).

Anxiety disorders are well-known conditions associated to suicidal behaviors. Patients with anxiety disorders are 3.0–3.5 times more likely to complete suicide, 2.5–3.0 times to have suicidal ideations, and 2.5 times to attempt suicide (Kanwar et al. 2013). A comorbidity for an alcohol or a substance use disorder may consistently increase this risk. Findings from NESARC study (Nepon et al. 2010) highlighted that individuals with both substance use and any anxiety disorder had an OR of 3.2 (2.4–4.3) for suicide attempts as compared with people without these psychiatric conditions. Furthermore, substance users with co-occurring anxiety disorders showed a significant higher risk ($OR = 1.6$; 95 % CI: 1.3–2.0) of suicide attempts than those without this comorbidity.

All these findings support the need of further research on innovative intervention strategies to optimally treat co-occurring anxiety and substance use disorders and to prevent clinically severe consequences.

119.2.5 Treatment and Management

Although several pharmacological and psychological treatments such as cognitive-behavioral therapy have been studied for treatment of anxiety disorders, there is a paucity of evidence on effective treatments for the comorbidity with alcohol or substance use disorders. Furthermore, relevant management is complicated because of different patterns of anxiety and substance use disorders may interact, making difficult to generalize results (Watkins et al. 2005). New research directions for treatment of comorbid anxiety and substance use disorders are actually needed and should be focused on (a) identification of specific comorbid relationships between these disorders and their underlying processes (e.g., anxiety sensitivity), (b) mechanisms that may maintain the comorbidity, and (c) well-conducted evaluations of treatments that target these mechanisms (Baillie et al. 2010).

Treatment of co-occurring anxiety and alcohol or substance use disorders can be oriented either by dealing primarily with one of the two disorders (generally the more compelling in terms of severity) or, alternatively, by addressing these together. Over the past several decades, empirical studies and clinical guideline recommendations have undergone a broad shift in approaching this comorbidity, highlighting the importance to provide simultaneous and integrated treatment for both disorders, regardless of the status of the comorbid condition (Watkins et al. 2005). However, research conducted in this field has yielded inconsistent results, with some studies demonstrating no clear advantage for the simultaneous treatment of anxiety disorders and addictive behaviors (Pasche 2012). For example, a relatively recent meta-analysis (Hobbs et al. 2011) suggests that, due to the potential serious consequences of unsuccessful treatment for alcohol use disorders, an integration with interventions addressing co-occurring anxiety disorders could be important, even if the amount of absolute benefit is moderate or even smaller. Inconclusive results were shown also by a systematic review (Hesse 2009) analyzing integrated psychosocial treatment for substance use and comorbid anxiety or depressive disorders, as, though promising, these did not give any significant additional benefit. Generally, a potentially effective strategy may be the early treatment of the disorder the patient is ready to address, while, simultaneously, a motivational approach may be used to improve readiness to change the comorbid problem (Smith and Book 2008).

At the same time, there is a lack of consistent evidence for effective pharmacological interventions for both anxiety and substance use disorders, whereas only sporadic intervention studies are available from the scientific literature, e.g., for alcohol use disorders. Selective serotonin reuptake inhibitors (SSRIs) seem effective in reducing and preventing anxiety symptoms, but there is a lack of clinical trials assessing their efficacy in comorbid patients. In a small placebo-controlled trial (Randall et al. 2001) on 15 outpatients with an alcohol dependence and social phobia, the paroxetine-treated group showed significantly lower symptoms on Clinical Global Index (CGI) and the Liebowitz Social Anxiety Scale, as compared with the placebo group, but there was a nonsignificant effect on quantity/frequency

measures of drinking. Studies on Buspirone, a partial 5-hydroxytryptamine 1A agonist, have shown mixed results on comorbid generalized anxiety and alcohol use disorders (Back and Brady 2008). Although benzodiazepines are effective in the treatment of anxiety disorders, their use in individuals with current or lifetime alcohol or substance use disorders may be complicated by their potential for abuse and dependence. More generally, although the use of medications for comorbid psychiatric disorder is encouraged, evidence is inconclusive whether there is the need of full detoxification before starting psychopharmacological treatment (Watkins et al. 2005).

Finally, use of agents specifically addressed to substance use disorders in individuals suffering from comorbid anxiety disorders is underexplored (Back and Brady 2008). In one randomized study conducted at three Veterans Administration outpatient clinics on 254 patients with an axis I psychiatric disorder and alcohol dependence, the efficacy of disulfiram and naltrexone, or their combination, was investigated. Subjects treated with an active medication showed more consecutive weeks of abstinence and less symptoms of craving than those treated with placebo, but there were no significant differences in other measures of alcohol consumption. Furthermore, subjects treated with disulfiram experienced significantly fewer obsessive-compulsive and phobic symptoms over time, whereas no clear advantage of combining medications was observed (Petrakis et al. 2005).

A secondary analysis of a study evaluating efficacy of naltrexone 50 mg⁄day in veterans suffering from alcohol dependence showed that among subjects taking antidepressant medications for mood and anxiety symptoms, those randomized to naltrexone had significantly smaller percent drinking days than those receiving placebo. On the other hand, for patients not on antidepressant medication, the difference between naltrexone and placebo groups was not significant (Krystal et al. 2008).

119.3 Conclusion

The dual diagnosis between anxiety and co-occurring alcohol or substance use disorders is a common but serious clinical problem. This comorbidity tends to complicate treatment, management, and prognosis of both disorders. Clinicians face a number of heterogeneous combinations of anxiety and substance use disorders. The prevalence of alcohol or substance use disorders among subjects with anxiety disorders is high worldwide. Etiological links and temporal relationships of this comorbidity are still unclear and, probably, multifactorial. Alcohol and substance may be misused by individuals in order to self-medicate their anxiety, avoidant, and phobic symptoms, though this remains often unrecognized and untreated. Clinicians should assess this comorbidity using structured diagnostic interviews and observing symptoms over a sustained period of abstinence to differentiate substance-induced from independent anxiety disorders. A comprehensive diagnostic assessment should include also several alcohol and substance use screening tools, such as ASI, ASSIST, and AUDIT questionnaires. While some pharmacological and psychosocial treatments

have shown effectiveness for separate treatment of anxiety and substance use disorders, there is a lack of evidence on treatments addressed to both disorders as dual diagnosis label means more complex needs rather than two distinct problems (Carrà and Clerici 2006).

Abstract

Posttraumatic stress disorder (PTSD) and substance use disorders (SUDs) frequently co-occur. Among individuals seeking treatment for SUDs, approximately 30 % to 50 % meet criteria for lifetime PTSD. Epidemiologic surveys demonstrate that individuals with PTSD have 4-5 times more likely to have a SUD at some point in their lives compared to individuals who do not have PTSD. Self-medication and susceptibility are two hypotheses that have been proposed to help explain the etiological relationship between PTSD and SUDs. It is also possible that common factors, such as genetic, neurobiological, or environmental factors, contribute to the high rate of PTSD-SUD co-occurrence. Integrated psychotherapy approaches for the treatment of patients with both disorders show promise. There are also a number of pharmacotherapeutic agents that have demonstrated preliminary efficacy in the treatment of co-occurring PTSD/SUD, but further investigation is needed. This chapter reviews these and other advances in the study of comorbid PTSD and SUDs, and suggests areas for future work.

120.1 Introduction

Posttraumatic stress disorder (PTSD) is a psychiatric disorder that occurs after exposure to an event (experienced or witnessed) involving actual or threatened death, serious injury, or threat to the physical integrity of oneself or others. The traumatic event must be followed by at least 1 month of symptoms, such as intrusive recollection, avoidance or emotional numbing, and hyperarousal, that interfere with the individual's ability to function. Substance use disorders (SUDs) commonly co-occur with PTSD. Moreover, comorbid PTSD/SUD is associated with a more complex and costly clinical course when compared with either disorder alone, so identification and treatment of both illnesses in individuals with comorbidity is essential to optimize clinical care.

Discussions of international issues in co-occurring PTSD and substance use are complicated by a number of factors. Definitions and experiences of trauma are culturally bound and in many countries can be connected with issues of politics and social justice. There is also debate about the cross-cultural application of the DSM-defined PTSD criteria. Modifications of the DSM criteria and textual modification have been suggested to improve cross-cultural applicability (Hinton and Lewis-Fernandez 2011). Similarly, patterns of substance use and definitions of SUDs also occur in cultural contexts that can tremendously alter the perspectives of acceptable use and willingness to honestly report use. In addition, we do not have accurate estimates of prevalence of either SUDs or PTSD alone or the comorbidity in many areas of the world. So, in the sections that follow, much of the data that is presented is based on studies conducted in a few countries. However, the diagnostic, phenomenologic, and neurobiologic underpinnings of the relationships and treatment options for PTSD and SUDs discussed are likely to apply broadly.

120.2 Epidemiology of PTSD/SUD Comorbidity

120.2.1 United States

Prevalence estimates for PTSD, SUD, and comorbid PTSD/SUD among US adults are primarily garnered from three sources: national epidemiological surveys and Veteran and treatment-seeking populations. Early estimates were provided by the National Comorbidity Survey (NCS; $N = 8{,}098$), conducted from 1990 to 1992, indicated a 7.8 % lifetime prevalence for PTSD and a 26.6 % lifetime prevalence for SUD among the general population (aged 15–54), (Kessler et al. 1994, 1995). Individuals with PTSD were between two and four times more likely to meet criteria for an SUD than those without PTSD. A decade later, the National Comorbidity Survey – Replication (NCS-R; $N = 5{,}692$) indicated a 6.8 % lifetime prevalence of PTSD and 35.3 % lifetime prevalence of any SUD (Kessler et al. 2005; Harvard School of Medicine 2007). More recently, the 2010 National Epidemiologic Survey on Alcohol and Related Conditions (NESARC; $N = 34{,}653$) estimated that 6.4 % of the population met lifetime criteria for PTSD, more than one in five (22.3 %) of those with PTSD met criteria for drug abuse or dependence, and nearly half (46.4 %) met criteria for any SUD (Pietrzak et al. 2011).

Veterans constitute a population of particular interest due to their increased risk for developing both PTSD and SUDs in comparison to the general population (Kang et al. 2003; Hoge et al. 2004; Sabella 2012). Post-deployment prevalence rates have been estimated at approximately 21 % for SUDs and between 15 % and 20 % for PTSD among Veterans of Operation Enduring Freedom/Operation Iraqi Freedom (OEF/OIF) (Hoge et al. 2004; Bray and Hourani 2007; Seal et al. 2007; Thomas et al. 2010). Severity of combat exposure has been directly linked to risk for development and chronicity of PTSD symptoms (Kang et al. 2003) and misuse of substances (Santiago et al. 2010). Administrative data from the Department of Veterans Affairs indicate that among Veterans serving in the Vietnam era or later, almost half (41.4 %) with an SUD were also diagnosed with PTSD (Petrakis et al. 2011). Conversely, a recent study followed a large cohort of Veterans diagnosed with PTSD ($n = 272{,}509$) over a 3-year timeframe and found that nearly one in five (19.33 %) were diagnosed with a comorbid SUD and presence of a comorbid SUD was positively associated with mortality at follow-up (hazards ratio = 1.70; Bohnert et al. 2013).

Treatment-seeking individuals have rates of comorbid PTSD and SUD that are consistently higher than the general population. Patients seeking treatment for PTSD are up to 14 times more likely than patients without PTSD to have an SUD (Jacobsen et al. 2001; Chilcoat and Menard 2003; Ford et al. 2007). Conversely, among patients seeking treatment for SUDs, lifetime PTSD rates range from approximately 30 % to over 60 % (Dansky et al. 1994; Triffleman et al. 1995; Back et al. 2000; Clark et al. 2001; Brady et al. 2004). Finally, a multimodal assessment of comorbidity among patients at a level I trauma surgery center indicated that 79 % had one or more SUD and/or PTSD comorbidity; three in

four (74 %) met criteria for an SUD, whereas one in four patients endorsed symptoms consistent with PTSD (Zatzick et al. 2012). Variations in prevalence estimates among treatment-seeking populations are most likely attributable to methodological differences, including differences in patient populations sampled and measurement techniques.

120.2.2 International Prevalence Estimates

As mentioned above, we do not have accurate prevalence estimates of the rates of either PTSD or SUDs in much of the world. While the World Health Organization (WHO) has sponsored a series of international studies of mental health disorders, the complexity of the trauma questions used, cultural differences in the definition of trauma, and reluctance to discuss traumatic events likely led to underestimates of PTSD prevalence (Kessler and Greenberg 2002). In general, the estimates for lifetime PTSD prevalence range from a low of 0.3 % in China to 6.1 % in New Zealand (Demyttenaere et al. 2004). As might be expected, some evidence suggests that the risk of PTSD is higher among people from less developed countries who have been exposed to prolonged traumatic experiences associated with wars and political and ethnic violence. For example, 65 % of Bosnian refugees resettled in the United States have PTSD (Weine et al. 1995) and 73 % of Palestinian children exposed to war trauma experienced PTSD (Thabet and Vostanis 1999). In a recent WHO survey, disability from common mental and physical disorders was assessed in nationally representative samples from 26 countries (Bruffaerts et al. 2012). While physical disorders were considerably more common than mental disorders, there was more disability associated with mental disorders as compared to physical disorders at an individual level. Of all physical and mental disorders, PTSD was associated with the highest level of disability.

While little is known about the prevalence of PTSD in many countries, even less is known about the prevalence of co-occurring PTSD and SUDs. An epidemiologic survey conducted in Australia in 2007 found that the 12-month prevalence of PTSD was 6.4 %, higher than the prevalence of any other anxiety disorder (National Survey of Mental Health and Wellbeing 2007). SUDs were much more common in individuals with mental illness as compared to those without mental illness, and nearly 40 % of those with anxiety disorders reported daily drug misuse. Data for PTSD specifically was not presented. This suggests that the common co-occurrence of PTSD and SUDs which has been found in the United States may exist in other countries. However, in an investigation of the prevalence of psychiatric disorders in South Africa (Stein et al. 2008), the authors note that local factors such as poverty and lack of access to substances may change the occurrence of certain psychiatric disorders and comorbidities.

120.3 Etiologic Relationship Between PTSD and SUD

120.3.1 Self-Medication Hypothesis

A number of theories have been posited to explain the etiology and functional associations between PTSD and co-occurring SUDs. The most prominent theory is the *self-medication hypothesis* (Khantzian 1985, 1990, 1997; Reed et al. 2007; Menary et al. 2011). According to the self-medication theory, substance use is negatively reinforced when it alleviates PTSD symptoms, such as sleep impairment, intrusive memories, nightmares, hyperarousal, and feelings of estrangement. In support of this theory, Saladin and colleagues (1995) compared individuals with PTSD only vs. PTSD/SUD and found that hyperarousal and avoidance symptoms were more severe among the comorbid PTSD/SUD group. Laboratory-based findings also provide support for the self-medication model. One study examined responsivity to trauma cues (i.e., presentation of personalized trauma narrative) and found that individuals with comorbid PTSD/SUD demonstrate increased craving for substances in response to the trauma cues (Coffey et al. 2002). Moreover, research has shown that trauma cue-elicited craving is significantly reduced following exposure therapy for PTSD (Coffey et al. 2006). Finally, increases in craving have been shown to be positively correlated with severity of PTSD symptoms (Saladin et al. 2003).

Among patients with PTSD/SUDs, the drug of choice (e.g., central nervous system depressant or stimulant) may reflect an attempt to alleviate a particular cluster of symptoms. For example, Saladin et al. (1995) found that PTSD/SUD individuals with more severe hyperarousal symptoms (Criterion D) were more likely to be dependent on alcohol than cocaine. Likewise, PTSD/SUD individuals with more severe avoidance (Criterion C) and flashback symptoms (Criterion B) were more likely to be dependent on cocaine. More recently, Tull and colleagues (2010) observed a significant relationship among PTSD hyperarousal symptoms and dependence on heroin, as opposed to crack/cocaine and alcohol dependence. In addition to self-medication of PTSD symptoms, individuals with PTSD/SUDs may also use substances to self-medication withdrawal symptoms, which may mimic symptoms of PTSD. For example, withdrawal from alcohol or drugs may result in sleep disturbances, difficulty concentrating, irritability and anger, and feeling "on edge." Thus, withdrawal symptoms may contribute to a reinforcing cycle of self-medication among individuals with PTSD/SUD.

Research examining the temporal order of onset of development of PTSD and SUDs also provides some insight with regard to etiology (Najt et al. 2011). In the majority of cases, the development of PTSD precedes the development of the SUD (Chilcoat and Breslau 1998; Compton et al. 2000; Jacobsen et al. 2001; Stewart and Conrod 2003; Back et al. 2005, 2006). Furthermore, PTSD and SUD symptoms have been shown to covary over time. For example, Ouimette and colleagues (2010) tracked weekly fluctuations in PTSD and SUD symptoms among 35 PTSD/SUD outpatients over a 26-week period. The findings provided support

for the self-medication hypothesis and showed that increases in PTSD symptoms were associated with increases in SUD severity. More recently, Simpson and colleagues (2012) used daily interactive voice response (IVR) to examine the relationship between PTSD symptoms and same-day as well as next-day alcohol craving among 29 outpatients entering SUD treatment (26/29 had PTSD). The findings showed that greater PTSD severity was associated with greater alcohol craving and greater hyperarousal symptoms were particularly associated with craving. Next-day craving was predicted by nightmares the previous night, emotional numbing, and hypervigilance. Finally, several studies investigating civilian and Veteran patients' perceptions of the interrelationship of PTSD and SUD symptoms demonstrate support for the self-medication hypothesis (Brown et al. 1998; Back et al. 2006).

The *high-risk hypothesis* (Chilcoat and Breslau 1998; Acierno et al. 1999) posits that the lifestyle of an individual with an SUD increases the likelihood of being exposed to a traumatic event and subsequently developing PTSD. For example, individuals with SUDs often spend time in dangerous environments and engage in high-risk behaviors associated with obtaining or using substances (e.g., prostitution, theft) that may put them at risk for experiencing a Criterion A event. The *susceptibility hypothesis* posits a biological vulnerability to developing PTSD among individuals with SUDs. Individuals who engage in chronic substance use often experience anxiety and arousal and exhibit poor coping skills (e.g., more avoidant or emotion-focused coping vs. problem-focused coping) (Sharkansky et al. 1999; Stewart et al. 2000; Jacobsen et al. 2001; Staiger et al. 2009). Lastly, there is some evidence that other common factors, such as genetics, common neurophysiologic systems, described below, and prior exposure to traumatic events, may play a role in the etiology of comorbid PTSD/SUD (Stewart and Conrod 2008; Kingston and Raghavan 2009; Khoury et al. 2010; Norman et al. 2012).

120.3.2 Neurobiology

A growing body of evidence from basic science and translational studies implicates common neurobiologic pathways and abnormalities involved in anxiety disorders and SUDs. One of the bridging neurobiologic constructs between anxiety disorders and SUDs involves the role of stress. Corticotrophin-releasing factor (CRF), one of the key hormones involved in the stress response, has been implicated in the pathophysiology of anxiety, affective, and addictive disorders. Stress stimuli that activate CRF circuits are also known to potentiate mesolimbic dopaminergic reward pathways in laboratory animals. Similarly, human laboratory studies have shown that emotional stress and negative affect states increase drug craving in drug- and alcohol-dependent individuals. Animal models indicate that early-life stress and chronic stress result in long-term changes in stress responses which can alter the sensitivity of the dopamine system to stress and increase susceptibility to self-administration of substances of abuse. This may provide the neurobiologic underpinnings of the well-established relationship between early-life adversity, PTSD, and SUDs in adolescents and adults (Brady and Sinha 2005).

120.4 Assessment

Symptom assessment is critical to the effective treatment of PTSD/SUD and should ideally encompass detection of trauma exposure and substance misuse, evaluation of diagnostic criteria for PTSD and SUD, and monitoring of symptom severity (Steenkamp et al. 2011; Tucker et al. 2011). Historically, instruments assessing PTSD and SUD were predominantly developed for use with in English-speaking, westernized cultures. However, in 1990, recognizing the need for cross-cultural assessment of mental illness, the World Health Organization (WHO) developed a tool that addressed criteria for both the American Psychiatric Association's Diagnostic and Statistical Manual and the International Classification of Disease (ICD). The resulting Composite International Diagnostic Interview (CIDI; Robins et al. 1989) was a comprehensive, structured, modular interview designed to assess mental disorders – including but not limited to PTSD and SUD. As of 2011, versions of the CIDI have been translated into approximately 25 languages for use in at least 20 countries (WHO 2004). Recognition of the important roles that culture and language play in the conceptualization, experience, and expression of PTSD and SUD is increasing (Westermeyer 1995; Hollifield et al. 2002). As a result, increased efforts have been made to translate and adapt a range of instruments previously validated with English-speaking populations (e.g., Mollica et al. 1992; Westermeyer 1995; Ertl et al. 2010; Ali et al. 2012) as well as to develop culturally specific instruments, to screen, diagnose, and monitor symptoms of PTSD and SUD in a variety of international populations (e.g., Dao et al. 2012; Jayawickreme et al. 2012; Kok et al. 2013).

Regardless of cultural context, there are several general constructs relevant to the assessment of PTSD and SUD. These constructs include determination of the presence, order of onset, frequency, duration, and severity of symptoms, as well as the degree to which symptoms interfere with or impair daily functioning, employment, and interpersonal relationships (for review, see Rodriguez et al. 2012). Several reviews of PTSD assessment (e.g., Hollifield et al. 2002; Elhai et al. 2005; Rodriguez et al. 2012; Wisco et al. 2012), SUD assessment (Westermeyer 1995; Fitch et al. 2004), and PTSD/SUD assessment (e.g., Jacobsen et al. 2001; Jane-Llopis and Matytsina 2006; Najt et al. 2011) are available in the extant literature. When assessing comorbidity, special consideration should be given to the relationships between symptoms, including PTSD symptoms as potential motivators for substance misuse. Validated self-report, semi-structured, and fully structured interview instruments are available to assist with (1) screening for trauma exposure, (2) screening for PTSD/SUD symptoms, (3) determining diagnosis, and (4) monitoring symptom change over time. Table 120.1 presents a sampling of validated measures frequently used in the assessment of PTSD and SUD.

In addition to self-report and interview, biological testing is recommended in assessing SUD and may overcome some of the culture-bound limitations of self-report and clinician-administered assessments. Urine drug screening (UDS) is the most common and preferred method for detecting illicit drug use given that it is cost effective and minimally invasive and provides a quantitative means for measuring the use of substance (Preston et al. 1997; Wolff et al. 1999; Richter and Johnson 2001).

Table 120.1 Assessment and screening instruments

Screening

Inventory of drug-taking situations	Annis and Martin 1985	

Additional biological assessment options exist for use as either adjunctive or alternative assessments of SUD: testing of bodily fluids, such as blood and saliva, breathalyzer analysis for recent alcohol use, hair analysis techniques, and a blood-based testing method known as percent carbohydrate-deficient transferrin (Aithal et al. 1998; Wolff et al. 1999; Arndt 2001). These methods are less frequently used due to higher cost, increased invasiveness, false positives, and/or narrow detection windows (Widdop and Caldwell 1991; Jaffe 1998).

120.4.1 Psychotherapeutic Treatment

Historically, psychosocial treatment approaches for individuals with PTSD and SUDs have adhered to the *sequential treatment model*, in which the SUD is treated first and trauma work is deferred until a period of sustained abstinence (e.g., 3–6 months) has been achieved (Schnitt and Nocks 1984; Nace 1988). This generally entails two separate providers (i.e., one provider addresses SUD and another addresses PTSD) in two separate clinics with little cross-communication. Proponents of the sequential model state that (a) continued substance use will impede therapeutic efforts and/or (b) trauma-focused work may increase risk for relapse (Nace 1988; Pitman et al. 1991). However, there is little empirical data to support these concerns. Given the high co-occurrence of PTSD and SUDs, the covarying interrelationship between PTSD symptoms and substance use severity, as well patients' preferences for treatment (e.g., less than 30 % of patients prefer sequential treatments; Back et al. 2006), recent advances in psychosocial treatments have focused on the development and testing of *integrated treatment models*. In contrast to sequential treatments, integrated treatments are provided by the same clinician and address both the SUD and PTSD concurrently. The integrated model posits that addressing the PTSD symptoms early in treatment will likely improve recovery from SUDs, particularly if substances are being used to self-medicate trauma-related symptoms (Brady et al. 2001; Back 2010; Hien et al. 2010; Mills et al. 2012).

Compelling support for the integrated model is provided by recent investigations examining the temporal course of symptom improvement among PTSD/SUD patients. Among 94 outpatients with alcohol dependence and PTSD, improvements in PTSD symptoms had an impact on improvements in alcohol-dependence symptoms, but decreases in drinking did not impact PTSD symptoms (Back et al. 2006).

Hein and colleagues (2010) replicated these findings using data from a larger sample ($N = 353$) from a National Institute on Drug Abuse (NIDA) Clinical Trials Network (CTN) study. For every unit of PTSD improvement, the odds of being a heavy substance user at follow-up decreased more than fourfold (Hien et al. 2010). A growing body of literature examining the tolerability and efficacy of addressing PTSD among SUD patients demonstrates that substance use typically decreases significantly and does not increase with the addition of trauma-focused interventions (Triffleman 2000; Brady et al. 2001; Najavits et al. 2005; McGovern et al. 2009; Hien et al. 2010; Back et al. 2012; Mills et al. 2012).

Prolonged exposure (PE; Foa et al. 2007) therapy has been deemed one of the most effective treatments available for PTSD (IOM 2008), but there is limited research exploring its efficacy in substance-abusing populations. PE involves having the patient revisit the traumatic memories (i.e., imaginal exposures) and approach safe but anxiety-producing situations in real life that are avoided by the patient (e.g., in vivo exposures). A recent meta-analysis demonstrated large effect sizes for PE in comparison to control conditions (Powers et al. 2010). Furthermore, a longitudinal study conducted among 65 patients 5–10 years after receiving PE demonstrated maintenance of effects with only 17.5 % of patients meeting diagnostic criteria for PTSD (Resick et al. 2012). PE has demonstrated effectiveness in addressing PTSD among a variety of traumatic stress populations, including victims of rape, physical assault, refugees, motor vehicle accidents, combat, terrorism, childhood abuse, and mixed trauma types (Foa et al. 2005; McDonagh et al. 2005; van Minnen and Foa 2006; Bryant et al. 2008; Nacasch et al. 2011; Resick et al. 2012). Despite that fact that PE is one of the most effective treatments for PTSD, the majority of integrated treatment interventions developed to date generally do not include PE components. Rather, treatment tends to focus on psychoeducation, exploring the relationship between PTSD symptoms and substance use, self-management of symptoms and negative emotions, and development of cognitive behavioral coping skills (Miller and Guidry 2001; Ford and Russo 2006; McGovern et al. 2009).

One of the most widely used and investigated integrated treatments to date is *Seeking Safety* (SS), a non-exposure-based 24-session manualized therapy that prioritizes establishing and maintaining safety (Najavits et al. 1998; Hien et al. 2004, 2008). Other key concepts include anticipating dangerous situations, setting boundaries, anger management, and affect regulation. In a study of 107 women comparing SS to relapse prevention (Hien et al. 2004), both treatments resulted in improved substance use and PTSD severity; however, no significant between-group differences in PTSD or SUD symptoms were observed. In a larger national multisite community study, SS was compared to a women's health education (WHE) group (Hien et al. 2009) in 353 women. Both SS and WHE resulted in significantly improved PTSD symptoms; however, neither group resulted in a significant reduction in abstinence rates over time.

More recently, Back and colleagues developed an exposure-based, manualized cognitive behavioral therapy for PTSD/SUDs (Back et al. 2001, 2012) (in press). The treatment, *COPE* (*Co*ncurrent Treatment of PTSD and

Substance Use Disorders Using *P*rolonged *E*xposure), combines evidence-based cognitive behavioral therapy for SUDs (Carroll 1998) with the key components of prolonged exposure for PTSD (Foa et al. 2007), which includes both in vivo and imaginal exposure techniques. COPE was initially trialed as a 16-session, individual intervention and tested in an uncontrolled psychotherapy development study among patients ($N = 39$) presenting with comorbid PTSD and cocaine dependence (Brady et al. 2001). In this study, no signs of increased substance were observed with the inclusion of PE. Treatment completers demonstrated significant improvements in all PTSD symptom clusters and a significant reduction in cocaine use from baseline to end of treatment (Brady et al. 2001). Reductions in PTSD and SUD symptoms were maintained at 6-month follow-up. Mills and colleagues (2012) recently completed a randomized control trial of COPE plus treatment as usual (TAU) vs. TAU alone. Participants were 103 patients (62.1 % female) with civilian PTSD and SUDs in Sydney, Australia. For this trial, COPE consisted of 13, individual sessions. From baseline to 9-month follow-up, significant reductions in PTSD symptom severity were found for both groups; however, the COPE group demonstrated a significantly greater reduction in PTSD symptom severity (mean difference –16.09) and lower rates of PTSD diagnosis as compared to the control group (56.4 % vs. 79.2 %). No significant between-group differences in rates of abstinence, number of SUD dependence criteria met, or retention were found. The findings suggest that integrated PTSD/SUD treatments employing PE techniques for PTSD can be used safely without an increase in substance use, can lead to sustained improvements across various domains (e.g., depression), and produce greater improvements in PTSD than TAU. Currently, COPE is being evaluated as a 12-session intervention in a randomized controlled trial among Veterans, and the preliminary findings are positive (Back et al. 2012). Recently, prolonged exposure has been incorporated into existing residential SUD treatment with promising preliminary results supporting its safety, feasibility, and efficacy (Henslee and Coffey 2010; Berenz et al. 2012).

120.4.2 Pharmacological Treatment

There are relatively few studies of medication treatments for co-occurring PTSD and SUDs. Sertraline, a serotonin reuptake inhibitor with FDA approval for the treatment of PTSD, was investigated in a double-blind, placebo-controlled, 12-week trial (Brady et al. 2005). Individuals with early onset PTSD and less severe alcohol dependence demonstrated improvements in alcohol use severity with sertraline treatment, while individuals with later onset PTSD and more severe alcohol dependence evidenced more favorable alcohol use outcomes when treated with placebo. Petrakis and colleagues (2005) investigated the use of agents targeting alcohol consumption, disulfiram and naltrexone, alone or in combination, in outpatients with alcohol dependence (AD) and a variety of comorbid psychiatric disorders (42.9 % PTSD). Individuals treated with either drug evidenced fewer drinking days

as compared to those on placebo, and those treated with disulfiram reported less craving. Individuals receiving active medication demonstrated greater symptom improvement (e.g., less anxiety) pre- to posttreatment as measured by the Brief Symptom Inventory. No advantage of combining disulfiram and naltrexone was reported. In a more recent study (Petrakis et al. 2011), paroxetine (serotonin reuptake inhibitor) was compared to desipramine (norepinephrine uptake inhibitor) in men with both AD and PTSD. Desipramine was superior to paroxetine with respect to study retention and alcohol use outcomes. Although the serotonin uptake inhibitors are the only FDA-approved medications for the treatment of PTSD, the current study suggests that norepinephrine uptake inhibitors may present clinical advantages. Further investigation of the use of medications as an adjunct to psychotherapeutic treatment in the treatment of co-occurring PTSD and SUDs is needed.

120.5 Conclusion

In summary, while we do not have information about the international prevalence estimates of co-occurring PTSD and SUDs, many studies suggest that these two disorders commonly co-occur. A number of theories have been posited to explain the functional relationship between these disorders, and there are clear neurobiologic connections. Medication treatments have shown some promise, but more investigation is needed. In terms of psychotherapeutic approaches, integrated treatment has been accepted as a safe and effective model of treatment. Although non-trauma-focused treatments offer some PTSD symptom reduction, data suggests that trauma-focused, exposure-based treatment offers greater symptom reduction than non-exposure-based treatment in SU treatment programs. Recent evidence demonstrates that improvement in PTSD positively impacts substance use outcomes, clearly supporting a more rigorous approach to the assessment and treatment of PTSD among patients with SUDs.

A Drug Treatment Program for Young Israeli-Military Veterans

121

Hagit Bonny-Noach and Haim Mell

Contents

Abstract

Over the last two decades, the phenomenon of drug use among Israeli military veteran backpackers in Southeast Asia and South America has become an Israeli problem requiring a social solution. The severe consequences of drug use among the young backpackers can be classified into two types: The first is related to the health consequences. These include mental problems following the use of various drugs. Some of them return from their backpacking trips in a psychotic state in various degrees of severity or other psychiatric conditions like depression or anxiety. The second is related to the law: breaking of local laws, police arrests, and incarcerations.

With the growing need for health promotion and drug use prevention services among backpackers, the Israel Anti-Drug Authority (IADA) established "The Backpackers' Project," focusing on drug use prevention, harm reduction, and unique health services and treatment targeting the young backpackers.

Two unique frameworks have been established with the aim to address this problem: the "Israeli Warm Home," which was established in India, as a collaboration between Israeli and Indian NGOs, in order to provide a first response to those affected by drug use, as well as prevention for those who have not yet been affected by it. The other framework is the establishment of "Kfar Izun" (Harmony Village), an innovative and unique recovery and rehabilitation center for young adults suffering from mental health problems due to the use of drugs, usually during backpacking trips.

121.1 Introduction

The post-army backpacking trip to Southeast Asia and South America has become a significant social phenomenon in the Israeli society over the past 20 years. According to the estimates of the Ministry of Foreign Affairs, close to 50,000 young Israelis go on backpacking trips each year, most of them for a duration between 3 and 12 months. Around 30,000 of them go to the Far East, usually to India (Bonny-Noach and Frish 2008; The Knesset Research and Information Center 2005).

For some young military veteran backpackers, the journey is a kind of "rite of passage," a way to disconnect and escape from the demands of society and a way to challenge themselves and their values (Bonny-Noach 2008a; Cohen 2003; Jacobson 1987; Mevorach 1996; Noy and Cohen 2005; Uriely et al. 2002). In a typical trip, the young backpacker is in a kind of moratorium stage – postponing the responsibilities expected in the adult world (Mevorach 1996) – like academic studies, finding and keeping a job, and building a family. Some develop "antiestablishment" viewpoints and "rebel against their parents'" generation.

Drug use is common among Israeli backpackers. The most commonly used drugs among backpackers are hallucinogens – cannabis products such as marijuana, hashish, Indian charas and hashish oil, hallucinogenic mushrooms, and LSD.

There are two main dangers for Israeli backpackers who use drugs. The first is getting into trouble with the local law, including getting arrested and imprisoned. In most cases they are ignorant of the local law. Sometimes they are sure that drug use is legal or feel that they are "above the local law." The second danger is the mental and physical damage that can occur due to drug use. An estimated 600 backpackers are seriously affected by drug use each year, some of them requiring hospitalization in psychiatric wards (Bonny-Noach 2008a, b; Knesset Research and Information Center 2005).

121.2 Treating Young ISRAELI Military Veterans with Dual-Diagnosis

121.2.1 The Backpackers' Project

The Israel Anti-Drug Authority (IADA) recognized the growing need for unique health promotion and prevention services for backpackers and established "The Backpackers' Project" in 1996, focusing on drug use prevention and harm reduction approach, providing tips for backpackers and information on what to do in case of emergencies. As part of the project, IADA distributed pamphlets containing information about the dangers of drug use. In 2002 IADA published an information booklet about the legal status of drug use in 39 countries that are popular travel destinations (Bonny 2002). In 2008 IADA published the book *Backpackers and Drug Abuse – A Documentary*, *Research*, *Treatment and Prevention Perspective* by Bonny-Noach Hagit. The book includes 26 chapters that portray a fascinating mix of backpackers' description documenting their experiences along with reports from scientific researcher.

In addition workshops organized by IADA for young combat soldiers prior to their release from the military presented the inherent dangers of drug use and its long-term consequences.

121.2.2 Treatment

Three unique frameworks have been established that aim to address the problem of drug use among backpackers.

121.2.3 The "Warm Home" in India

The establishment of the "Israeli warm home" in India is part of the attempt to prevent drug use and to treat young backpackers based on the concept of harm reduction. It serves as a place of meeting for Israeli backpackers and provides a range of activities and services, such as a library for borrowing books, the possibility to record Israeli music and to see movies, Internet and phone services, and other social activities to prevent drug abuse.

In case of emergency, offering immediate aid is a very important step which may significantly influence the likelihood of deterioration or improvement in the patient's condition and the likelihood of them developing mental disorders in the future. Backpackers affected by drug use are afraid of receiving treatment in a foreign place, using public services that do not always meet Western standards. Sometimes young backpackers who are found in a psychotic state are taken care of by their friends, who hide them and do not guide them to the necessary treatment they require.

When needed, they are rescued and brought back to Israel. So far the home has provided a first response to hundreds of backpackers in distress. The home is located in tourist centers, operating half of the year in Manali in the North and the other half of the year in Goa in the South, in accordance with the touring season.

121.2.4 Rescue

The Magnus International Search and Rescue is a private company which works closely with the Israel Anti-Drug Authority. The company locates travelers with whom contact has been lost for various reasons and works to reconnect them with their families, often within hours of receiving a request. When necessary, the company plans and carries out rescue operations at short notice while providing support and consultation for the families at home. A big part of the company's work is in aiding victims of drug use, particularly travelers suffering from drug-induced psychosis. After locating the travelers, they stabilize their condition, calm and reassure them, fly them back home, and guide them to continue treatment and rehabilitation.

121.2.5 Case Study: The Author (Mell) Accompanied a Rescue Operation from India

A few months ago, I accompanied Mr. Magnus (from Magnus International Search and Rescue) on a mission to bring back to Israel from Varanasi (India) a 21-year-old man who was in a psychotic state after massive use of charas (Indian hashish). The young man spoke freely with God, Moses, and Mohammed. He stood next to the Ganges River and threw his equipment and documents into the river as if he were saying goodbye to the world. He was spotted by four backpackers, who took care of him in a guesthouse. Despite not previously knowing him, they felt that it was their duty to help an Israeli in distress, and they contacted his parents. His parents requested our help in bringing him back home. When we arrived at the guesthouse, receiving directions from the four backpackers via their cell phone, they were very suspicious of us. During the 3 days, they took care of him, they identified with his psychosis, and it was harder to convince them than it was to convince the patient himself that we must take him with us – some kind of "folie à deux." Mr. Magnus told the patient, "don't worry, from now on I'll take care of all your needs," and gave him a fatherly hug and took him out of there. We transferred him to a proper hotel and made sure that he showered and dressed in clean familiar clothes that we had brought with us from his home and ate and drank and, most importantly, that he was able to sleep well with the help of benzodiazepines. This basic assistance significantly improved his condition. When a person experiences psychosis for the first time in his life, it leads to extreme anxiety. The fact that he did not sleep, eat, or shower properly enhanced his distress. Attending to his basic needs assisted in calming him down and in reducing the psychotic symptoms he was experiencing. I saw the craving for hashish in a new light when we arrived at the airport. Although we checked his

clothing and equipment while he was sleeping, a policeman who carried out a random check at the airport found two joints of hashish in his pocket. He confiscated them, put them in an ashtray nearby, and let us continue. The young man looked right and left and, the moment the policeman looked elsewhere, dashed over and grabbed the lost joints. I caught him by the arm, and for the first time in my life, I "hit a patient" – I shook his arm and threw away the joints and physically held him until we boarded the airplane. When we arrived in Israel, 36 h after meeting him, he was in a condition that did not require hospitalization – only a short period of ambulatory psychiatric treatment, with full remission.

121.2.6 Kfar Izun

Harmony Village (Kfar Izun) is an innovative and unique recovery and rehabilitation village for young adults suffering from mental health problems due to the use of drugs, usually during backpacking trips. The village was founded in 2001, on the beach near Cesarea. The village allows treatment without the need for registration and without the stigmas usually associated with treatment in psychiatric institutes. The uniqueness of the treatment provided at "Kfar Izun" is also reflected in the treatment environment – the village is located on the beach, in a relaxing and special surrounding. It is an "open village" both physically (no fence or security) and in terms of attitude. All patients come at their own will. The open village is an incentive to take responsibility for the situation, and the patients trust that they can take back control of their lives.

The village's therapeutic outlook meant that it was not possible to adopt the approach of treatment as an addiction, since the main problem here was not addiction. Thus, in terms of treatment received, two major decisions were taken: The first decision was to adopt the Salmon frontline treatment for the combat of stress reaction, which includes three treatment principles, immediacy, proximity, and expectations, and to combine it with methods of treating patients in distress, on the premise that most of the cases stemmed from a posttraumatic event and from distress, both for the patients and for their families. The second decision taken was to engage in self-learning all the time and make changes to the therapeutic concept if needed (Bonny-Noach and Frish 2008; Frish 2008).

121.2.6.1 Immediacy

One of the recommendations of "Kfar Izun" is that treatment begins immediately upon the patients' return from abroad and that the village is ready and equipped to receive patients immediately as they get off the airplane. This is not always implemented due to the skepticism of family members, who want to see firsthand the severity of the situation of their children.

121.2.6.2 Proximity

The village is located on the beachfront in an open surrounding, and the patients' rooms are similar to bungalows (similar conditions prevailed during the backpackers' trip).

In addition, the treatment staff (almost all of whom were once backpackers themselves) makes sure to recreate some of the environments and experiences from the backpacking trips.

121.2.6.3 Expectations

Each patient is told that the crisis experienced is temporary and will pass quickly and they will return to normalcy after a period at the village. The presence of other patients who went through similar experiences is a very meaningful and important source of support. The other patients are proof that they are not the only one suffering from such a crisis and recovery is possible. Also, the limited treatment period helps patients realize that they are expected during this period to succeed and to function normally and that their current condition will not last forever.

The professional staff includes psychiatrists, psychologists, and social workers. In addition to conventional treatment (group therapy, individual therapy, family therapy, and psychiatric pharmacologic treatment[1]), there is also some oriental therapy, body psychotherapy, naturopath, nutrition therapy, and reflexology.

An evaluation research, both quantitative and qualitative, of "Kfar Izun" (Ezrahi et al. 2006) showed that the success rate of patients treated at the Harmony Village was high. Success was measured at several levels: 24 % recuperated and left the village without visible pathological symptoms; 31 % were diagnosed as having mental illnesses in remission; 39 % showed a slight improvement in their psychiatric condition; 6 % showed no improvement. The qualitative research findings compared graduates of the village (up to 6 years) and a control group and found lower clinical states of mental stability in the control group than in the graduates group. The functional-behavioral findings showed that most of the graduates returned to an independent lifestyle, which includes integration in the work force or having high education, development of long-term plans, and setting of normative targets in comparison to their peers. It was also shown that many patients keep in touch with the village's staff, and it is clear that most of them have returned to a normative and productive lifestyle.

Abstract

The comorbidity of psychotic and substance use disorders (SUDs) is a major issue in mental health because of its high frequency and poor prognosis. Moreover, it is often neglected both for the difficulty to assess SUDs in psychotic patients and for scarce attitude to evaluate and treat substance misuse by psychiatric service staff. On the other hand, psychotic patients with SUDs can receive inadequate treatment for psychosis by SUD services for similar reasons.

Assessing and treating this comorbidity require the knowledge and the integration of specific tools and interventions that should be tailored toward patients' clinical condition and that can be difficult to manage in daily clinical practice.

122.1 Introduction

Since the 1980s the literature has gradually shown how the care of mental illness has frequently to deal with the coexistence of substance use disorders (SUDs), namely, abuse or dependence, and other mental disorders, a situation usually defined as "dual diagnosis " or "comorbidity" (Kessler 2004). Dual diagnosis is a case of heterotypic comorbidity, that is, the simultaneous presence of mental disorders belonging to different clusters, while homotypic one can be defined as the coexistence of two or more disorders within the same diagnostic cluster, e.g., a cannabis use disorder and an alcohol use disorder (Angold et al. 1999).

The relevance of dual diagnosis lies in its high prevalence, at least for some settings, and its detrimental effects on response to treatment and clinical and social outcomes, which are worse than in patients affected by a single diagnosis (Morojele et al. 2012).

Dual diagnosis may include any mental disorder and any SUDs, therefore an extremely broad and various condition. However, some authors have restricted their interest to situations where a substance misuse accompanies the most severe mental disorders, such as schizophrenia or bipolar disorder (Carrà et al. 2012). SUDs are the most frequent comorbidity among psychotic disorders and can further dramatically worsen an unfavorable prognosis (Wright et al. 2000).

122.2 The Comorbidity of Psychotic Disorders and Substance Use Disorders

122.2.1 Epidemiology

122.2.1.1 The USA

In the USA, about 25 % of the general population has suffered from a mental disorder in the last 12 months. Among them, the three main psychotic disorders, namely, schizophrenia, delusional, and schizoaffective disorder, seem to have a prevalence of about 1–2 % (Reeves et al. 2011; West 2008).

SUDs are more common than psychoses. In 2011, according to the National Survey on Drug Use and Health (NSDUH), 8 % of the general population over 12 years of age resulted suffering from an SUD. Among them, 5.5 % suffered from an alcohol use disorder, 1.5 % had another SUD, and 1 % had both (SAMHSA 2012). The most frequently abused substances were alcohol, marijuana, analgesics, cocaine, and heroin.

Evidence about the prevalence of dual diagnosis among people with psychotic disorders in the US general adult population comes from three large studies, the Epidemiologic Catchment Area (ECA) study, the National Comorbidity Survey (NCS), and the National Epidemiological Survey of Alcohol and Related Conditions (NESARC).

The ECA study was carried out between 1980 and 1984 on a sample of more than 20,000 subjects aged over 18 years and found that among individuals with schizophrenia, SUDs had a prevalence of 47 % (odds ratio $= 4.6$, $p < 0.001$).

Indeed, 34 % of subjects had an alcohol use disorder (OR = 3.3, $p < 0.001$), and 28 % a drug use disorder (OR = 6.2, $p < 0.001$ – Regier et al. 1990). Conversely, comorbid schizophrenia was found in 3.8 % of subjects with an alcohol use disorder and 6.8 % of those with a drug use disorder (Regier et al. 1990). The NCS study was conducted between 1990 and 1992, on a sample of approximately 8,100 individuals between 15 and 54 years of age, and found a prevalence of SUDs of 44.8 % among those suffering from chronic psychotic disorders (Kessler et al. 1996). Finally, the NESARC study interviewed more than 40,000 noninstitutionalized adults in 2000–2001, finding that psychotic disorders have a prevalence of 1.5 % among people affected by alcohol use disorders and of 4.2% among people suffering from substance use disorders (Lev-Ran et al. 2012).

Smaller surveys show prevalence rates between 20 % and 65 % among people suffering from a severe mental illness (including psychosis), depending on geography, service setting, population composition, and evaluation tools (Cuffel and Chase 1994; Drake et al. 1989; Carrà and Johnson 2009). The prevalence of psychotic disorders among substance users is lower: according to the NESARC study, prevalence is less than 10 %, and generally comorbid schizophrenia is rare among opioid users in addiction services (Kidorf et al. 2004). However, there are some differences among users of specific substances. The prevalence among inhalant users is an exception, with 20 % of them affected by psychosis (Lev-Ran et al. 2012). These differences about the prevalence of psychosis among substance users may reflect the complex etiology of dual diagnosis.

122.2.1.2 Europe

European evidence about psychotic and substance use disorders show prevalence rates in the general population of about 1 % and between 0.3 % and 3 %, respectively (Wittchen et al. 2011; Eurostat 2011). The most commonly abused substances are alcohol and cannabis (Wittchen et al. 2011). In Europe, unlike in the USA, there are no studies that routinely and comprehensively investigate the prevalence of dual diagnosis across all the countries. However, the European Schizophrenia Cohort (EuroSC), a multicenter prospective study carried out in Europe on a cohort of 1,200 patients with schizophrenia, found a prevalence rate of 24 % for comorbid substance dependence mostly due to alcohol, albeit with some differences among the countries in which the study was carried out. Dual diagnosis had a prevalence rate of 35 % in the UK, 21 % in Germany, and 19 % in France (Carrà et al. 2012). Smaller studies have shown similar prevalence rates across European countries. Moreover, according to various local studies, psychotic disorders have a prevalence of about 5–15 % among individuals affected by SUDs (Carrà and Johnson 2009; Gual 2007).

In summary, in Europe prevalence rates of substance misuse among people with psychotic disorders seem to be lower than in the USA (Carrà et al. 2012). The differences between USA and Europe may, at least partly, depend on important differences in lifestyle and care pathways of populations surveyed. Thus, there is the need of a prudential approach in interpreting these data, as the epidemiology of dual diagnosis depends upon many factors, which may vary across different countries. Evidence must be interpreted taking into account local settings' features.

122.2.1.3 Critical Issues of Dual Diagnosis Epidemiological Studies

Most of the studies on comorbidity of psychotic and substance use disorders deal only with schizophrenia, neglecting other psychoses, so very fragmented relevant evidence is available for the latter (Wittchen et al. 2011). Furthermore, most of the evidence on dual diagnosis comes from the USA, which limits its generalizability, because of the organizational features of their health-care system that influence its accessibility. Moreover, available epidemiological studies on dual diagnosis have shown various methodological limitations.

First, it must be considered that the recruitment of people with "dual diagnosis" may not be so obvious: the assessment techniques show variable validity (Dixon 1999). Second, it is common to merge categories of dependence and abuse (Weaver et al. 2001). Although this can be useful for rough estimates of dual diagnosis prevalence, it makes difficult to achieve accurate data.

There are also issues regarding the recruitment of samples: convenience samples help to ascertain and explain the critical aspects of treating specific population, but they may provide misleading findings about the real prevalence of dual diagnosis. It is well known that dual diagnosis is significantly more common among some special populations, e.g., patients admitted to acute psychiatric settings, homeless, and users of the criminal justice system (Winklbaur et al. 2006). Finally, two interrelated problems must be taken into account: the spread of polysubstance abuse, including alcohol, and the difficulties in ascertaining a problematic substance use. Polyabuse is particularly common among patients suffering from psychotic disorders (Weaver et al. 2001; Dixon 1999; Drake et al. 1993), so each patient might have more than one SUD, making almost impossible distinguishing them. Moreover, patients often deliberately hide their consumption of substances, leading to an underestimation of their prevalence (Kavanagh et al. 2002).

As a whole, the epidemiological research about dual diagnosis shows many uncertainties, partly due to organizational problems and partly due to the very nature of the patients. In fact, psychotic disorders and SUDs are severe illnesses, and suffering from these conditions makes people exposed to several confounding factors, which can hamper validity of correlations and causal links. However, an epidemiological understanding is needed in order to implement appropriate treatment programs.

122.2.2 Potential Etiological Relationships Among Psychotic and Substance Use Disorders

Substance use and psychotic disorders seem to be linked by a mutual risk relationship (Morojele et al. 2012; Brady and Sinha 2005). Their strong epidemiological, biological, and clinical association has worked as a springboard for a large number of research initiatives aimed at understanding the etiology of this association. The efforts have been mainly directed in ascertaining if one has a significant role in the etiology of the other. Furthermore, some authors have hypothesized that both these disorders may be due, at least partly, to a common cause (Volkow 2009).

However, there are no firm conclusions about any etiological links between SUDs and psychosis, even if various risk factors for dual diagnosis have been found, and some etiological models have been developed.

122.2.2.1 Correlates and Risk Factors for Dual Diagnosis

Genetics

It is known that both SUDs and psychotic disorders have their own genetic risk factors, namely, a polygenic inheritability with multiple genes giving each one a small contribution to the global risk of developing these diseases (Kirow and Owen 2009; Strain and Anthony 2009).

Genetics account for about 30–60 % of the risk of developing an SUD. The genes' contribution in the etiology of psychotic disorders is less clear, even if some authors state that genes can account for up to 80 % of the risk for schizophrenia (McCann and Ricaurte 2009; Sullivan et al. 2003).

Until a few years ago, it was thought that vulnerability to SUDs and psychosis depended on distinct mechanisms of inheritance (Krystal et al. 2006). However, more recently some genes have been identified as contributing to the pathogenesis of both disorders. Among others, there are various genes coding for factors involved in brain development and in neuronal plasticity, such as the genes for neuregulin-1 (NRG1), some neurexins (NRXN1 and NRXN3), the catechol-O-methyltransferase (COMT), and the monoamine oxidase A (MAOA – Volkow 2009).

Male Sex and Young Age

These characteristics are strongly associated with comorbid psychotic and substance use disorders. However, in clinical practice it is recommended not to neglect the search for substance misuse among women and the elderly, since this condition is often overlooked, with poor treatment outcomes (Winklbaur et al. 2006; Kavanagh et al. 2002; Dixon 1999).

Low Educational Level and Unemployment

According to various studies, these factors are associated with both conditions (Volkow 2009), probably because they favor drift toward social relationships and situation with high risk of substance consumption (Palomo et al. 2007).

Substance Availability and Attitude Toward Substance Consumption

Living in social contexts characterized by high availability of substances and belonging to a social network familiar with consumption seem to favor its spread among individuals with psychotic disorders (Kavanagh et al. 2002). It seems that these factors are among the main determinants of patients' patterns of consumption (Dixon 1999).

Personality and Childhood Disorders

These conditions may predispose to a problematic substance use (Krystal et al. 1999). They include two dimensions of personality, sensation seeking and sociopathy. Sensation seeking is defined as a temperamental dimension characterized by impulsive search for gratification and poor tolerance toward frustration (Cloninger and

Svrakic 2009). Sociopathy is a dimensional connotation of personality characterized by greed for personal advantage and gratification, especially at the expense of others, through manipulation or violence; lack of empathy; inability to plan long-term behaviors; disregard for the safety or health of themselves or others (APA 2000). Moreover, a childhood history of attention-deficit/hyperactivity disorder (ADHD) has been correlated with a high prevalence of dual diagnosis (Drake et al. 1993).

Early Onset of Illness and Good Premorbid Functioning

An early onset of psychosis is generally associated with a poorer premorbid functioning. However, dual diagnosis seems assciated with both an early onset of illness and a good premorbid functiong. The reasons of this epidemiological evidence are not yet clear. Some authors have hypothesized that subjects affected by dual diagnosis probably would have had a later onset of psychosis, which is associated with a good premorbid functioning, but the exposure to drugs has anticipated its onset (Dixon 1999).

Subthreshold Symptoms Among Substance Users

It is well known that subclinical psychotic symptoms are risk factors for subsequent onset of psychotic disorders (Van Os and Allardyce 2009). Furthermore, subclinical psychotic symptoms increase the risk of substance consumption (Rietdijk et al. 2011). Therefore, prodromal manifestation of psychosis could be risk factors both for chronic psychotic disorders and SUDS.

In summary, it seems that the SUDs and psychotic disorders share many genetic and psychosocial risk factors (Volkow 2009). In addition, the risk factors associated with dual diagnosis are largely similar to those for the pathological consumption of substances found in the general population (Strain and Anthony 2009).

122.2.2.2 Etiopathogenesis: Models and Evidence

The Self-Medication Model

An intriguing hypothesis proposes that self-medication by substance abuse is a coping attempt by people with schizophrenia, matching the pharmacological properties of substances with the particular psychiatric symptoms and states experienced (Khantzian 1985, 1997). However, this should imply diagnostic and symptomatological differences in substance selection between individuals suffering from psychosis and the general population (e.g., choice of stimulants and negative symptoms should be associated). Neither prediction is supported by research evidence. Among people suffering from schizophrenia, no replicable patterns of substances chosen and symptoms experienced have been identified. Substance consumption pattern is actually similar to that found in other diagnostic groups (e.g., El-Guebaly and Hodgins 1992) and reflects the substance use pattern found in the general population where the sampling took place (Palomo et al. 2007; Krystal et al. 2006). As a matter of fact, given the frequent occurrence of multiple substance misuse as discussed above, it is not possible to attribute any observed symptomatological and clinical difference to a single drug class. The only strong evidence is that regarding the association between fewer negative symptoms and dual

diagnosis, though it is not still clear whether this may involve lifespan or just current misuse (see Potvin et al. 2006 for a review). However, a less definitive form of the self-medication hypothesis that does have some supporting evidence suggests that substances are used to relieve dysphoria and anxiety and to alleviate tension (Krystal et al. 2006; Addington and Duchak 1997) rather than medicating core psychotic symptoms.

However, some neurobiological evidence might support the self-medication hypothesis. For example, nicotine dependence (which affects about 70 % of schizophrenic individuals) may determine an improvement of cholinergic neurotransmission to the nicotinic receptors, whose function has proven to be impaired in schizophrenia. It may also increase the expression of glutamate decarboxylase, with a consequent increase in GABAergic activity, also reduced in this disorder. These ultrastructural effects will be the biological substrates of the improvement in cognitive performances observed among nicotine-dependent people with schizophrenia, especially for working memory and selective attention (Volkow 2009; Winklbaur et al. 2006).

Furthermore, cocaine would alleviate some symptoms associated with psychotic disorders, first of all the extrapyramidal effects of antipsychotics, because of its action as dopamine reuptake inhibitor. Cocaine may also have a role in balancing the low functioning of the reward circuit observed in schizophrenia, which could be further worsened by high-power antipsychotics (i.e., haloperidol). The hypothesis seems to be supported by some evidence, although limited, about the beneficial effects of atypical antipsychotics in the treatment of psychotic disorders comorbid with substance misuse (Brady and Sinha 2005). This may be due to the lower dopaminergic activity of the second-generation neuroleptics (Volkow 2009; Winklbaur et al. 2006). Finally, cocaine and other drugs of abuse may have the effect of enhancing receptivity for glutamate in the nucleus accumbens (NA), through an increase in the expression of AMPA-type receptors, helping to offset the glutamatergic hypofunction recently observed in schizophrenia (Palomo et al. 2007).

Although confirmed by various studies, the self-medication hypothesis does not seem entirely convincing. If we accept this hypothesis, it should be possible to observe patterns of substance use typical of schizophrenia, adopted by dual diagnosed users to cope with specific symptoms. However, patterns of consumption among people with psychotic disorders are not different from those adopted by the social context to which they belong (Palomo et al. 2007; Krystal et al. 2006).

Furthermore, it has been argued that if drugs of abuse improved the symptoms, probably the prognosis of patients with dual diagnosis would be better, but the literature is almost unanimous in affirming this is not the case (Palomo et al. 2007). However, it could be possible to rebut that, given the deficit in planning long-term actions, people with schizophrenia might choose the temporary benefit of a substance effect at the expense of broader and less immediate negative impact on their lives (D'Souza et al. 2009).

To conclude, there is insufficient evidence to conclude that patients with psychosis are more exposed to substance use disorders only because of their willing to self-medicate their symptoms.

Environmental Stress Vulnerability

According to this model, the problematic use of substances would be one of many factors that can precipitate the development and exacerbation of psychotic disorders in susceptible individuals (Winklbaur et al. 2006). Alcohol, cannabis, and methamphetamines have been proved capable of causing persistent psychoses, along with transient psychotic syndromes (Ross and Peselow 2012). However, this model seems simplistic, as several studies have reported that psychotic disorders are not merely caused by SUDs, given the mutual risk relationship that seems to bind these two syndromes (Volkow 2009).

Vulnerability to Comorbid Dependence

In this model, suffering from a psychotic disorder is per se a risk for substance use disorders, as both illnesses may share various biological substrates. The model is supported by evidence at various levels. Individuals affected by schizophrenia seem to have a lower capacity of anticipating and counteracting the negative consequences of their substance use and to avoid offers of drugs and exposure to associated conditions due to their poor social skills (Palomo et al. 2007; Kavanagh et al. 2002). The main neurobiological evidence in favor of this model comes from the reward system and its connections. First, positive symptoms of schizophrenia have been correlated with an increased activity of the dopaminergic projections going from the mesencephalic ventro-tegmental area (VTA) to NA, the so-called reward system. However, an increase in the activity of this pathway is also the biological substrate of the positive reinforcing properties of any substances, so its hyperactivity could increase the risk of both psychotic symptoms and substance use relapse (Chambers et al. 2001). Second, schizophrenia and substance use disorders may both cause a decrease in the activity of efferent projections from the prefrontal cortex and the hippocampus to the NA. These fibers usually counteract excessive signaling from the reward way. In schizophrenia there is possibly a developmental abnormality in prefrontal cortex and hippocampus, which may result in a deficit of these projections. Furthermore, hyperactivity of the reward system can inhibit their activity, in case of activation of this way due to substance consumption. So both psychoses and substance use disorders can hamper the physiological inhibition of dopaminergic signaling in the NA, which results in a diathesis toward psychotic relapses and substance consumption (Ross and Peselow 2012).

A further suggestion of a common substrate for psychoses and SUDs comes from various studies of functional magnetic resonance imaging that have demonstrated that patients with SUDs and schizophrenia have a reduced activation of NA during the anticipation of reward cues. Moreover, the magnitude of this deficit of activation seems correlated to the severity of their negative symptoms (Krystal et al. 2006).

When evaluating the etiological models of dual diagnosis, it is important to keep in mind that these hypotheses probably describe only some of its facets, so they should not be conceived as mutually exclusive. For instance, attempts to self-medicate psychotic or unspecific symptoms could be reinforcing elements for substance consumption, and people with schizophrenia may be highly vulnerable to

such reinforcement. It is also possible that pathogenesis mechanisms shared by all or most of the drugs of abuse coexist with mechanisms related only to specific psychotropic substances (Volkow 2009).

122.2.2.3 Cannabis and Psychotic Disorders

In the last 20 years, a body of evidence has accumulated that shows that cannabis can cause, in a dose-dependent manner, psychotic symptoms, psychotic relapses, and the onset of chronic psychotic disorders, sometimes clinically diagnosable as schizophrenia (Bossong and Niesink 2010; Moore et al. 2007). Some studies also support the evidence that the age of onset of psychotic disorders is earlier in those with a cannabis-related disorder (Large et al. 2011).

However, there are also different evidences. Sevy and colleagues (2010) state that the difference in the age of onset of chronic psychosis between patients with cannabis use disorder and patients without it may not be related to cannabis use but to demographic and clinical variables, namely, male gender, lower socioeconomic status, better premorbid childhood social adjustment, and more severe positive symptoms. Other authors state that earlier age of onset of psychotic symptoms in cannabis users is not due to an etiological role of cannabis, but to the fact that cannabis use is common among young people. So, the results observed might have been due to the recruitment bias of people in which the psychotic illness started earlier by itself (Wade 2005). However, it is unlikely that cannabis causes by itself schizophrenia *ex novo*. Some statistical models have been developed showing that the use of cannabis can only precipitate psychosis in people who would have however developed the disease and that cannabis can worsen the course of this disorder (Degenhardt et al. 2003). Furthermore, it has been claimed that if cannabis could cause schizophrenia, the observed increase of cannabis use, for example, in Australia, where the study was run, would have gone together with an increase in prevalence of schizophrenia, which was not observed (Degenhardt et al. 2003). However, it has been argued that the onset of schizophrenia can occur many years after the exposure to cannabis, so being difficult to be simultaneously detected (Moore et al. 2007).

The debate about the relationship between cannabis and psychosis has been up and running in the last few years, also because of many methodological issues that make difficult to test a clear research hypothesis, such as the number of related confounders.

Two recent systematic reviews added evidence about the etiological role of cannabis in the pathogenesis of psychotic symptoms and disorders. Moore and colleagues (2007) found an increase in incidence of psychotic symptoms and disorders in cannabis users, with odds ratio ranging from 1.41 (CI 95 %: 1.20–1.65) to 2.09 (CI 95 %: 1.54–2.84) in a dose-dependent manner.

Large and colleagues showed in another systematic review that cannabis and other illicit substances are associated with earlier onset of psychosis. This relationship was not demonstrated for alcohol and psychosis. More in detail, cannabis users experienced an onset of psychosis 2.7 years earlier than non-cannabis users (Large et al. 2011).

The psychotogenic properties of cannabis are also supported by neurobiological data about both delta-9-tetrahydrocannabinol (THC), which is the main psychoactive component in cannabis (Bossong and Niesink 2010), and the two most important endogenous cannabinoids, namely, anandamide and 2-arachidonoylglycerol.

There is some evidence about the property of THC facilitating dopaminergic neurotransmission from the mesencephalic ventro-tegmental area (VTA) to the nucleus striatum. Animal studies have shown that cannabinoids are released by dopaminergic neurons of the VTA and act on type 1 endocannabinoid receptors (CB1) on the glutamatergic and GABAergic neurons that modulate the dopaminergic neurons. This results in a decrease in their activity and a consequent increase in the dopaminergic firing from the VTA to the striatum, which has been correlated to positive psychotic symptoms (hallucinations, delusions, disordered thought, and behavior). Cannabinoids are also involved, together with dopamine, in the phenomena of long-term depression and long-term potentiation of neural projections from the cortex to the striatum (Bossong and Niesink 2010; Kuepper et al. 2010). The former have been correlated with the development of psychotic symptoms (Kuepper et al. 2010; D'Souza et al. 2009). THC may also influence projections from VTA to the prefrontal cortex, where they could acutely induce an increase in dopamine. However, chronic administration of THC seems to cause a chronic decrease in prefrontal dopamine, and both an excessive increase and decrease of prefrontal dopamine have been associated with a cognitive impairment, for instance, in attention and memory, which is typical of negative and cognitive symptoms of schizophrenia (Kuepper et al. 2010; D'Souza et al. 2009). Furthermore, carriers of an allele of the catechol-O-methyltransferase (COMT) gene with a valine instead of a methionine at the codon 158 (val158met) have shown more proneness to the psychotic and cognitive effects of cannabis. This polymorphism causes an increase in the activity of COMT, which results in a decrease in prefrontal dopamine levels (Kuepper et al. 2010).

THC may also act on the CB1 receptor on GABAergic interneurons to reduce their activity, which could result in a loss of their inhibitory activity on pyramidal cells, causing a loss of coordination in their activity. Other studies revealed that cannabinoids may reduce the glutamatergic synaptic transmission in several brain regions, such as the hippocampus, the prefrontal cortex, the NA, and the amygdala (D'Souza et al. 2009). The reduced GABAergic and glutamatergic activity caused by cannabinoids resembles what is observed in schizophrenia, even if its meaning is still poorly known (Moore et al. 2007).

More generally, Bossong and Niesink (2010) formulated two hypotheses about the role of cannabis in psychotic disorders. Recent findings show that the CB1 receptor is very important for a correct brain development, mainly during adolescence, a period in which the development of neural circuits for superior brain functions is completed. A heavy exposure to exogenous cannabinoids may disturb this process, causing alterations in local neural circuits that might result in schizophrenia. Evidence about the hazard of cannabis for neural development comes from a recent meta-analysis of 14 studies about brain abnormalities in nonpsychotic cannabis users. Analyses have shown that cannabinoid consumption is associated

with a significant reduction in hippocampal gray matter, which could be critical during adolescence, as it may compromise the last phases of neural development, so having effects on cognitive functions (Rocchetti et al. 2013). Another hypothesis considers exogenous cannabinoids, altering perception and memory, which might block or alter the perception of exogenous stimuli, relevant for brain maturation in adolescence.

In summary, many studies, both in vivo and in vitro, on animals and humans, confirm that exogenous cannabinoids can interfere with the physiological brain activity and cause pathological processes very similar to the ones observed in psychotic disorders. However, many results have not been confirmed by subsequent studies, making still largely unknown the real impact of cannabinoids on the brain (Volkow 2009).

Thus, current evidence about the relationship between cannabis and psychosis shows that cannabis can cause transient psychotic positive, negative, and cognitive symptoms in a dose-dependent manner, besides unspecific symptoms such as anxiety (D'Souza et al. 2009), and can cause a relapse of chronic psychotic disorders (Kuepper et al. 2010; Moore et al. 2007). However, cannabis seems to be neither a necessary nor a sufficient cause for the onset of chronic psychotic disorders. It is one of the many factors, partly known and partly unknown, that interact to give each person a specific risk for chronic psychosis (Bossong and Niesink 2010; Kuepper et al. 2010; D'Souza et al. 2009; Volkow 2009). Thus, preventing or reducing the use of cannabinoids is useful to delay or maybe avoid the onset of psychotic disorders, especially in people at high risk. It is also important to give such an advice to pregnant women, due to the lipophilic structure of exogenous cannabinoids and the evidence about their detrimental effect on the neural development. In fact, even if the onset of psychosis were inevitable, delaying the onset could allow many patients to reach a developmental level sufficient to have a decent life (Large et al. 2011).

122.2.3 Clinical Features, Course of Illness, and Diagnosis

122.2.3.1 Clinical Features and Course of Illness

Clinical pictures of comorbid psychotic and substance use disorders are complex and difficult to be assessed (Morojele et al. 2012). Both disorders may be exacerbated by exposure to environmental stressors and can worsen each other, both in the short and the long term (Ross and Peselow 2012; Volkow 2009; Brady and Sinha 2005).

In clinical practice, patients can be affected by both a psychotic disorder and an SUD, but their psychotic symptoms may also be manifestations of a substance-induced psychosis (SIP). This term describes psychotic syndromes due to substance use, abuse, intoxication, and withdrawal. Furthermore, a patient can have both a primary psychotic disorder and an SIP (Center for Substance Abuse Treatment 2005).

In case of an SIP, signs and symptoms are usually not as bizarre and complex as the ones seen in schizophrenia and other primary psychotic disorders, and they will persist for days and weeks from the cessation of substance consumption

(Keshavan and Kaneko 2013; CSAT 2005). Therefore, longitudinal observation is of primary importance to differentiate a situation of comorbidity from a substance-induced disorder, because it can be objectively impossible to distinguish a psychosis in a substance user from an SIP. It is also possible that people develop psychotic disorders as a consequence of heavy and prolonged substance consumption, but psychotic disorders may last for several months and years or also lifelong even after the cessation of the substance use. This has been observed for cannabis (Niemi-Pynttäri et al. 2013) and methamphetamines (Grant et al. 2012; CSAT 2005). Also several years of alcohol dependence, especially after various episode of acute withdrawal (delirium tremens), can induce a persisting psychosis (Ross and Peselow 2012).

Any substance, if taken in large quantities and over a long enough period can induce a psychotic state (CSAT 2005). It is also important to know that even low levels of substance use can induce a psychotic relapse (CSAT 2005). However, the clearest psychotogenic effect has been shown for stimulants, such as amphetamine and cocaine, cannabis, and NMDA antagonist hallucinogens, such as phencyclidine and ketamine. Also lysergic acid diethylamide (LSD) and 3,4-methylenedioxy-N-methylamphetamine (MDMA) can cause hallucinations, but usually only during acute intoxications. Alcohol and benzodiazepines can induce psychotic symptoms only in acute withdrawal states, while opiates and nicotine have not clearly shown psychotogenic properties (Keshavan and Kaneko 2013). Alcohol, cannabis, and cocaine are the most frequently abused substance by dually diagnosed patient, but especially because of the high prevalence of polysubstance use, it is important not to exclude the hypothesis of concurrent different drugs (Weaver et al. 2001; Dixon 1999; Drake et al. 1993).

People with psychosis who misuse substances may be different from the abstinent ones in frequency and intensity of positive, negative, and cognitive symptomatology. There is evidence about a higher frequency of positive symptoms, with less negative and cognitive symptoms, in those with substance use disorders (Harrison et al. 2008; Kavanagh et al. 2002; Soyka et al. 2001; Dixon 1999).

Neuromaging studies have shown that heavy and ongoing alcohol, cannabis, and methamphetamine abuse increases the cortical thinning seen in schizophrenia, especially in the prefrontal and temporal cortex, maybe worsening the progressive deficit of the executive functioning observed in psychosis (Aoki et al. 2013; Large et al. 2011; Winklbaur et al. 2006).

Dually diagnosed people are prone to adverse outcomes in several domains. Clinically, they have a high risk of treatment noncompliance, poor clinical response, more frequent psychotic relapse and hospitalization, violent behavior, suicide attempts, and medical problems, such as infectious diseases, so being frequent users of emergency services (Drake et al. 2004; Noordsy and Green 2003). They also face some adverse social and economic outcomes. They are in fact more at risk of victimization, housing instability and homelessness, unemployment and poverty, and committing offences with related criminal justice issues (Kavanagh et al. 2002; Dixon 1999). Besides, dual diagnosis imposes a high emotional and economic burden on families and friends of patients, increasing the risk of social drift (Ross and Peselow 2012; Kavanagh et al. 2002; Alverson et al. 2000; Dixon 1999).

122.2.3.2 Assessment

The assessment process has obvious consequences in terms of treatment and prognosis.

An adequate assessment starts from clinical suspicion. Cues of a history of substance abuse can be found in risk factors described above or in a childhood history of attention-deficit disorder (Drake et al. 1993). Moreover, because of the high prevalence of comorbid severe mental illnesses and substance use disorders, the presence of one of them should be considered by itself a reason to search for the other (Ross and Peselow 2012; Morojele et al. 2012).

The assessment can be very difficult for various reasons, especially in emergency settings. Patients' clinical conditions may be very complex, and their cooperation is not warranted, for instance, because of agitated or violent behavior, disorganized speech, high sedation or paranoid psychotic symptoms, acute or chronic cognitive impairment. Besides, the patient may not want to talk about his symptoms or his substance use because of embarrassment, fear of negative responses, or scarce insight (Kavanagh et al. 2002). Therefore, it could happen that the clinician has to achieve a diagnosis based only on scarce and fragmentary data.

To date, there are various tools to clarify a comorbid clinical picture. The most adequate approach consists of combining two or more of them. More in detail, clinical history, physical examination, clinical interview, laboratory tests, and neuroimaging should be used together to obtain the most reliable information (Ross and Peselow 2012).

First of all, it is essential to establish a positive therapeutic alliance between the clinician and the patient, setting a nonjudgmental and trustful relationship (Alverson et al. 2000; Drake et al. 1993). The clinical history can be evaluated by asking the patient. It is important to ascertain if he has ever attended psychiatric services or has ever received a psychiatric diagnosis or has been prescribed a psychopharmacological treatment. Likewise, the clinician must ask about any psychotropic substance consumption, substance use disorder, or related treatment. If the patient assumes substances, it is important to know what substances, or at least what substances the patient believes to assume, as well as quantity and frequency of consumption (Morojele et al. 2012). Besides, the patient's last drug consumption time is very important for diagnostic assessment, especially in case of emergency (National Collaboratory Centre for Mental Health 2011). If more reliable information is needed, the clinician should ask patients' collaterals, such as family members, friends, or partners. However, it is important to keep in mind that even patients' collaterals can be unreliable, for various reasons. They can be interested in hiding the patients' drug consumption, for example, because of legal reasons, or they simply may not know how the patient lives.

The clinical interview can be integrated with structured interviews or questionnaires. They have been found to produce highly reliable diagnoses (Dixon 1999), but they must be tailored toward the patient's clinical conditions. The following tests have shown adequate reliability: for patients with higher functioning and less severe mental illness, the Addiction Severity Index (ASI) and the Drug Abuse Screening Test (DAST) and, for alcohol use disorder, the CAGE and the Alcohol Use Disorders Identification Test (Ross and Peselow 2012; Morojele et al. 2012).

However, these instruments may not be reliable for patients with the most severe mental illnesses, for two reasons. First, these tools focus on substance-related dysfunction, of which the most severely ill patients could not be aware. Second, they may not be sensitive to the cognitive impairment common among the most ill patients (Ross and Peselow 2012). Two screening tools developed for such patients are the Dartmouth Assessment of Lifestyle Instrument and the Substance Use Event Survey for Severe Mental Illness. Regardless of which screening tool will be chosen, it is important to verify if it can be easily administered to a patient and if it has been validated for dually diagnosed populations (Samet et al. 2004). Furthermore, these instruments should be used when the patient is stabilized, and using too lengthy self-report tools should be avoided. Repeating the administration of these tools may also help to assess variations in the course of substance disorders or mental illnesses (Drake et al. 1993).

The physical examination is as important as clinical history, and every sign or symptom must be evaluated (Keshavan and Kaneko 2013). Its main purpose, besides looking for any condition that deserves medical or surgical treatment, is to search for the physical stigmata of a drug use disorder or of a mental illness. Cues of a substance use disorder can be signs of intoxication, withdrawal, or chronic use, but they can overlap each other and with signs of comorbid physical illnesses and unspecific vegetative symptoms (i.e., tachycardia and diaphoresis because of anxiety – Morojele et al. 2012). The clinician should search for signs useful to unmask intoxication or withdrawal syndromes. Signs and symptoms of intoxication and withdrawal by psychotropic substances are described elsewhere in this book. Here, the importance of evaluating if the patients' behavior suggests delusions or hallucinations and if there are physical signs of activation or inhibition, including pupils' diameter, will only be stressed. Besides, a horizontal, vertical, or rotary nystagmus can suggest NMDA receptors antagonist intoxication, such as phencyclidine or ketamine (Keshavan and Kaneko 2013; Ross and Peselow 2012). Also the chronic stigmata of a substance use disorder must be searched for, such as signs of cirrhosis or of intravenous drugs use (Ross and Peselow 2012). A poor nutritional state could be observed in case both of an SUD and of different severe mental illness.

Laboratory tests provide objective evidence of substance consumption, as well as signs of medical illness or somatic consequences of drug use. Urine tests are a cost-effective tool to assess drug consumption. They usually detect drugs taken in the last 48 h before the test. THC is an exception: due to its lipophilic structure, it can be stored in fat cells and found in urine samples for up to 6 weeks after consumption. Other instruments include breath analysis for alcohol, which can detect consumption only in the last few hours before the test, and plasmatic blood levels, useful to detect many substances of abuse. Blood cells, liver function, and carbohydrate-deficient transferrin (CDT) are indirect measures of alcohol consumption (Ross and Peselow 2012; Drake et al. 1993). Also the hair radioimmunoassay can be useful (Ross and Peselow 2012).

Finally, structural neuroimaging, such as computed tomography (CT) or magnetic resonance imaging (MRI), could be useful to exclude an organic etiology of neuropsychiatric signs and symptoms (Keshavan and Kaneko 2013).

In summary, diagnosing a primary psychosis, a psychosis due to substances or organic disease, or a condition with comorbid psychotic and substance use disorders can be challenging. It requires a holistic, integrated approach that must be tailored toward patients' conditions, setting, and available tools.

Overlooking one of these conditions or incorrectly assuming multiple diagnoses can, respectively, affect the prognosis or lead to unnecessary treatment and iatrogenic harm (Ross and Peselow 2012).

122.2.4 Treatment and Prognostic Issues

Treating people with comorbid psychosis and substance-related disorders can be very difficult. It can follow a sequential, a parallel, or an integrated approach. The sequential treatment takes care of one disorder at a time, from the first to the second once that the former is stable or in remission. In the parallel treatment, psychosis and the substance abuse disorders are treated simultaneously but separately. It is mostly up to the user to follow and coordinate both of them. The integrated model of treatment provides that treatment for both the disorders is provided by the same team (Chow et al. 2013).

The sequential and parallel treatment have often been proven to be unable to meet users' needs, especially because the lack of coordination (Horsfall et al. 2009). Thus, patients may be referred from one service to another and users can be treated only for one of their two disorders. They may also receive incompatible or inconsistent and fragmented treatment. It is also possible that, facing many difficulties and seeing their needs unmet, they give up both treatments (Drake et al. 2008).

The integrated model is designed to reduce the gap between mental health and substance misuse services (Chow et al. 2013). However, in many countries it is hard to be implemented because national health systems keep these services separate and unifying them would implicate complex political choices and administrative efforts (National Collaboratory Centre for Mental Health 2011; Kavanagh et al. 2002). Thus, manualized integrated treatment, with one team looking after both disorders, is difficult to be broadly implemented. Furthermore, evidence about the efficacy of integrated treatment models is inconclusive, partly because of several methodological issues of research on this topic (Cleary et al. 2008). However, many authors have observed that integrated treatment, although not harmful, might not be more effective than standard care (Chow et al. 2013; Cleary et al. 2008). Indeed, even if there is uncertainty about its effectiveness, it is reasonable to implement part of its philosophy to counteract daily practice problems. In fact, many obstacles due to the services' dichotomy can be managed establishing a strong synergy between them (National Collaboratory Centre for Mental Health 2011).

The aim of ensuring a good quality of care to dually diagnosed individuals should start with setting formal collaboration protocols between local services. For each patient with dual diagnosis, they should set out their respective responsibilities, first of all agreeing on which are patients' main needs and which service has to coordinate treatment interventions (Horsfall et al. 2009). In case of psychosis, the

British National Collaborating Centre for Mental Health states that coordination should be kept by psychiatric services, due to the complex care needs of psychosis. Second, services have to regularly communicate and share information, to reduce redundant interventions and to fill care gaps. Similar agreements and collaborations should be set with other services and institution involved in patient's life, such as assisted housing institutions or the judiciary system (National Collaboratory Centre for Mental Health 2011; Kavanagh et al. 2002).

Besides organizational aspects, an appropriate treatment strategy should take into account two further issues, i.e., the stage of patients' motivations and coexisting physical, social, and financial problems (Horsfall et al. 2009; Drake et al. 2004). People suffering from severe mental illnesses have commonly low motivation to change. This is partly due to low self-esteem, tolerance of frustration, and social skills. Positive, cognitive, and negative symptoms of psychosis and being in contact with a substance-promoting social context all are factors that may further limit motivation (Horsfall et al. 2009). It is important to consider the role that the substance consumption has in patients' life, keeping in mind that different substances can have a different functional meaning in patients' life (e.g., cocaine against depressed mood and cannabis to facilitate socialization), and to evaluate patients' opinions and emotions about their personal situation and the treatment course, given that motivation can be hampered by many factors, including social and financial problems (Alverson et al. 2000).

Though treatment interventions in dual diagnosis are the same used for substance misuse and severe mental disorders, it is paramount to coordinate the efforts and to tailor care programs according to patient's characteristics. Irrespective of which of the two disorders may have supposedly come first, they should be treated simultaneously as for people with a single disorder (Drake et al. 2004).

122.2.4.1 Pharmacological Treatment

Pharmacological treatment of dual diagnosis involves treatment for both psychosis and substance use disorders. However, it must be paid attention to the risk of pharmacokinetic and pharmacodynamic interactions. There is currently poor evidence to support one antipsychotic over another or first- versus second-generation antipsychotic when treating schizophrenia with comorbid harmful substance use, abuse, or dependence, in relation to superiority in either reducing substance use or improving psychiatric symptoms (Lingford-Hughes et al. 2012). Among atypical antipsychotics, clozapine seems to be the most effective, both on psychotic symptoms and substance consumption (Green 2006; San et al. 2007). Clozapine has proven to be effective for several categories of misused substances, including cigarette smoking, stimulants, alcohol, and cannabis (Coyle 2006; Noordsy and Green 2003).

Mood stabilizers can be useful in case of schizoaffective disorders. Valproate has been proven to be effective in comorbid alcohol use disorders, and carbamazepine in substance misuse disorders. The efficacy of lithium among other drugs is scarcely known (National Collaboratory Centre for Mental Health 2011).

Methadone is associated with some risk of interactions. It is metabolized by the CYP3A4 cytochrome, so inductors of this cytochrome, such as barbiturates,

carbamazepine, phenytoin, and rifampicin, may decrease its serum level, which may result in a withdrawal syndrome. Cannabinoids, grapefruit juice, SSRIs, and other drugs may inhibit this cytochrome, thus increasing methadone's serum levels (National Collaboratory Centre for Mental Health 2011). There is also risk of interaction with antiretroviral therapy for HIV infection. For a complete explanation of the risk of interactions between methadone and other drugs, as well as for other drugs, it can be useful to consult the summary of product characteristics (SPC).

Lastly, it is important to pay attention to prescribing anticholinergic for extrapyramidal side effects and benzodiazepine, as they can be abused for their stimulating and sedative effect, respectively (Noordsy and Green 2003).

122.2.4.2 Psychological and Psychosocial Interventions

It is difficult to state which types of psychological and psychosocial interventions are more effective for comorbid substance use and psychotic disorders (Chow et al. 2013). Patients' stage of motivation is fundamental to tailor the intervention (Drake et al. 2004). A rationale framework for treatment includes several phases, i.e., engagement, motivation, active treatment, and relapse prevention (Horsfall et al. 2009; Drake et al. 2004). Engagement means establishing a trustful relationship between the clinician and clients. In this phase it is important to pay attention to the social and cultural background of users and to work for their gradual involvement, being flexible in interacting with them. Outreach interventions can be useful in this phase (Drake et al. 2004). About motivation to treatment, motivational interviewing is considered essential, especially in the early stages of treatment, to explore and try to modify the actual availability of clients to be engaged in treatment. For active treatment, many interventions are available. Among them, group approaches, mainly developed from cognitive-behavioral therapy, have proven to be useful across several types of populations, maybe depending on nonspecific factors such as education, skill building, and peer support (Horsfall et al. 2009). However, not all group interventions may be suitable for people with psychosis. For instance, 12-step programs for SUDs may be unhelpful, as this approach requires some introspection and talking about several intimate aspects of one's life. Therefore, adherence among people suffering from psychotic disorders could be hampered by their limitations in emotional expression and low social skills (Horsfall et al. 2009). Also residential treatment may be useful for dually diagnosed people, as it has proven to be effective for dual diagnosis clients who have failed outpatient programs (National Collaboratory Centre for Mental Health 2011). In terms of relapse prevention, one of the most effective interventions is contingency management, namely, setting rules about facilities and penalties depending on treatment compliance and substance consumption (Horsfall et al. 2009).

122.2.4.3 Admission to Psychiatric Wards

People with comorbid psychotic illness and SUDs have more frequent hospital admissions and use of emergency services. It happens quite frequently that they need to be admitted to a hospital ward, often a psychiatric one, for a psychotic relapse or for an intoxication syndrome (Morojele et al. 2012; Palomo et al. 2007).

However, they could be difficult to be managed due to their substance, alcohol, or drug craving or trafficking, violent or manipulative behavior, inappropriate relationship with other inpatients. However, psychiatric and substance misuse services, being a sort of safe and nonjudgmental environment, can become a favorable setting for substance consumption and dealing and related issues (Alverson et al. 2001). Therefore, it is important that some rules are set about their hospitalization, especially regarding visit arrangements, search procedures, and other security issues. Drug tests should be part of the routine. The aim is to have an environment free from drugs and alcohol, and these procedures should be explained to patients and their families. Treatments proven to be effective in outpatient settings are to be continued during the admission (National Collaboratory Centre for Mental Health 2011).

122.2.4.4 Prognostic Factors and Course

Dually diagnosed patients usually make slower progresses and have higher dropout rates (Horsfall et al. 2009). To deliver an effective treatment, it is important to frequently monitor patients' stages of motivation and to monitor retention in treatment, as this is directly related to psychosocial outcomes (Horsfall et al. 2009; Alverson et al. 2000).

Factors that may affect outcomes include dissatisfaction for quality of life, peer pressure, and lack of an alternative daily occupation or of satisfying social network once abstinence is attained, all of these can make patients relapse into consumption (Alverson et al. 2000). Positive prognostic factors include availability of a regular and interesting activity (other than substance consumption); a decent housing; a loving, caring relationship with someone sober and sensible about patient's mental illness; and a positive relationship with a mental health professional. Negative prognostic factors are related to patient's history, especially having experienced dire poverty, violence, or abuse and being grown up with someone in the family or in the household affected by a substance use disorder or a severe mental illness (Alverson et al. 2000).

Treatment of dual diagnosis challenges what we know about treatment of both substance use disorders and psychosis. It needs great efforts and even greater flexibility. Nonetheless, treatment needs of the comorbid population need to be met in order to guarantee a subjective quality of life at least as high as that of their nondependent counterparts.

122.3 Conclusion

The aim of this chapter was to give a brief overview of the epidemiological relevance, the main clinical features, and the treatment options of the comorbidity of psychotic disorders and substance use disorders. However, a large proportion of the etiology and physiopathology of these two syndromes is still unknown, and recent progresses in the knowledge of their neurobiology have a scarce impact on clinical practice.

Actually, the cornerstone of dual diagnosis treatment seems to be the coordination in the treatment of psychosis and substances consumption. A bulk of evidence

has shown that this strategy is peculiar for the efficacy of various treatment options, with great relevance both at health delivery and at individual level. An effective coordination should be achieved, first of all, in physicians' and other carers' minds.

Besides the need of coordinated treatment, it is important that every person involved in the care of dually diagnosed individuals understands the role of substance consumption in patients' life, as treatment should be tailored to give patients the opportunity to conceive and live a reliable alternative to drug abuse.

However, the need for further knowledge in this field cannot be quenched. Evidence about treatment outcomes in substance consumption is still scarce and partly contradictory, mainly because of methodological issues and, probably, because of the effect of undetected confounders.

Therefore, the comorbidity of psychosis and substance use disorders is a largely unexplored field, in which the clinical practice greatly relies on experience, flexibility, and common sense, but such a situation must be an even stronger trigger to the development of methodologically reliable scientific evidence.

Attention Deficit/Hyperactivity Disorder and Substance Abuse

123

Frances R. Levin

Contents

Abstract

Although attention-deficit hyperactivity disorder (ADHD) has been increasingly diagnosed and treated in adult populations, adult ADHD in substance-dependent populations remains under-recognized. Converging data from epidemiologic and clinical samples show that adult ADHD is overrepresented among individuals with substance use disorders. This chapter provides information regarding the potential causes for this overrepresentation and factors that might lead to both under and overdiagnosis in individuals with substance use disorders, with attention paid to DSM-V criteria. While stimulants are considered a first-line treatment for adults with ADHD, it is less clear what the first-line pharmacologic or psychotherapeutic treatment approaches should be for adults with ADHD and

co-occurring substance use disorders. Data collected from several clinical trials suggest that under closely monitored conditions, stimulants can be used safely to treat co-occurring ADHD and substance use disorders. However, the findings are mixed regarding the efficacy of both nonstimulants and stimulants in treating ADHD in this comorbid population. Taken together, the available published studies do provide some guidance on how to best approach this patient population. Future avenues of research are discussed.

123.1 Introduction

ADHD is a developmental disorder characterized by inattention, hyperactivity, and impulsivity such that there is significant impairment in functioning (DSM-5 2013). It has been increasingly recognized that many children continue to have impairing symptoms into adolescence and adulthood warranting clinical attention. ADHD is highly inheritable and although it is relatively common in adults, it often goes undiagnosed and untreated (Kessler et al. 2006; Smith et al. 2009). Some of the potential reasons include (1) practicing adult psychiatrists and psychologists may not have been trained to recognize this condition, (2) patients present with other psychiatric conditions that become the focus of clinical attention, (3) the condition is not viewed as a major clinical concern, (4) the psychiatric symptoms associated with ADHD are incorrectly explained by other conditions (e.g., bipolar disorder, active substance use disorder).

Clearly, there is substantial morbidity associated with ADHD. Compared to those with ADHD, adults with ADHD have greater legal difficulties, motor vehicle accidents, higher divorce rates, increased workplace costs, and poorer life satisfaction (Jerome et al. 2006; Kessler et al. 2009; Mannuzza and Klein 2000; Wu et al. 2007). In a large adult population in an employer-sponsored health plan, patients with ADHD incurred substantially higher total annual health-care expenditures than those without ADHD (44,306 vs. $2,418; Hodgkins et al. 2011). Longitudinal studies have demonstrated that adults diagnosed with ADHD in childhood have lower-ranking occupational positions and formal schooling as adults (Mannuzza et al. 1997). Impulsive/hyperactive symptoms in childhood are associated with greater risk of early onset of substance use (Chang et al. 2012), abuse, and dependence in adolescence and adulthood (Elkins et al. 2007). Moreover, persistence of symptoms may increase the likelihood of substance dependence into adulthood, notably for both men and young women (Biederman et al. 2010; Mannuzza et al. 1993).

Recognizing the link between ADHD and substance abuse is relevant to clinicians in that substance abusers with ADHD who enter addiction treatment have been shown to have worse outcome than those without ADHD, despite more treatment exposure (Carroll and Rounsaville 1993; Levin et al. 2004; Wilens et al. 1998). Further, substance abusers with ADHD entering treatment have higher rates of other psychiatric comorbidity (e.g., depression) that may worsen treatment success unless these additional comorbidities are simultaneously addressed (Clure et al. 1999; Levin et al. 1998; Wilens et al. 1998). While there is increasing

evidence that ADHD is associated with increased rates of substance abuse (and vice versa), there remains modest empirical evidence regarding how to best treat this patient population.

This chapter will present epidemiologic data supporting the link between these disorders, possible etiologies to explain this link, some of the complicating issues associated with screening and diagnosing adult ADHD among those with and without substance use disorders, treatment options for this comorbid group, and the controversies that exist in treating active substance abusers with ADHD.

123.2 ADHD Features

123.2.1 Epidemiology

ADHD is a common childhood disorder with prevalence rates in the United States ranging from 5 % to 10 %. While it is estimated that up to 60 % of children continue to have impairing symptoms into adulthood, the minority continue to meet full DSM-IV criteria into adulthood (Biederman et al. 2000; Fayyad et al. 2007; Kessler et al. 2005; Mannuzza et al. 1993; Rasmussen and Gillberg 2000). While the prevalence rate commonly given for adult ADHD is 4.4 % (Kessler et al. 2006), a recent meta-analysis of six prevalence studies has found that this rate may be closer to 2.5 %. Regardless of the exact rate, the significant association of ADHD and substance use disorders is becoming increasingly clear. Specifically, data from the National Comorbidity Survey Replication Study (NCS-R) has found that adults with ADHD have higher rates of having a substance use disorder (SUD) than those without ADHD (15.2 % vs. 5.6 %). Similarly, individuals with SUD are more likely to have ADHD than those without an SUD (10.8 % vs. 3.8 %).

In clinical substance abuse treatment settings, this association may be more pronounced. In a meta-analysis, Oortmerssen et al. (2012) found that the overall rate of adult ADHD was 23.1 % (CI: 19.4–27.2 %), somewhat higher than the rates of ADHD observed in nonclinical samples. This disparity is likely explained by Berkson's bias (1946) which is the phenomenon that patients evaluated in clinical settings are more likely to have comorbid conditions. Individuals who are experiencing more psychological distress and the consequences of having multiple comorbidities are more likely to seek out treatment. Perhaps somewhat surprising from this meta-analysis was the finding that the rate of ADHD was lower in cocaine-dependent individuals compared to other drug-abusing groups. Based on the self-medication hypothesis, it might be expected that those with ADHD would more commonly seek out stimulants, such as cocaine, to ameliorate their ADHD symptoms rather than alcohol or other illicit drugs (Khantzian 1983, 1985). However, this finding does not necessarily negate this hypothesis. Individuals with ADHD may seek out chemical solutions that are readily attainable (such as nicotine, marijuana, or alcohol) and are perceived to lessen undiagnosed ADHD symptoms or associated dysphoria or anxiety.

Substance abusers with ADHD frequently have additional psychiatric disorders which further complicate the diagnosis and treatment of the ADHD. In the NCS

Replication, adults with ADHD were more likely to have major depression (OR = 2.7), dysthymia (OR = 7.5), bipolar disorder (OR = 7.4), or an anxiety disorder (OR = 3.7). Alternatively, for those with mood disorders or anxiety disorders, adult ADHD is overrepresented (2.9 and 2.8, respectively). Multiple comorbidities among those with ADHD have been observed in clinical samples of substance abusers (King et al. 1999; Levin et al. 1998). Moreover, Wilens et al. (2005) have found that the presence of ADHD and an additional substance use disorder significantly increases the risk of conduct disorder, a mood disorder, or an anxiety disorder. This is clinically relevant in the presence of these other Axis I conditions, the treatment of ADHD may be viewed as less important and not warrant clinical intervention (Kessler et al. 2006). In a review of the literature, Kooij et al. (2012) outline the main comorbid disorders associated with ADHD. These include (1) mood disorders, (2) substance use disorder, (3) impulse control disorders, (4) anxiety disorders, (5) sleep disorders, and (6) learning disabilities. While it is beyond the scope of this chapter to discuss these additional comorbidities, it is incumbent on the clinician to assess for these conditions or provide appropriate referral (i.e., to learning or sleep specialists) if necessary.

Recently, there has been increased recognition of the overlap of obesity and eating disorders (primarily bulimia, binge eating) among those with ADHD (Mikami et al. 2008; Pagoto et al. 2009). Notably, the impulsive symptoms associated with ADHD may be "driving" the eating disordered behavior rather than the inattentive symptoms. Impulsivity has been shown to predict problematic substance use and perhaps not surprisingly there has been a greater awareness of the neurobiologic and behavioral commonalities of obesity and substance use disorders (Acosta et al. 2008; Volkow et al. 2010). Similar to other comorbid conditions, the initial priority in treatment might be the condition or conditions warranting immediate clinical attention, but attention to multiple conditions simultaneously might be preferable when possible.

123.2.2 Etiology

The development of ADHD is influenced by multiple genes, non-inherited factors, and their interaction (Thapar et al. 2007). There is no single genetic or environmental cause of ADHD and the presence of risk factors does necessarily result in the development of the disorder. Chance events, such as non-inherited spontaneous genetic changes, may play a role. The population of individuals with ADHD are heterogeneous with regard to genetic risk factors and exposure to environmental risks. Genes may alter the sensitivity to environmental risks and inherited factors can also influence the probability to exposure to certain environmental risks, making distinctions between genetic and environmental risks difficult. While the evidence is strong that there is an inherited contribution to ADHD, how exactly that risk is passed on is unclear. Likewise, while there is evidence that environmental risk factors are important independent and modifiers of ADHD risk, which environmental risk factors are most important and how the mechanism by which they exert their influence on the development of ADHD is unclear.

First-degree relatives of those with ADHD are two to eight times more likely than the general population to develop ADHD (Faraone et al. 2005). Mean heritability estimates are approximately 79 % (Lichtenstein et al. 2010). High heritability estimates include the effect of genetic inheritance, but likely also shared environmental influences between parents and their children. The most robust evidence of association with ADHD has been the DRD4 variant of the D4 receptor gene (Gizer et al. 2009), which binds both dopamine and norepinephrine. Another dopamine receptor gene, DRD5, has also been associated with the risk of developing ADHD (Gizer et al. 2009). The dopamine transporter gene (DAT1) has been associated with the risk of ADHD and to interact with environmental factors such as maternal alcohol (Brookes et al. 2006) and cigarette use (Becker et al. 2008). The catechol-O-methyl transferase (COMT), which degrades dopamine, has been associated with conduct disorder in ADHD (Langley et al. 2010), but not antisocial behavior alone (Caspi et al. 2008), suggesting a specific role COMT variants in modifying ADHD.

There are a number of environmental risk factors associated with ADHD, including alcohol (Linnet et al. 2003), cigarette (Langley et al. 2005), and other substance use during pregnancy, but it is not known if these associations are causal or simply markers for other environmental risk factors not yet determined. Environmental toxins, such as lead (Nigg 2008) and polychlorinated biphenyls (PCBs) (Sagiv et al. 2010), have been studied as potential risk factors for ADHD with inconclusive results, as these toxins produce cognitive impairment that may mimic, rather than cause, ADHD.

Despite extensive research over the recent decades, the causes of ADHD remain largely unknown, even less is known about risk factors, other than treatment, that may modify outcome. There are no reliable biomarkers for ADHD and no prenatal genetic testing. Like all complex disorders, ADHD is not explained by any single risk factor alone and not all of those exposed to a given risk show the disorder. For clinicians, the most useful tool remains taking a careful family history, which might reveal diagnosed or undiagnosed cases of ADHD.

123.2.3 Diagnosis

For DSM-5 the adolescent adult diagnosis requires five or more of the nine symptoms of inattention and/or five or more of the nine symptoms of hyperactivity-impulsivity, whereas children are required to have six inattentive or six hyperactive-impulsive symptoms. The additional four criteria require (1) several symptoms prior to the age of 12; (2) several impairing symptoms in at least two settings; (3) clear evidence of the symptoms that interfere or reduce the quality in social, academic, or occupational functioning; and (4) symptoms that do not occur only during the course of schizophrenia or another psychotic disorder or are better explained by another mental disorder. Individuals may have one of the three subtypes: (1) predominantly inattentive, (2) predominantly hyperactive-impulsive, or (3) combined presentation (i.e., the individual meet five out of 9 symptoms of hyperactivity-impulsivity and five out of 9 symptoms of inattention).

Importantly, an adult cannot be diagnosed with ADHD if he/she did not have ADHD symptoms as a child. However, a full symptom count is not necessary. Importantly, ADHD cannot "come and go." If an individual met the criteria for ADHD but for the past 6 months dues not meet full criteria, then they are considered to be in partial remission if there remains clear impairment. If an individual never met full criteria, then they can be either diagnosed with other specified ADHD (if a reason is given by the clinician, such as never had adequate number of inattentive or hyperactive-impulsive symptoms) or unspecified ADHD (if no specific reason is given). However, for both diagnostic categories the ADHD symptoms have to produce significant distress or clear impairment in social, occupational, or other areas of functioning. These two diagnostic categories provide substantial leeway for clinicians to make an ADHD diagnosis. It remains unclear what percentage of clinicians would medically treat individuals who do not meet full diagnostic criteria but meet diagnostic criteria for these two latter categories.

123.2.3.1 Issues Complicating Adult ADHD Diagnosing with Special Focus on Substance Abusers

Several issues that are problematic when assessing individuals for ADHD include (1) the developmental appropriateness of the symptoms, (2) the age criterion, (3) determining what defines other specified or unspecified ADHD, (4) additional psychopathology, and (5) secondary gain. These issues are further complicated by the presence of a past or ongoing substance abuse problem. Because ADHD was initially viewed as a childhood disorder that adults "outgrew," some of the core symptoms of ADHD tend to be child specific. Certain symptoms, such as "can't stay seated," runs/climbs excessively, or "can't play/work quietly," are not easily endorsed by adults. Unless the interviewer is experienced in diagnosing ADHD and makes these symptoms more adult relevant, then it is likely that ADHD will be underdiagnosed. This has been somewhat mitigated in that unlike DSM-IV, DSM-5 now includes examples of these symptoms that are more adult relevant. For example, adults may report that they choose very active jobs rather than report that they "can't sit still." Further, an adult may not report that they "squirm" or "fidget" or "driven by a motor" but rather they are more likely to report being a "workaholic" or feel overwhelmed or overscheduled.

The age criterion has been modified by DSM-5. In DSM-IV, the full diagnosis of ADHD requires that impairing symptoms occur prior to the age of 7. For DSM-5, some symptoms need to be present prior to the age of 12. However, even with raising the age criterion, some patients might have difficulties with childhood recall. Similarly, parents or older family members may not recall elementary school behaviors. Report cards can sometimes pinpoint when the impairing symptoms began or if there were behavioral problems in early school grades. For substance abusers who may have estranged relationships with their parents, corroborative information may be particularly difficult to attain.

Expert clinicians such as Barkley and Biederman (1997) questioned the validity of the age criterion and growing evidence supported this (Faraone et al. 2006). Specifically, Faraone et al. (2006) found that adults with late-onset ADHD

(symptoms that began after the age of 7 but most commonly before the age of 12) had comparable psychiatric comorbidity, functional impairment, and familial transmission of ADHD as seen in those diagnosed with early onset ADHD, suggesting that there is concurrent validity of the late-onset variant with the full diagnosis. These data, along with others, supported the DSM-5 change in which the age criterion will be raised to under the age of 12. While some clinicians have probably been diagnosing adults with ADHD, even when the early onset of symptoms could not be determined, other clinicians may have not have diagnosed individuals if the age criterion was not met. The possible impact is that the relaxed criterion will lead to higher rates of detection, particularly among adult substance abusers, who may have cognitive difficulties due to alcohol or drug use recalling symptoms prior to the age of 7 (Bates et al. 2002; Pope et al. 2003).

The new diagnostic categories, other specified and unspecified ADHD (which replace the DSM-IV ADHD.NOS diagnosis), may also lead to some consternation. While clinicians can arrive at this diagnosis through various routes, perhaps the most common one is when an individual meets the full adult criteria except for the age criterion. However, other possibilities include meeting less than five inattentive or hyperactive/impulsive criteria adulthood. It remains a question of clinical judgment of whether three or four symptoms of inattention or hyperactivity-impulsivity should be present in adulthood to meet a clinical diagnosis of other specified ADHD. At present, if an adult had childhood or adolescent ADHD and currently has less than five symptoms in adulthood, then based on current DSM-IV criteria, the individual would be considered to be in partial remission. Further, what is not clear with the DSM-5 (and DSM-IV) criteria is what an adequate number of childhood symptoms is. At present, "several" symptoms in childhood are necessary to meet an adult diagnosis, rather than the full symptom count which is required when diagnosing a child. Also, in contrast to DSM-IV in which childhood symptoms had to be impairing, the symptoms only need to be present in DSM-5. It remains to be seen whether these changes will result in better identification of adult ADHD or overdiagnosis.

Kooij et al. (2012) noted that although pharmacotherapy is effective for adolescents and young adults with ADHD, prescribing by physicians of patients with ADHD drops substantially from age 15 to 21, with this decrease greater than the age-related decline in symptoms. To some degree this might be due to the incorrect assumption that fewer symptoms are associated with less severity and reduced need for medications. For substance abusers, the diagnosis may be complicated in that acute use or withdrawal from alcohol or other substances may "mimic" ADHD and lead to overdiagnosis. When used chronically, alcohol, marijuana, nicotine, and cocaine can produce restlessness and agitation during withdrawal (Grahman et al. 2003; Miller and Gold 1998). Both nicotine and cocaine withdrawal have been associated with concentration difficulties.

As mentioned previously, numerous psychiatric disorders are overrepresented among those with ADHD. The presence of these additional conditions can lead to both overdiagnosis. If the clinician incorrectly assumes that the observed ADHD symptoms are better accounted for by another psychiatric disorder, then the ADHD

may go undiagnosed. Alternatively, if there are psychiatric symptoms that are better explained by another disorder but attributed to ADHD, then this will lead to overdiagnosis. In many cases, it is not entirely clear unless the patient is monitored over time. From a practical perspective, when there is some diagnostic confusion, the clinician makes his/her best education guess and treats the condition warranting clinical attention. However, in many instances there might be ADHD along with depression and/or anxiety requiring more complicated therapeutic regimens. Not surprisingly, the addition of a substance use disorder further complicates the diagnostic assessment. For example, both hypomania and ADHD share excessive talkativeness, restlessness, racing thoughts, impulsive behaviors, difficulty with concentration, decreased attention and distractibility, and mood swings/anger outbursts. Not surprisingly, because of the numerous overlap in symptoms, distinguishing whether an adult has ADHD, hypomania, or both conditions can be quite difficult. This can be mitigated by the presence of fluctuating episodic mood swings or psychosis, symptoms not associated with ADHD alone.

Notably, ADHD is often underdiagnosed in substance abuse treatment settings not because of difficulties distinguishing ADHD from other conditions but rather because of the lack of awareness or training in diagnosing ADHD. These patients may attribute their impatience, restlessness, or procrastination to being "hot-headed," "easily bored," or "lazy." Further, many of the consequences of ADHD (such as work failure and poor educational attainment) also are associated with substance use disorders (Kalbag and Levin 2005).

While underdiagnosis is common, there are several reasons why adolescents and adults might "feign" ADHD symptoms, leading to overdiagnosis. Because it is a clinical diagnosis, it is possible for individuals to endorse ADHD symptoms and meet criteria for ADHD, even when they do not suffer from the disorder. Being diagnosed with ADHD might allow increased time for test taking or special accommodations in the classroom. Athletes, both nonprofessionals and professionals, might report having ADHD symptoms in order to obtain stimulants, with the hope of improving their performance. Similarly, high school and college students may report having ADHD symptoms to enhance their academic performance or combat fatigue when they need to stay awake to study for finals or finish coursework. Moreover, some individuals, particularly those with underlying substance use disorders, may feign ADHD symptoms in order to procure a stimulant prescription to get high.

Another reason for overdiagnosis is mistakenly assuming that inattentive or hyperactive symptoms are due to ADHD rather than medical conditions such as sleep apnea, anemia, and thyroid problems (Kooij et al. 2012; Murphy and Gordon 2006). Finally, inadequate consideration to the impairment criterion may lead to overdiagnosis. There are many times when individuals can be inattentive or impulsive and demonstrate many of the symptoms associated with ADHD. However, individuals with ADHD have substantial impairment from these symptoms. Examples of impairment are critical to obtain during the comprehensive interview. For substance abusers this may be difficult since impairment may be due to the addictive behavior rather than the ADHD symptoms.

Moreover, for active substance abusers, the diagnosis may be complicated in that acute use or withdrawal from alcohol or other substances may "mimic" ADHD and lead to overdiagnosis. When used chronically, alcohol, marijuana, nicotine, and cocaine can produce restlessness and agitation during withdrawal (Grahman et al. 2003; Miller and Gold 1998). Both nicotine and cocaine withdrawal have been associated with concentration difficulties. Preferably, if a period of abstinence can be attained, it may help tease out ADHD symptoms from those that are substance induced.

There are several diagnostic instruments that have been modified for use in adults or have been specifically designed for adults to attain an adult ADHD diagnosis. These include the Kiddie Schedule for Affective Disorders and Schizophrenia for School-Age Children-Epidemiological Version (Kiddie SADS-E; Orvaschel 1985); the Structured Clinical Interview for DSM-IV, Childhood Version (KID-SCID; Hien et al. 2001); the Adult ADHD Clinical Diagnostic Scale (ACDS) V1.2 (Adler et al. unpublished instrument); and the Conners' Adult ADHD Diagnostic Interview for the DSM-IV (CAADID; Epstein et al. 2001). These instruments attempt to improve diagnostic accuracy by including adult symptoms that are developmentally appropriate and provide a structured approach ensuring that all of the ADHD criteria are met. While these instruments have good face validity, their reliability has not been evaluated in active substance abusers.

123.2.4 Screening for ADHD

Although the diagnosis of ADHD requires a comprehensive clinical assessment, screening instruments can prove useful in identifying those who might have ADHD. Commonly used instruments include the Brown Attention-Deficit Disorder Rating Scale for Adults (Brown 1996), the Wender Utah Rating Scale (WURS; Ward et al. 1993), the Conners' Adult ADHD Rating Scales (CAARS; Conners et al. 1999), the ASRS-v1.1 (Adler et al. 2006), the ADHD Rating Scale (Murphy and Barkley 1996), and the Attention-Deficit Scales for Adults (ADSA; West et al. 2003). The Brown scale has good psychometric properties but does not include questions about hyperactive symptoms. The WURS is often used for screening adults for childhood ADHD symptoms and is based on Wender Utah Criteria for ADD (Wender et al. 1985). The CAARS has the advantage of allowing for self-report and observer report and is available in screening, short, and long versions. These scales include core DSM-IV symptoms but also associated ADHD symptoms such as mood dysregulation and low self-esteem. The ADSA is one of the few instruments that have been evaluated in substance-abusing populations and found to have clinical utility in identifying ADHD (West et al. 2003). The Adult Self-Report Scale (ASRS; 18) has the convenience of being short (six items) and has reasonable psychometric properties. The ADHD Rating Scale – IV (Murphy and Barkley 1996) incorporates the 18 ADHD symptoms and requires the individual to self-rate the frequency/severity of symptoms.

Until recently, most of these instruments have not been tested in substance-abusing populations. Using the ASRS-V1.1, Daigre et al. (2009) found that it had

good sensitivity (87.5 %) in a substance-abusing population. As mentioned above, the ADSA has also been evaluated in active substance abusers and was found to have fairly good sensitivity (0.71) and specificity (0.82). The ASRS-V1.1 is substantially shorter than the ADSA (6 vs. 54 items), suggesting it might have greater utility in busy, clinical settings. Recently, a study was conducted to assess the clinical utility of three of the short, commonly administered instruments (e.g., the WURS, Adult ADHD Rating Scale, and the ASRS-V1.1) in treatment-seeking cocaine abusers (Dakwar et al. 2012). The psychometric properties of the instruments were tested by comparing the sensitivity, specificity, and positive and negative predictive values of these instruments with the Conners' Adult ADHD Diagnostic Interview for DSM-IV (CAADID; Epstein et al. 2001) serving as the "gold standard." All three instruments demonstrated adequate sensitivity, specificity, and positive/negative predictive values, with the WURS having the greatest sensitivity and the Adult ADHD Rating Scale performing best on predictive parameters. While these findings suggest that standard ADHD instruments may be reasonably applied to screen for ADHD in active substance abusers, the studies conducted to date have been rather small and did not control for acute intoxication or withdrawal.

Another screening approach that might be considered is to use neurocognitive testing or other physiologic findings to identify those with ADHD. While there are numerous neuropsychological tests, neuroimaging findings, and electrophysiologic data that have found differences between those with and without ADHD, none of these tests have adequate positive predictive value (i.e., if the result is positive, then the individual has the disorder) to be used as a cost-effective method to accurately identify those with ADHD. To date, continuous performance tasks have demonstrated the most reasonable sensitivity and specificity (Gordon et al. 2006), but cannot be used to make an ADHD diagnosis. Moreover, while some practitioners include neurocognitive tests as part of their ADHD assessment, it is not required or necessary in order to make an ADHD diagnosis. Given that chronic alcohol and drug abuse has been shown to alter cognitive functioning, it remains dubious to use these tests to screen substance abusers for ADHD. However, this does not negate the clinical utility of these approaches to better understand the pathophysiology of ADHD and/or substance abuse and the potential remediable areas of cognitive deficits that an individual patient may have as a result of his/her ADHD.

123.2.5 Abuse Potential and Misuse of ADHD Medications

Prescription amphetamine misuse peaked in the last 1990s but still remains a problem warranting attention. With the substantial increase in stimulant prescriptions, misuse and diversion of medication for nonmedical purposes have become a considerable clinical concern, particularly on college campuses. Wilens et al. (2008) define misuse and diversion of ADHD medications in the following manner:

> Misuse includes taking ADHD prescriptions not prescribed to the individual or talking medication differently than they were prescribed (e.g., more than prescribed, taking alcohol or other drugs). Diversion of stimulants is the transfer of ADHD prescription medications from one individual who does have a prescription to another individual who does not have a prescription. This transfer includes the selling, trading, or giving away prescription medication.

While some surveys include concurrent use of alcohol or drugs with appropriately prescribed stimulants for AHD as "misuse," other surveys do not. This can lead to wide variability in misuse rates. Further, differences in sample attainment and manner in which questions are asked can also lead to variability in rates of misuse. Nonetheless, surveys do provide an indication of how widespread prescription stimulant misuse and diversion occurs. The 2010 National Survey on Drug Use and Health, a large epidemiologic survey conducted in the United States, found that 0.4 % of Americans aged 12 years or older reported current (last 30 days) nonmedical use of prescription stimulant medications (2010). While these rates are substantially lower than current nonmedical use of pain relievers or tranquilizers (2 % and 0.9 %, respectively), the risks of prescribing stimulant medications in a population vulnerable to misuse and abuse must be considered carefully (i.e., college students abusing alcohol or other drugs).

In a comprehensive review of 21 studies representing over 113,000 subjects, the rates of past year nonprescribed stimulant use ranged from 5 % to 9 % in grade school- and high school-age children and 5–35 % in college-age individuals (Wilens et al. 2008). In a large random survey of undergraduates at a large public American university, 54 % of student misusing stimulants reported using stimulants to concentrate, 43 % for alertness, and 43 % to get high (Teter et al. 2005). This is not simply a problem in the United States. In a survey with 307 fraternity members in the United Kingdom, 55 % reported nonmedical use of stimulants. The reasons given for stimulant misuse included the following: to stay awake (74 %), to concentrate on work (59 %), to help memorize (30 %), and to stay awake and have fun (17 %). Perhaps most concerning was that 90 % reported stimulants were "easy" or "very easy" to obtain and 89 % thought stimulants were "not dangerous at all" or "slightly dangerous."

Notably, those who use stimulants are more likely to use nicotine, alcohol, or other drugs (Wilens et al. 2006). Further, most misuse of stimulants was by oral administration, although intranasal use has been commonly reported (White et al. 2006). Repeatedly, surveys have found that the vast majority of misused stimulants are immediate preparation rather than extended-release preparation (Bright et al. 2007; Kroutil et al. 2006; Wilens et al. 2006). In an adult sample prescribed stimulants for their ADHD, most with substance abuse histories, misuse of IR preparation occurred substantially more frequently than those using ER preparations alone or both IRB and ER preparations (81 % vs. 16 % and 3 %, respectively).

Importantly, numerous surveys that document high rates of misuse often do not adequately address the motivation or context of the "misuse." For example, while some studies report that a substantial minority of individuals who are prescribed stimulants for their ADHD misuse their medications (Jardin et al. 2011), until recently, the reasons for misuse have not been adequately explored.

Two surveys conducted among US college students prescribed stimulants for their ADHD found that misuse was more common among those that used alcohol and other drugs (Jardin et al. 2011; Rabiner et al. 2009). While it is somewhat reassuring that most students used their ADHD medications as prescribed, misuse and diversion were not infrequent (Rabiner et al. 2009). However, the primary motives for misuse were to concentrate better while studying, to be able to study longer, to feel less restless while studying, and to concentrate better in class. Much less common reasons included to get high or to counteract the effects of other drugs. Rabiner and colleagues posit that undergraduates with ADHD might not perceive their treatment to be adequate and may be "underdosed." It remains unclear whether the prescriptions written for college students meet their needs for symptom coverage required into the early morning hours for studying or finishing papers.

For some students who misuse stimulants but are not prescribed stimulants for ADHD, expert clinicians have speculated that some of these adolescents and young adults may be self-medicating undiagnosed ADHD (Rostain and Ramsay 2006; Upadhyaya et al. 2005). Upadhyaya et al. (2005) found that a substantial group of college students who misuse stimulants had ADHD symptoms, although they were not diagnosed with ADHD. While it may seem that stimulant use to fight fatigue in college or to self-medicate undiagnosed or untreated ADHD might be of lesser clinical concern than stimulant use to "get high," this is still worrisome because repeated stimulant use that is not medically monitored might lead to problematic use. Further, there may be underlying cardiac problems or an untreated psychiatric illness (e.g., bipolar disorder) that might be exacerbated by stimulant use.

As noted above, several surveys suggest that long-acting preparations have less abuse potential. There are several explanations for this. Many of the long-acting preparations are difficult to crush and thereby enhance absorption. While immediate-release methylphenidate can be crushed and snorted or dissolved in water and injected, this is not possible with various formulations such as the osmotic release oral system (OROS) methylphenidate or lisdexamfetamine (LDX). OROS-methylphenidate (Concerta) uses an osmotic delivery system in which the tablet is coated with immediate-release methylphenidate for initial dosing, and the long-acting component is delivered by an osmotic pump that slowly releases methylphenidate (Daughton and Kratochvil 2009). LDX, a prodrug, is a therapeutically inactive molecule until it is converted to l-lysine and active d-amphetamine and is associated with a longer duration of effect and reduced abuse potential (Jasinski and Krishnan 2009). Volkow et al. have shown that drug liking is associated with the rapid rise of plasma stimulant levels and brain concentration (Parasrampuria et al. 2007; Volkow et al. 1995). Therefore, it is not surprising that there is less diversion with long-acting formulations, with slower onset of action and lower peak plasma levels, than immediate-release preparations.

Under controlled conditions, the lower abuse potential of long-acting preparations has been confirmed in adults without substance abuse histories, those with histories of drug abuse, and active substance abusers. Kollins et al. (1998) found that healthy adult controls were more likely to report "good drug effects" with short-acting methylphenidate compared to sustained-release methylphenidate. In a subsequent

study with healthy adult controls, therapeutic oral doses of IR-methylphenidate were compared to OROS-methylphenidate. Those who received IR-methylphenidate reported "liking the effect" more than those with receive OROS-methylphenidate (Spencer et al. 2006).

In a double-blind, placebo-controlled study in adults with drug abuse histories, low and high doses of IR- MPH (50 and 90 mg) and OROS-MPH (54 and 108 mg) were administered. While the lower and higher dose of IR-MPH produced greater subjective effects than placebo, only the higher dose of OROS-MPH produced greater subjective effects than placebo (Parasrampuria et al. 2007). Another study in adults with stimulant abuse histories and intravenous doses of LDX and IR-d-amphetamine was compared to placebo. IR-d-amphetamine, but not LDX, produced greater subjective effects than placebo (Jasinski and Krishnan 2009). When oral doses are administered, low doses of LDX (50 and 100 mg) did not produce greater subjective effects than placebo. However, the highest dose of LDX (150 mg) produced greater drug liking than placebo, suggesting that high doses might be more likely to be abused (Jasinski and Kovacevic-Ristanovic 2000).

Another formulation that has been tested for its abuse potential is the methylphenidate transdermal system (MTS; Daytrana). The MPH patch (Daytrana) contains a multipolymeric adhesive layer attached to a transparent backing. MPH is slowly released with peak levels achieved 7–9 h after the patch is applied (Daughton and Kratochvil 2009). In a small sample of stimulant abusers, a double-blind, crossover design was conducted in which the MPH patch was applied to an unheated or heated arm or to the buccal mucosa and compared to placebo as well as subcutaneous methylphenidate. Regardless of where the MTS was applied, MTS produced greater positive subjective effects than the placebo and was comparable to subcutaneous methylphenidate (Jasinski and Krishnan 2009). However, because MTS was not compared to an immediate-release methylphenidate preparation, it cannot be definitely determined whether the patch has less abuse potential than an IR-MPH formulation.

These finding suggests that long-acting stimulants are preferable for populations at risk for substance abuse, but positive subjective effects can be elicited by changing the route of administration or taking more than prescribed. To date, there are limited data assessing the safety or abuse potential of stimulants in substance abuse populations with ADHD. In a laboratory study in nontreatment-seeking cocaine abusers with ADHD, participants were maintained on low or high doses of sustained-release methylphenidate or placebo and were administered intravenous cocaine. Under controlled laboratory conditions, the combination of intravenous cocaine and sustained-release MPH did not produce any untoward events. The high dose MPH group produced less (rather than greater) subjective effects than placebo when cocaine was administered. Moreover, in a subsequent study in which participants were allowed to self-administer cocaine while maintained on low and high doses of MPH or placebo, those maintained on the high dose MPH were less likely to self-administer the high dose of cocaine compared to those maintained on placebo (Collins et al. 2006). This is notable because it suggests that the sustained-release MPH preparation does not enhance and perhaps reduces the likelihood of greater

cocaine use among cocaine abusers with ADHD. However, this small study did not compare the abuse potential of short- and long-acting formulations to nonstimulants that are used to treat ADHD.

There remains much consternation regarding whether or not to prescribe stimulants for active substance abusers with ADHD. While the Collins et al.'s (2006) study has obtained some reassuring data regarding the use of sustained-release MPH in active cocaine users, a comparison of subjective effects and self-administration of immediate- and long-acting stimulant formulations and nonstimulants used to treat ADHD (e.g., clonidine extended release, atomoxetine) in active substance abusers with ADHD has not been conducted.

Perhaps not surprisingly, atomoxetine has been repeatedly shown to have less abuse liability than stimulant preparations in healthy controls and occasional drug users (Heil et al. 2002; Lile et al. 2006) and in active stimulant abusers (Jasinski et al. 2008). While this might suggest that atomoxetine should be the first-line treatment, there are some limitations with its use. Compared to stimulants, atomoxetine may take several weeks before it adequately reduces ADHD symptoms, side effects often occur prior to noticeable clinical improvement, and it has not been shown to be as effective as stimulants in treating those with ADHD (Faraone and Glatt 2010).

123.2.6 Pharmacologic Treatments for ADHD

123.2.6.1 Stimulant Medications

Amphetamine analogs and methylphenidate are the stimulant medications and are first-line treatments for both children and adult ADHD in the United States. Methylphenidate is a piperidine derivative that is structurally related to amphetamine, whose mechanism of action is primarily due to dopamine and noradrenergic reuptake blockade in the striatum (Brunton et al. 2011). Amphetamine stimulates the cerebral cortex and the reticular activating system primarily by enhancing dopamine release, although it also blocks dopamine reuptake (Brunton et al. 2011). Both methylphenidate and amphetamine analogs are available in many immediate-release and extended-release preparations. Lisdexamfetamine, a prodrug, was FDA-approved initially for childhood ADHD and more recently for adult ADHD. Because it is a prodrug, it is a therapeutically inactive molecule until it is converted to l-lysine and active d-amphetamine and is associated with a longer duration of effect and reduced abuse potential. Side effects most commonly associated with amphetamine and methylphenidate administration include insomnia, emotional liability, nausea/vomiting, nervousness, palpitations, elevated blood pressure, and rapid heart rate. Rare but serious adverse effects include severe hypertension, seizures, psychosis, and myocardial infarction.

123.2.6.2 Nonstimulant Medications

Two nonstimulant medications have been approved for ADHD. Atomoxetine is FDA-approved for pediatric and adult use and guanfacine-extended release is

FDA-approved for pediatric use. All other nonstimulant medications, such as bupropion, desipramine, and modafinil, are "off-label" for ADHD and are generally considered second- or third-line treatments. Atomoxetine, a centrally acting noradrenergic reuptake inhibitor (Adler et al. 2005; Michelson et al. 2003), has the advantages of a lower abuse potential than stimulants, has long-lasting therapeutic effects, and is not a controlled substance. However, the initial therapeutic effects are gradual, sometimes taking 2–6 weeks to achieve therapeutic efficacy. This contrasts the onset of action of stimulants which can show clinical effects shortly after the first dose (Daughton and Kratochvil 2009). Common side effects of atomoxetine include sedation, appetite suppression, nausea, vomiting, and headache. Rare but serious side effects reported in children and adolescents include increased suicidal ideation and hepatotoxicity. While clinically effective, in a meta-analysis, atomoxetine had a medium effect size compared to large effect sizes for immediate-release and sustained-release stimulants (Faraone and Glatt 2010).

Guanfacine-extended release, an alpha-2 agonist, has been shown to be nearly as effective as stimulants in youth (Faraone and Glatt 2010), and although it has not been as extensively studied in adults, guanfacine appears efficacious for adult ADHD symptoms (Taylor and Russo 2001). Commonly, guanfacine is used adjunctively with stimulants to further reduce ADHD symptoms among those that have had a partial response to stimulants (Spencer et al. 2009). Common side effects of guanfacine include somnolence, headaches, sedation, and blood pressure decreases (Connor et al. 2012; Sallee et al. 2009). ADHD improvements have been observed after 1 week of medication administration and may be particularly useful for those with comorbid sleep and tic disorders (Sallee et al. 2009; Wolraich et al. 2005).

Several antidepressants, such as desipramine, bupropion, and venlafaxine, have been evaluated for ADHD, and while they have some efficacy in reducing ADHD symptoms, they are less effective than stimulant medications (Wolraich et al. 2005). Bupropion has been well studied and has shown efficacy for both children and adults with ADHD, albeit less so than stimulant medications (Daughton and Kratochvil 2009; Faraone and Glatt 2010). Common side effects include irritability and insomnia. Drug-induced seizures increase significantly at doses greater than 450 mg/day.

Clonidine, a noradrenergic alpha-2 agonist antihypertensive agent, has been shown to be effective for the treatment of ADHD but unlike guanfacine has not been FDA-approved (Connor et al. 1999). Modafinil, a novel wake-promoting agent that is FDA-approved for narcolepsy and shift work sleep, has been shown to improve ADHD symptoms in children, adolescents, and adults, albeit less so than stimulant medications (Biederman et al. 2006; Swanson et al. 2006; Taylor and Russo 2000). Although modafinil has some stimulant-like properties (e.g., promoting wakefulness), it has minimal reported abuse potential reported and has not been shown to be as effective as traditional stimulant medications and therefore was grouped with the nonstimulant second-line agents.

There are certain instances where nonstimulant medications would be considered first line, such as if a motor tic disorder is present or in the case of cardiovascular disease. While most treatment guidelines suggest avoiding nonstimulants for

those with a past or current substance abuse, there are certain clinical situations when it might be reasonable to use stimulants, particularly long-acting preparations, under controlled conditions.

123.2.6.3 Treatment of SUD Using Stimulants

Given that stimulants and several nonstimulant medications have been shown to be efficacious for ADHD, it is of clinical interest whether some of these medications are independently useful in treating substance use disorders. While this topic is beyond the scope of this chapter, certain conclusions can be drawn from the empirical literature. For well-selected patients with cocaine dependence or methamphetamine dependence, stimulant replacement can be safely given. There are very few instances of cardiovascular adverse events when agonists are given to a carefully screened cocaine abusers. Clinical trial eligibility excludes individuals at high medical and psychiatric risk and if introduced into the wider treatment community, more adverse events would likely to occur.

To date, the most promising results are with the higher-potency amphetamine analogs, or a combination of a dopaminergic intervention with a contingency management behavioral intervention (Mariani and Levin 2012). Notably, there are positive results from single-site trials, suggesting that stimulants, particularly amphetamines, may reduce cocaine use (Grabowski et al. 2004; Mooney et al. 2009). Modafinil and bupropion have also some clinical utility in specific subpopulations of cocaine and other stimulant abusers, but more work targeting these subgroups is needed (Anderson et al. 2009; Dackis et al. 2003; Elkashef et al. 2008).

Prescribing stimulants to active substance abusers needs to be handled cautiously and skillfully. Within a clinical trial, there is close monitoring and medication is administered in small quantities. In community settings, misuse or diversion would be more likely to occur and strategies on how to manage these risks are needed prior to initiating a course of stimulant therapy. While many clinicians avoid using stimulants in adolescents and adults with active substance abuse, there is a compelling rationale that by treating ADHD symptoms, substance use may diminish or cease, particularly if the stimulant has direct agonist effects on the substance being abused. As in the treatment of substance abusers with other psychiatric disorders, concurrently treating the symptoms of both the substance use disorder and the ADHD is more likely to produce a positive treatment outcome than treating one disorder alone. As more data are obtained, the utility of stimulants as an agonist approach will be determined and how to prescribe stimulants to active substance abusers will be further refined. To date, most recommendations are clinically derived with suggested approaches provided below.

123.2.7 Pharmacotherapy Selection for ADHD and Co-occurring SUD

The common wisdom is to avoid stimulants in substance abusers with ADHD. However, it remains unclear why this approach is so strongly endorsed. While it is

true that adolescents and college students who are prescribed stimulants are more likely to use their medication with other drugs of abuse or divert their medication, the majority do not. Further, there is no evidence that adults who are being treated for the substance abuse and ADHD simultaneously routinely abuse prescribed stimulants when closely monitored. Thus, it is preferable to examine the available data, albeit limited, to help guide clinical practice.

To date, there have been ten outpatient, double-blind, placebo-controlled treatment trials conducted in substance-dependent individuals. One trial included those that were primarily alcohol dependent (Wilens et al. 2008), one focused on nicotine-dependent individuals (Winhusen et al. 2010), two focused on primarily cocaine dependent (Levin et al. 2007; Schubiner et al. 2002), one focused on cocaine dependent while maintained on methadone (Levin et al. 2006b), one targeted methamphetamine abusers (Konstenius et al. 2010), and two entered patients with various substance dependencies but not one primary substance of abuse (Riggs et al. 2004; Thurstone et al. 2010). Four of the trials evaluated a nonstimulant medication. One trial evaluated bupropion in cocaine-abusing methadone-maintained ADHD patients (Levin et al. 2006b) and another evaluated atomoxetine in cannabis-dependent ADHD individuals (McRae-Clark et al. 2010); bupropion was not found to be helpful in reducing ADHD symptoms or substance use, while atomoxetine was better than placebo on ADHD secondary outcome measures, but not marijuana use. However, another trial found that atomoxetine was superior in reducing ADHD symptoms in alcohol-dependent individuals and outperformed the placebo group on some secondary alcohol outcome measures (Michelson et al. 2003).

Not surprisingly, because methylphenidate is a commonly used first-line treatment for ADHD, it has been studied more extensively. While methylphenidate showed promise in uncontrolled trials in reducing ADHD symptoms and cocaine use (Levin et al. 2006a; Somoza et al. 2004), double-blind trials have been mixed. In one trial, methylphenidate was superior to placebo in improving ADHD symptoms on some measures, but not others, and was not better than placebo in reducing cocaine use (Schubiner et al. 2002). In another trial, results were negative for both ADHD and cocaine use; although on a secondary outcome measure for cocaine (proportion of cocaine-positive urines over time), sustained-release methylphenidate was superior to placebo (Levin et al. 2006a). Finally, two recent trials evaluated OROS-methylphenidate for substance-abusing adolescents and adult nicotine-dependent individuals with ADHD. In the nicotine-dependent adults, OROS-methylphenidate plus a nicotine patch was superior to placebo plus a nicotine patch in reducing ADHD symptoms but not smoking cessation (Winhusen et al. 2010). The other trial conducted in adolescents found that OROS-methylphenidate was superior to placebo on some ADHD outcome measures, although not the primary one, but again, was not superior to placebo in reducing substance use (Riggs et al. 2011). An earlier trial with pemoline in adolescents found that pemoline was better than placebo in reducing some ADHD outcome measures but not substance use.

Importantly, none of these trials observed misuse or abuse of the prescribed medications. In fact, laboratory data suggest that amphetamine administration reduces cocaine choice in nontreatment-seeking cocaine-dependent individuals

(Rush et al. 2010). Despite concerns that prescription stimulant use may lead to increased craving for cocaine or amphetamine use, this effect has not been reported in the controlled clinical trials conducted to date. Taken together, the clinical trials using methylphenidate (and pemoline) have been mixed in reducing ADHD symptoms, with perhaps a "signal" in reducing cocaine use. Atomoxetine outperformed placebo in reducing ADHD symptoms and alcohol use in alcohol dependent but has not shown superiority over placebo with cannabis-dependent individuals. While prescription stimulant medications may be diverted for nonmedical use, clinical data suggests that the use of stimulants in a structured therapeutic context can be accomplished safely. Possible reasons for the modest response to medications for substance abusers with ADHD include (1) inadequate dosing, (2) less responsiveness if actively using substances, (3) lack of abstinence to clarify the ADHD diagnosis, (4) use of older, poorly absorbed sustained-release stimulant formulations, (4) additional comorbidities, and (5) poor compliance. Until these issues are addressed, it will be difficult to draw conclusions based on the available literature. Notably, there have been no published clinical trials evaluating amphetamine analogs for adult substance abusers with ADHD, despite a recent meta-analysis suggesting that amphetamines outperform methylphenidate products.

123.2.8 Non-pharmacologic Interventions for ADHD and Possible Approaches for Those with SUD

Whereas there is a fairly large literature evaluating various pharmacologic interventions for adult ADHD (and a much larger one for childhood ADHD), there remains limited data regarding the use of psychotherapies for ADHD adults and no trial has evaluated psychotherapy alone for ADHD adults with substance abuse. Common approaches used for childhood and adult ADHD and substance abusers include (1) contingency management, (2) cognitive-behavioral interventions, and (3) integrated pharmacologic and behavioral treatments. While contingency management approaches have been used in children and are highly successful when applied to adult substance abusers (Budney et al. 2006; Higgins et al. 1991), application of a contingency system for adult ADHD behaviors is not readily apparent. More often, it is often the family members, colleagues, or significant others who change their behaviors to accommodate the individual with ADHD. For example, a spouse may take charge of the finances and taxes or a co-worker or assistant will help organize their ADHD colleague's schedule or other work-related activities. At present, there have been no contingency management strategies that have been developed for ADHD adults with substance abuse.

Cognitive-behavioral therapy is an integral component of many addiction treatment programs, but it is not clear whether these approaches would work as well for those with comorbid ADHD. Cognitive interventions for children with ADHD were evaluated in the Multimodal Treatment Study of Children with ADHD (MTA Study 1999), and it was found that combined medication and behavioral treatment was not superior to medication management for core ADHD symptoms, but may have

provided modest advantages for non-ADHD symptom and positive functioning outcomes (Jensen et al. 2007). To date, there have been seven controlled psychotherapy trials conducted in adults with ADHD in which cognitive-behavioral, metacognitive therapy, and cognitive remediation have been studied (Vidal-Estrada et al. 2012). For all of these studies, some if not all of the patients were receiving ADHD medications. Often the patient samples had a partial response to medication and still had impairing ADHD symptoms. One of these studies was conducted in 86 adults with ADHD. Individuals were randomly assigned to either 12 weeks of cognitive-behavioral therapy or relaxation with educational support. Notably, treatment retention was high (92 %) and 81 % completed the follow-up assessments. Patients randomized to the 12 weekly individual CBT sessions had significant greater reduction in ADHD symptoms and improvements were maintained 6 and 12 months after study completion (Safren et al. 2010). This study is clinically relevant to substance abusers because their therapeutic response to ADHD medication is often modest. The addition of CBT that targets both the ADHD symptoms and substance abuse is likely to lead to enhance the benefits associated with pharmacotherapy.

Working with substance abusers with ADHD, Aviram et al. (2001) found that it is useful for therapists to identify the commonalities between the cognitive, behavioral, and physiologic symptoms associated with ADHD and those associated with drug use. Impairments from ADHD may lead to diminished self-esteem and depression, which in turn, may lead to drug use and further diminish the patient's coping abilities. The deficits must be countered in treatment by providing tangible coping skills and techniques, many of which are incorporated into the cognitive behavioral treatment model (ASAM 2009). This integrative approach has been applied successfully to substance abusers with bipolar illness (Weiss et al. 2007) and likely to have utility for adult substance abusers with ADHD.

123.2.9 Clinical Management of ADHD and Co-occurring SUD

Most clinical recommendations suggest that nonstimulants should be the first-line treatment for substance abusers with ADHD. However, it is often not clear whether this applies to anyone with a substance use history or to those with current substance abuse. Often, what is lost in these assertions is (1) what to do when a nonstimulant has not been effective for ADHD or cannot be tolerated for a particular patient; (2) the reality that nonstimulants have clinical utility but are often not as efficacious as stimulants; (3) the laboratory and clinical data findings that demonstrate that long-acting stimulants have lower abuse potential than immediate-release stimulants, albeit some potential for abuse; and (4) that there has been no evidence of abuse of long-acting stimulants prescribed for ADHD in substance abusers enrolled in clinical trials. While it is a clinical reality that some misuse and diversion will occur, particularly in substance abusers, this risk needs to be balanced against the risk of untreated or inadequately treated ADHD. Regardless of what class of medication is chosen, the appropriateness of the medication choice

should be regularly assessed based on the patient's clinical response and overall functional status. While it is not unreasonable to use atomoxetine or extended-release guanfacine as first-line treatments for active substance abusers with ADHD, the avoidance of stimulants, particularly long-acting formulations, may prevent a substantial number of individuals from receiving adequate treatment.

Although there are no clear-cut data to produce clinical guidelines, we would propose classifying patients with ADHD and substance abuse into three groups to help guide clinical choices. First, it is important to determine whether the patient has a current or past SUD. A remote history of substance abuse probably represents a low-risk group. However, patients, and when appropriate families, should be advised that their SUD history may increase their risk. Given that there is an increased risk, physicians might consider using extended-release preparations, monitor prescription renewal times, and closely monitor for evidence of substance use.

As described earlier, patients with ongoing substance use but not currently meeting criteria for abuse or dependence probably are at moderate risk for misuse (such as taking prescription medication in conjunction with other substances of abuse) or diversion of prescription stimulants. Compared to the low-risk group, there is a need for more frequent office visits, urine toxicology testing, and close attention to substance use patterns. For these patients, nonstimulants may be a reasonable first choice, but if stimulants are considered, then extended-release preparations are preferable. Patients with an active SUD represent a high-risk group in that they are at elevated risk for misuse or diversion of prescription stimulant treatment of ADHD. For this group, nonstimulant medications are likely to be chosen, but this should not preclude the use of stimulant medications in certain circumstances. For example, an extended-release stimulant may be indicated in an intensive structured and monitored outpatient treatment program (Riggs and Winhusen 2009; Winhusen et al. 2010).

There are several safeguards that may help reduce the likelihood of misuse and diversion. These include (1) maintaining careful prescription records, (2) frequent patient visits, and (3) use of extended-release formulations. It is important to explain to patients that urine toxicology screens will be conducted randomly, and if the patient does not show a significant reduction in alcohol or drug use, other treatment strategies will be needed. Further, patients should be encouraged to regularly take their medication rather than on an as-needed basis, to avoid intermittent palliation of symptoms. "Red flags" suggesting that there may be misuse, diversion, or abuse of prescription stimulants include frequent lost prescriptions or discordant pill counts, demands for immediate-release preparations, escalating doses, physiologic toxicology (hypertension, tachycardia, or chest pain), or psychosis.

Because there is an increased risk of stimulant misuse or diversion when ADHD patients have a co-occurring SUD, there needs to be an open dialogue about not misusing or diverting their medication. Moreover, patients should be told to safeguard their medication since other friends or family may steal the medication. While tailoring the clinical approach based on level of patient risk (low, moderate, or high) may mitigate risk if an abusable medication is prescribed, it will not eliminate it entirely. Good clinical judgment requires flexibility and a willingness to balance risk with therapeutic benefit.

Abstract

From Personality Traits to Addictive Disorders Substance use disorders (SUD) are highly prevalent in patients with personality disorders (PD) and vice versa.

Evidence for causal relationships between addictive disorders and PD can be derived from long-term longitudinal studies, epidemiological findings, genetics, and retrospective studies. Although they are inextricably linked, little is known about the role of a broad range of personality traits and disorders in the evolution of SUD and whether they differ according to substance.

Biogenetic research has been confined largely to antisocial, borderline, and schizotypal personality traits and disorders. Understanding the neurobiological mechanisms by which certain personality traits may provide vulnerability to or resilience against SUD would help to develop strategies for SUD prevention.

The existence of addictive behaviors with regard to different substances probably suggests different phenotypes that should be defined for treating patients with this dual disorder. In that sense we must look for the integration of personality traits and substance use disorders via common psychopathological spectra based on common, biological dysfunctions.

Traditionally, both illnesses have been treated as separate conditions, but, in the last few years, the close connection between them has been increasingly acknowledged. Most SUD patients have pathological personality traits or disorders and often do not receive the appropriate diagnosis and treatment.

It is always necessary to search for a diagnosis of personality disorders and traits in patients with SUD. At the same time, a vigorous treatment should be simultaneously established for both psychopathological manifestations.

124.1 Introduction

The population with dual disorders/pathology (addiction and other mental disorders) is heterogeneous and the prevalence of comorbidity differs according to diagnostic groups. One of the overarching issues in relation to comorbidity is the nature of the connection between addiction disorders and other psychiatric disorders. The rapid development of technical advances in neuroscience has led to a better understanding of the molecular biology, neurotransmitter systems, and neural circuitry involved in substance use disorders and other mental disorders.

Addictive behaviors associated with other psychiatric disorders, which we refer to as dual pathology, are probably neurodevelopmental disorders (Szerman et al. 2013). These are disorders that begin very early in development and may present with different phenotypes, such as addiction-related or other psychiatric symptoms, at different stages during a person's lifetime.

From the clinical point of view, we know that one of the most relevant comorbidities is personality disorders and addictive behaviors. Substance use disorders (alcohol, nicotine, and other substances) are highly prevalent in patients with personality disorders (PDs) and vice versa and are associated with considerable health, economic, and social burdens (Hasin et al. 2011).

Various factors may contribute to the particularly strong association between lifetime diagnoses of personality disorders and increased rates of transition from substance use to substance use disorder (SUD) and other addictive behaviors. There is in any case a strong association between a lifetime diagnosis of any mental disorder and rates of transition from substance use to SUD. "Though this was true for all mental disorders, it was particularly true for personality disorders and psychotic disorders" (Lev-Ran et al. 2013). Moreover, reports from the NESARC

study sample show a high degree of personality disorders comorbidity within the DSM-IV clusters and between clusters (Grant et al. 2005).

As recently stated, axis I disorders should not have a strong or consistent association with persistent SUD. In contrast, antisocial personality disorder, borderline personality disorder, and schizotypal personality disorder seem to be significantly associated with SUD (Hasin et al. 2011).

Personality disorders and addiction disorders constitute a problematic area of psychiatry. In all current mental diagnostic and classification systems, these disorders are defined on a phenomenological basis. In the field of addiction disorders and personality disorders, there is the additional difficulty of there being many different and conflicting schools of thought about the nature of these conditions.

There has been substantial criticism of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV), due to problems of diagnostic overlap, a lack of clear boundaries between "normality" and disease, a failure to take into account findings from new research, and also a lack of diagnostic stability over time (Zimmerman et al. 2011). Most neuroscientific evidence suggests that the neurobiology of psychiatric disorders, including personality disorders, does not seem to align with the current diagnostic classifications and categorical distinctions derived from Kraepelin's classic descriptions (DSM-IV or ICD-10). Current diagnostic categories may be inadequate. There are numerous recent studies suggesting that the biology of mental illnesses may fail to align neatly with the classic Kraepelinian classification that has served clinical practice and research for well over a century (Insel and Wang 2010). The prevailing "neo-Kraepelinian" diagnostic system only provides for a categorical diagnosis and therefore does not allow for the possibility of dual diagnosis. Also the current nosological approach does not provide a framework for internal (subthreshold symptoms) or external (comorbidity) heterogeneity of the different diagnostic categories (Szerman et al. 2013). Finally, the majority of studies have not tested multidimensional models of mental disorders and we need to move towards the conceptualization of new models of brain disorders.

124.2 Personality Disorders and Addiction Disorders

A high level of comorbidity that cannot be explained by conceptual or measurement artifacts strongly suggests that the co-occurrence of addiction disorders and personality disorders is not solely due to random or coincidental factors. It seems reasonable to explore the assertion that both conditions are in some way causally linked. Evidence for causal relationships between addiction disorders and PD can be derived from long-term longitudinal studies, epidemiological findings, genetics, and retrospective studies (Verheul et al. 2009). They are inextricably linked and little is known about the role of a broad range of personality traits and disorders in the progression of SUD and whether they differ according to substance.

124.2.1 Primary Substance Use Disorder Model Versus Primary Personality Disorder Model

Currently there is no direct evidence supporting **the primary substance use disorder model** (it postulates that substance abuse contributes to the development of PD) and there is in fact some indirect evidence against it (Verheul et al. 2009).

The primary personality disorder model describes a comorbid relationship in which pathological personality traits based on certain biological conditions contribute to the development of an addiction disorder. This model has received the strongest empirical support, showing multiple symptomatic pathways from personality to addiction: behavioral disinhibition, stress reduction, and reward sensitivity (Verheul et al. 2009).

124.2.2 Changes in the Conceptualization of Addictive Behaviors and Personality Disorders from a Biological Perspective

Is it possible to explain complex mental and behavioral disorders such as addiction and personality disorders at a biological level?

Biological psychiatry has been based on the desire to uncover the relationship between mind and brain through systematic research. To understand a psychiatric disorder, we need to know why the pathology causes the behavioral disturbance, the neural structures implicated in the pathology, and the cause of the dysfunction in the neural structures. Genes, neural bases, and environment are no longer viewed as separate entities but rather as being intimately interconnected, as in a continuum. Nevertheless in relation to the abovementioned evolution, it may seem that psychiatry in general and particularly in relation to addiction and personality disorders does not follow the progress of biological research with the same confidence as other areas of medicine.

- Addiction Disorders

  The term "addiction" should be used instead of the term "dependence" as described in DSM-IV to avoid confusion with physical dependence, which is neurobiologically and clinically distinct from addiction. "We refer to addiction as the phenotype characterized by the compulsive administration of the drug and the loss of control over its intake despite its adverse consequences to the individual" (Volkow and Muenke 2012).

  The diagnostic concept of dependence in DSM-III (1980) was focused around neuroadaptation to drugs (evidence of acquired tolerance and/or withdrawal symptoms). This concept was revised in DSM-III-R (1987), which focused on a behavioral syndrome including dyscontrol, salience and neuroadaptation, as well as compulsive behavior (Sellman 2009).

  Progress in neurobiology has provided a new way to identify the neurobiological mechanism involved in the development of drug addiction.

  Over the past decades, differing biological addiction theories have been proposed by researchers (Badiani 2011), but all psychoactive substances with abuse potential

have a counterpart or correspond to some endogenous system such as the opioid system, the endocannabinoid system, the cholinergic-nicotinic system, the dopaminergic system, and so on. An inherited or acquired deficiency in these neurobiological systems and circuits may explain addictive behavior and other psychiatric symptoms including personality traits or disorders (Szerman et al. 2013).

Substance use disorders are considered in most investigations as a function of time, type, or amount of substance consumed, although addictive drugs do not have to precipitate addictive behaviors or drug dependence in most individuals (Feltenstein 2008).

In "the classic addiction perspectives" (Swensen and Moal 2011), the emphasis is often on the effects of substances on the brain, creating the impression that dual disorders are a natural consequence of these substances (Nestler et al. 2005). This old model of addiction assumes that drugs of abuse "hijack" the brain's reward system, disrupting the normal behavioral responses to natural rewards (Welberg 2011).

The classic addiction paradigm based on drug-induced neuroplasticity and on acquired vulnerability, largely dominant in laboratory research, has changed to a new "individual-centered" paradigm approach that takes individual variation to be the focal point: the strong association of addiction with certain personality traits (Volkow et al. 2011) or comorbid mental disorders (Swensen and Moal 2011). Basic neuroscientific research has demonstrated the key roles of biological and genetic/epigenetic factors in an individual's propensity to these disorders including the propensity to behavioral addictions. A challenge for the future is to understand the development of compulsivity at neurochemical level not only in relation to drugs but also in the range of emerging behavioral addictions (Sellman 2009) and compulsive traits.

The inclusion in the next DSM-5 of behavioral addictions like pathological gambling has to change our way of understanding and dealing with addictions. From a neurobiological perspective, we should not maintain an explanatory model that only provides results on neuroadaptation to the continued use of substances of abuse.

- Personality Disorders

> It's time to go back to the beginning, to Darwin, and build a logical structure based on universal principles of evolution. (Millon)

The Different, Current, Theoretical Frameworks for Personality Disorders (PD):

For years personality disorders have hung around like orphans (axis II), but personality problems are not exactly new. In fact, the focus for personality disorders will depend largely on the perspective from which they are approached:

1. Psychodynamic model: the PD conceived as a result of internal organization.
2. Trait-based model: it focuses on the type of behavior and interpersonal relationships.
3. Biological model: the PD as being organized around biogenetic factors.
4. Sociological model: personality is formed through social circumstances and PDs appear under harmful circumstances.

The focus for personality disorders will depend largely on the perspective from which they are approached. Until recent years there was only the psychological approach, and the explanation of personality disorders was based on studies of the psychological mechanisms and interactions with the environment. The dysfunctional biological bases were excluded or had not yet been considered. The identification of neural correlates of PD may have profound implications on our basic understanding of the biological substrates underlying human behavior.

Biogenetic and heritability research has been confined largely to antisocial, borderline, and schizotypal personality disorders, with very little research specifically concerning the other DSM-IV personality disorders (Nigg and Goldsmith 1994).

Longitudinal studies indicate that PDs as syndromes exhibit consistency over time but show rates of improvement that are inconsistent with their DSM-IV definitions (Skodol et al. 2009). On the other hand, considerable research has shown excessive co-occurrence among PDs diagnosed using the categorical system of DSM-IV (Zimmerman et al. 2005) and all PD categories have arbitrary diagnostic thresholds without empirical evidence for setting the boundaries between pathological and normal personality functioning. Moreover, comorbidities between different diagnostic categories are probably defining different phenotypes that should be taken into account when diagnosing and treating these patients.

Over the last century, scientific consensus has been reached on a taxonomic model of personality traits. Personality can be thought of as a set of characteristics that influence people's way of thinking, feeling, and behaving in a variety of settings. A variation in personality traits is predictive of many outcomes in life including mental health, mental disorders, and, within this, substance use disorders (De Moor et al. 2012).

For this purpose, a more encompassing trait system for the diagnosis of personality disorders has been proposed in the DSM-5 (Sect. III). Prototypical disorders are characterized by core impairments in personality functioning and different levels of abnormal personality traits grouped in six broad dimensional domains: negative emotionality, introversion, antagonism, disinhibition, compulsivity, and schizotypy. Personality traits have been shown to interact with environmental cues to modulate biological responses.

Personality traits are more stable than PDs and predict stability and change in personality disorders. Personality traits are often related to psychopathology and investigating their neural substrates may inform etiological and pathophysiological models of psychiatric disorders (Woodward et al. 2011). In this sense, the existence of addictive behaviors with regard to different substances probably suggests different phenotypes that should be defined for treating patients with this dual disorder: integration of personality traits and substance use disorder via common psychopathological spectra based on common, biological dysfunctions.

Little is known about the neurobiological correlates of human personality traits and how they relate to substance abuse or dependence. Nonetheless evidence is increasingly growing, for example:

– Variability in harm avoidance (a temperament trait associated with sensitivity to aversive and non-rewarding stimuli, higher anticipated threat, and negative

emotions during stress as well as a higher risk for affective disorders), a trait that can be explained by differences in the activity of the μ-opioid system (Tuominen et al. 2011).
- The evidence that borderline PD patients suffer from a definite abnormality in opioid activity (New and Stanley 2010).
- A role for functional mu-opioid receptor gene polymorphisms in the expression of attachment behavior in human subjects, especially as a function of separation from the caregiver (Barr et al. 2008).
- Positive emotionality (a personality construct indicated by well-being, achievement/motivation, social competence, and closeness, which may relate to global cortical processes that are active during resting conditions, introspection, or mind wandering) has been associated with striatal dopamine D2 receptor availability in healthy controls and is considered a trait that protects against substance use disorders (Volkow et al. 2011).
- Neural mechanisms of anger regulation as a function of genetic risk for violence: vulnerability to aggression in carriers of the low-MAOA genotype is supported by decreased middle frontal response to the word "no" and the unique amygdala/thalamus association pattern in this group with anger reactivity but not anger control (Alia-Klein et al. 2009).
- The studies show the difficulties in identifying common genetic variants that influence complex phenotypes such as personality traits. Genome-wide association studies (GWAS) may reveal these variants in a large meta-analysis. The identification of these genetic variants that account for the heritability remains an important goal that will enable the understanding of the biological process underlying personality as well as psychiatric disorders, including addiction disorders and personality traits (GWAS 2009).

124.2.3 A Need to Diagnose Addiction Disorders and Personality Disorders

In general population research, all ten DSM-IV (and DSM5) personality disorders were shown to have strong associations with alcohol and tobacco dependence and with drug use disorders (abuse and dependence) (Hasin et al. 2011).

The association between personality disorders and substance use disorders appears to differ according to the specific personality disorder. Traditionally, both illnesses have been treated as separate conditions, but in the last few years, the close connection between the two has been increasingly acknowledged. Most SUD patients have pathological personality traits or disorders and often do not receive the appropriate diagnosis and treatment. It is much more difficult to assess the personality dysfunctions of patients with ongoing SUD. A successful diagnosis is essential for well-adapted and high-quality treatment; therefore, it is extremely important that all the disorders of a patient are diagnosed (Langås et al. 2011).

According to more recent epidemiological and biological studies and also the newest DSM-5 proposals, we will focus on the three major personality disorders in

relation to addictive behaviors: schizotypal (SPD), borderline (BPD), and antisocial (ASPD) personality disorders. Other personality disorders are also significantly associated with persistent SUD, but in a less consistent manner.

124.2.4 Schizotypal Personality Disorder and Addiction Disorders

Schizotypal personality disorder is the prototypical schizophrenia spectrum condition, sharing similar phenomenological, cognitive, genetic, physiological, neurochemical, neuroanatomical, and neurofunctional abnormalities with schizophrenia (Fervaha and Remington 2012). Nonetheless, despite the similarities in neurodevelopmental alterations at frontal and temporal levels, they are milder than those that are found in schizophrenia because of the ability to recruit other related brain regions to compensate the dysfunctional ones.

These patients are also less vulnerable to psychosis, because of the existence of protective factors that mitigate the subcortical DA activity. Despite its phenomenological proximity to schizophrenia, SPD has been recognized as a distinct disorder, the criteria of which represent the persistent maladaptive patterns of a personality disorder rather than the overt, symptomatic break from reality of a psychotic disorder. SPD also shares phenomenological features with schizoid and paranoid personality disorders.

An important factor supporting the inclusion of SPD as a prototypical DSM-5 personality disorder is the fact that many of its current criteria have been validated by external validators (e.g., neurochemical, neuropsychological, functional, and structural findings) (Chemerinski et al. 2012).

Schizotypal personality traits encompass a broad range of personality characteristics and experiences, including unusual perceptions and beliefs, social anxiety or withdrawal, and disorganized thoughts or behaviors. These traits cluster into positive, negative, and disorganized factors that are conceptually similar to the symptom dimensions of schizophrenia. The expression of these traits ranges from benign, odd perceptual experiences or beliefs to more severe symptoms.

Some recent research found that two factors were specific to SPD: a cognitive-perceptual factor (ideas of reference, magical thinking, and unusual perceptual experiences) and an oddness factor (odd thinking and speech, constricted affect, and odd appearance or behavior). The criteria belonging to these factors had appropriate psychometric properties. Support for a consistent factor that reflected interpersonal problems was not found and the authors postulated that interpersonal dysfunction was secondary to the two primary SPD factors (Hummelen et al. 2012).

According to Fenton et al. (2012), ideas of reference and social anxiety were the strongest schizotypal criteria predictors of drug use disorder persistence, and according to Buckner et al. (2012), social anxiety might be a risk factor for cannabis dependence.

The relationship between schizotypal personality disorder and tobacco is also receiving increasing attention. A recent study examined the relationship between sub-factors within schizotypal symptoms founding a relationship between

smoking and eccentric behavior and odd speech but not between other domains (Esterberg et al. 2009). Another study examined the prevalence of tobacco addiction and its associations with personality disorders among smokers, and although all PDs were significantly associated with tobacco dependence, when sociodemographic factors were controlled, only schizotypal, borderline, narcissistic, and obsessive-compulsive PDs were associated with tobacco addiction after adding controls for axis I and other axis II disorders (Pulay et al. 2010).

124.2.4.1 Cannabis Use Disorder and SPD: A Long-Lasting Debate

There may be a developmental process in the relationship between cannabis use and schizotypal symptoms (Bailey and Swallow 2004). Cannabis acutely increases schizotypy, and chronic use is associated with elevated rates of psychosis. Cannabis use may reveal an underlying vulnerability to psychosis in those with high schizotypal traits.

An important group of cannabis users shows dimensions of schizotypy, which provides further evidence that cannabis use is associated with increased levels of psychosis-related personality traits. Also, higher cognitive-perceptual schizotypy was selectively associated with cannabis use, although the disorder was associated with greater use of alcohol and tobacco too (Esterberg et al. 2009).

Findings suggest that regular cannabis users are significantly more prone to cognitive and perceptual distortions as well as disorganization (but not interpersonal deficits) than non-regular users and those who have never used, and the onset of schizotypal symptoms generally precedes the onset of cannabis use (Schiffman et al. 2005). This was the only study to address a temporal order in the sense that schizotypal symptoms preceded cannabis use, suggesting that this association is not an artifact of cannabis effects. Meanwhile, other researchers found that early SPD symptoms could not fully explain the association between early cannabis use and later schizotypal symptoms (Anglin et al. 2012).

Interestingly, in another recent study, scores from a measure of schizotypal traits were used to separate 1,665 young adults into schizotypy, non-schizotypy, and "unconventional" groups. "Nearly a quarter of the schizotypy group endorsed cannabis use at least weekly, a rate nearly two to four times that of the other groups. The schizotypy group also reported a much greater frequency of cannabis-related problems compared to the other groups. Despite this, interest in treatment for cannabis use in the schizotypy group was not elevated. Curiously, 85 % of individuals in the schizotypy group reported interest in psychological/psychiatric treatment more generally but not cannabis dependence treatment. Cannabis use was not associated with abnormal patterns of positive or disorganized schizotypy traits in the schizotypy group relative to the other groups but it was associated with lower severity of negative traits" (Cohen et al. 2011).

Another controversial issue is the "amotivational syndrome." This syndrome has been described as a form of chronic cannabis intoxication, although there is no scientific evidence to prove its existence, caused allegedly by cannabis. Although

there are individuals with genetically determined schizotypal traits, with subclinical psychopathological features such as anomalous subjective experiences, negative symptoms, anhedonia, decreased vitality, apathy, associability, restricted affect, and subpsychotic formal thought disorder (Raballo and Parnas 2011), they probably suffer a vulnerability to cannabis use disorder. The negative-like symptoms and cognitive deficits of SPD have also been assessed with the use of external validators. These are mostly associated to the frontoparietal-temporal circuit dysfunction prevalent in this disorder.

124.2.4.2 Why Do These Patients Feel Such a Fatal Attraction to Cannabis?

Data reported so far clearly indicate the presence of a dysregulation in the endocannabinoid system (both in terms of cannabinoid receptors and endocannabinoid ligands) in animal models of psychosis as well as in schizophrenic patients (Zamberletti et al. 2012).

Anandamide (endocannabinoid ligand) and also exogenous cannabis, both attenuate the hypothalamus activation produced by stress. This adjustment depends on the availability of the anandamide precursor, arachidonic acid, which seems to be low in schizotypy subjects (Monterrubio and Solowij 2006).

Recent research suggests that delta-9-tetrahydrocannabinol (THC, the main psychoactive component of cannabis) increases dopamine levels in several regions of the brain, including striatal and prefrontal areas, showing the interactions between THC, endocannabinoids, and dopamine in cortical as well as subcortical regions (Kuepper et al. 2010) implicated in schizotypal disorder. Exploratory analyses of Schizotypal Personality Questionnaire factor scores revealed correlations between disorganized schizotypal traits and dopamine release in the striatum, thalamus, medial prefrontal cortex, temporal lobe, insula, and inferior frontal cortex produced by amphetamine. Amphetamine-induced dopamine release may be a useful endophenotype for investigating the genetic basis of schizotypal spectrum disorders (Woodward et al. 2011).

Based on these observations, the pharmacological modulation of the endocannabinoid system has been taken into account as a new therapeutic possibility for psychotic disorders and could perhaps be considered for this dual disorder: schizotypal disorder and cannabis use disorder.

124.2.5 Borderline Personality Disorder and SUD

Borderline personality disorder (BPD) is a complex, serious psychiatric disorder characterized by pervasive instability in regulation of emotion, self-image, interpersonal relationships, and impulse control, and it is associated with severe functional impairment (APA 1994).

The reported prevalence is 15–25 % in clinical settings (the most prevalent PD in clinical settings) and 1.4–5.9 % in the community and it is equally prevalent in men as in women. These figures indicate that a large number of people with this disorder

are undiagnosed and untreated, while according to studies such as the McLean Study of Adult Development (2005) and the Collaborative Longitudinal Study of Personality Disorders (2005), BPD has an unexpectedly good course, contrary to what was previously imagined (Gunderson 2009).

BPD is the personality disorder with the greatest SUD co-occurrence, together with antisocial personality disorder (ASPD). Cross-sectional studies have found that 23–84 % of BPD patients report meeting criteria for some SUD, and up to 65 % of substance users in treatment meet criteria for BPD (Trull et al. 2000). A 10-year follow-up study has shown that although 90 % of BPD patients meeting criteria for a SUD at baseline experienced a remission, recurrences and new onsets were less common but always more frequent than in axis II comparison subjects (35–40 % vs. 21–23 %) (Zanarini et al. 2011).

New onsets of SUD do not differ significantly between remitted and non-remitted BPD patients. Even when remitted, they seem to have a higher vulnerability than patients with other PDs (with the likely exception of ASPD) to the development of SUD. This conclusion is consistent both with the concept of shared etiological factors between BPD and SUD as a spectrum relationship and with the "clinical wisdom that substance abuse is a particularly hazardous form of comorbidity for patients with BPD" (Walter et al. 2009).

If Cluster B is considered as having an independent risk for the development of SUDs (Cohen et al. 2007), many of the core features of BPD are also independent risk factors for their development. Both impulsivity and affective dysregulation/negative emotionality have been identified as key vulnerability factors in the development and maintenance of addictive disorders (Lubman et al. 2011; James and Taylor 2007).

As already stated, BPD, together with SPD and ASPD, seem to be the only axis II disorders associated with persistent SUD, while no axis I disorder shows this kind of association. Identity disturbance and self-damaging impulsivity are the strongest BPD criteria predictors of persistence (Fenton et al. 2012; Hasin et al. 2011).

124.2.5.1 The Role of Negative Emotionality and Impulsivity in the BPD-SUD Relationship

Both emotional dysregulation and impulsivity are core aspects of BPD pathology and probably of SUD comorbidity.

Impulsivity has for a long time been considered the most relevant factor in relation to drug addiction. The amount of published research is impressive and the advances in neurobiological techniques in the last decade have helped to deepen and focus knowledge on a very complex subject, progressively helping to clear up its still debated role in the addictive process and in BPD.

One important factor that worsens impulsive behaviors and impulse control deficits in some BPD patients is the phenotype with comorbid attention-deficit/hyperactivity disorder (ADHD). Well-observed impulsive behaviors might be explained by comorbid ADHD or may be the consequence of dysregulation of BPD salient emotions (Sebastian et al. 2013).

Advances in research indicate that impulsivity is a personality trait known to be related to greater vulnerability to SUD, along with novelty seeking and negative emotionality, while positive emotionality (PEM) is associated with resilience. Striatal D2 receptors modulate activity in the orbitofrontal cortex (OFC) and cingulate, two brain regions that process natural and drug rewards. In healthy controls, PEM has been associated with striatal dopamine D2 receptor availability. It was also positively correlated with the OFC and cingulate, as well as with other frontal, parietal, and temporal regions. As dysfunction of the OFC and cingulate is a hallmark of addiction, these findings support a common neural basis underlying the protective personality factors and brain dysfunction that lie beneath substance use disorders (Volkow et al. 2011).

Borderline personality disorder is characterized by a lack of effective regulation of emotional responses. Emotion dysregulation in BPD involves a dysfunction of the frontolimbic systems supporting negative emotionality. Deficient processing of negative emotions in BPD might then be related to an abnormal reciprocal relationship between limbic structures representing the degree of subjectively experienced negative emotion and anterior brain regions that support the regulation of emotion (Ruocco et al. 2013). Although human affective responses appear to be regulated by limbic and paralimbic circuits, much less is known about the neurochemical systems involved. The mu-opioid neurotransmitter system is distributed in and regulates the function of brain regions centrally implicated in the affective processing of an experimentally induced negative affective state (Zubieta et al. 2003).

124.2.5.2 BPD and the Opioid System

The role of the opioid system in BPD is a source of fruitful research.

Based on the key role of the central opioidergic system in addiction, recent research has investigated the relationship between certain personality traits that are supposed to be relevant in addiction and the opioid receptor status in healthy subjects. In such subjects, certain personality traits (novelty seeking, harm avoidance, reward dependence, and persistence), which might be predisposing for addictive behavior, are correlated to the opioidergic neurotransmission in core structures of the human reward system (Schreckenberger et al. 2008).

The opioid system regulates affective and sensory components of pain (Zubieta et al. 2001), as well as social exclusion, separation, and abandonment, particularly within perceived rejections. From an evolutionary perspective, it is not surprising that the neurocircuitry and neurochemistry of physical pain overlaps with that involved in complex social emotions (Stein et al. 2007).

Reduced pain sensitivity has been experimentally confirmed in patients with BPD, who also tolerate higher temperatures. In the study of Schmahl et al. (2006), pain stimulation produced an increased response in the dorsolateral prefrontal cortex and deactivation in the anterior cingulate and the amygdala, brain areas involved in the cognitive and affective evaluation of pain.

Approximately 60 % report not feeling pain during acts of self-mutilation such as cutting or burning. BPD self-mutilating patients who experience analgesia during self-injury show an increased threshold for pain perception even in the absence of

distress; it was postulated that this may reflect a state-independent increased pain threshold which is further elevated during stress (Bohus et al. 2000). One approach to self-injury in BPD patients is that it represents a method of endogenous opioid generation.

In BPD patients, symptoms of perceived rejection and loss often serve as triggers to impulsive, suicidal, and self-injurious behaviors, affective reactivity, and angry outbursts, suggesting that the attachment and affiliative system may be implicated in this disorder. Neuropeptides, including opioids, play a crucial role in the regulation of affiliative behaviors and thus may be altered in BPD (Stanley and Siever 2010).

Hypersensitivity to negative stimuli and excessive stimulation of negative affect are linked to increased brain activity in the amygdala and related brain structures, together with an orbital, prefrontal, and anterior cingulate hypoactivity (New et al. 2007). The amygdala, implicated in emotional responses and information evaluation and regulation, has a high concentration of mu-opioid receptors. In BPD, there are decreased basal opioid levels, balanced by an upward regulation of mu-opioid receptors. This decreased basal level would express in nuclear BPD symptoms: chronic dysphoria and emptiness and self-harm behavior, while releasing opioids, might facilitate relief (Stanley and Siever 2010).

Some important research stated that there are differences between patients with borderline personality disorder and comparison subjects in baseline in vivo mu-opioid receptor concentrations and in the endogenous opioid system response to a negative emotional challenge, which can be related to some of the clinical characteristics of patients with borderline personality disorder. The regional network involved is implicated in the representation and regulation of emotional and stress responses (Prossin et al. 2010).

Interestingly, high impulsivity and low deliberation scores have been postulated as being associated with significantly higher regional mu-receptor concentrations and greater stress-induced endogenous opioid system activation; effects were obtained in prefrontal cortex, OFC, anterior cingulate, thalamus, accumbens, and basolateral amygdala (all involved in motivational behavior and the effects of drugs of abuse) (Love et al. 2009). Research results concluded that individual differences in the function of the endogenous mu-receptor system predict personality traits that confer vulnerability to or resilience against risky behaviors such as the predisposition to develop substance use disorders. These personality traits are also implicated in psychopathological states (such as personality disorders).

124.2.5.3 BPD and Alcohol and Opioid SUD

The prevalence of BPD in heroin-dependent individuals is very high. A cohort of 495 heroin users enrolled in the Australian Treatment Outcome Study and criteria for BPD were met by 45 % of the cohort (Darke et al. 2005).

Also there is a high degree of comorbidity between borderline personality disorder (BPD) and alcohol use disorders. The research suggests a negative synergy between BPD and alcohol use disorder. In some recent epidemiological community

research, antisocial, borderline, histrionic, and narcissistic personality pathology factors were significantly associated with increased risk for alcohol use disorder (Agrawal et al. 2013).

Patients with BPD tend to abuse substances that target mu-opioid receptors, such as alcohol and opiates, substances that likewise provide relief from their suffering and discomfort. Shared vulnerability between opiate and alcohol addiction and BPD could be linked to an underlying dysregulation of neuropeptides, including opioids, which play a critical role in regulating affiliative behavior and a sense of well-being.

Specifically, alcohol-induced release of β-endorphins stimulates μ-opioid receptors (MORs), which is believed to cause dopamine release in the brain reward system. It has been suggested that individual differences in opioid or dopamine neurotransmission are responsible for enhanced liability to abuse alcohol (Spreckelmeyer et al. 2011).

Alcohol use may be viewed as an attempt to regulate negative emotional states through the regulation of the opioid system. Not all BPD patients are drinkers, but BPD drinkers showed higher within-person variability for the most intense negative affects than BPD non-drinkers (Jahng et al. 2011).

Future research could focus on normalizing opioid dysregulation, in addition to evidence-based psychotherapy, in an effort to improve interpersonal functioning.

124.2.6 Antisocial PD and SUD

Antisocial personality disorder (ASPD) is highly associated with persistent substance use disorders, mainly alcohol, cannabis, and tobacco use (Hasin et al. 2011).

In addition to the full ASPD syndrome, which requires both childhood conduct disorder and the adult features, other antisocial behavioral syndromes, including conduct disorder (CD) alone without the adult syndrome, and the adult antisocial behavioral syndrome without childhood CD (AABS) are also frequently diagnosed in patients with SUD (Mariani et al. 2008).

CD is a disorder that occurs during childhood and adolescence and is defined by rule-breaking, aggressive, and destructive behaviors. Progression from CD to ASPD is the norm and not the exception (Gelhorn et al. 2007) and we need to have in mind other clinical categories (different phenotypes) such as attention-deficit/hyperactivity disorder (ADHD) and SUD, to discern possible commonalities.

ASPD criteria focus on antisocial behaviors rather than on personality traits central to traditional conceptions of psychopathy. Psychopathy is a disorder, defined by Hare's Psychopathy Checklist – Revised (PCL–R) as being characterized in part by a diminished capacity for guilt, remorse, and poor behavioral control (Hare et al. 1991). Conceptualizations of psychopathy are not the same as diagnoses of conduct disorder or antisocial personality disorder. As such, only around 20–50 % of patients with ASPD also meet the criteria for psychopathy. Recent research strongly reinforces the suggestion that psychopathy is a neurobiological condition and these data maintain diagnostic precision (Blair 2012). Although the

neuropathological basis of psychopathy has not been clearly established, psychopaths have a significantly thinner cerebral cortex in different brain regions, mainly in the left insula. These neurostructural differences were not due to differences in age, IQ, or substance use disorders (Ly et al. 2011).

Strong associations between conduct disorder, attention-deficit/hyperactivity disorder, antisocial personality disorder, and substance use disorders seem to reflect a general vulnerability to externalizing behaviors. Recent studies have characterized this vulnerability on a continuous scale, rather than in distinct categories (Witkiewitz et al. 2013).

Patterns of genetic, environmental, and phenotypic relationships between antisocial behavior and substance use disorders indicate the presence of a common externalizing liability. Research regarding etiology, assessment, and treatment of externalizing disorders should target externalizing liability over a range of severity (Markon and Krueger 2005).

In that sense, considering the utility of endophenotypes, such as impulsivity, and using them "transdiagnostically" across disorders, such as ADHD, substance abuse, and ASPD, would help to achieve better diagnoses and treatment.

Psychopathy and SUD are highly prevalent in incarcerated populations. Recent research found that high impulsivity indirectly mediated the relationship between psychopathy and stimulant dependence meanwhile low anxiety sensitivity indirectly mediated the relationship between psychopathy and opioid dependence. Finally, impulsivity indirectly and inconsistently mediated the relationship between psychopathy and alcohol dependence. These results suggest that individuals with psychopathic traits are at increased risk of misusing certain drugs due to underlying personality-based differences (Hopley and Brunelle 2012).

The specific psychopathic trait, callous-unemotional (CU), is associated with more antisocial behavior, and those patients are at the highest risk of recurrent alcohol and cannabis use. Nevertheless the conduct disorder is probably more relevant than the CU traits in relation to SUD (Charles et al. 2012).

Deceitfulness and lack of remorse were the strongest antisocial criteria predictors of drug use disorder persistence (Fenton et al. 2012), while early-onset alcohol abuse and conduct disorder predicted adult ASPD (Khalifa et al. 2012).

124.2.6.1 ASPD and Alcohol Use Disorder

Among people with alcohol use disorder, ASPD is related to a more severe presentation and course of the disorder, such as an earlier age at onset and more rapid progression to dependence. Cloninger stated that alcoholics with an earlier age of onset (alcoholics type II) have relatively greater psychopathology than those with later onset (alcoholics type I). Alcoholism type II generally begins during adolescence and alcohol consumption frequently is accompanied by fighting and arrests. For type II alcoholics, who are primarily characterized by high novelty seeking, alcohol use is motivated by the desire to induce euphoria. This desire, which may also lead to abuse of other drugs, generally begins during adolescence or early adulthood (Cloninger 1987). Also type II alcoholics were

characterized by greater severity of alcohol-related problems, childhood behavioral problems, craving, hostility and antisocial traits, and poor social functioning (Johnson et al. 2000). Other researchers detected differences between type I and type II alcoholics not only in their age at onset and the type of alcohol-related problems but also in certain neurobiological markers: for instance, preliminary results from diagnostic groups with a relatively small number of subjects and substantially different mean ages for each group suggest that the endogenous cannabinoid system may be hyperactive in type II alcoholics and hypoactive in type I alcoholics (Lehtonen et al 2010).

ASPD is considered to be an important cofactor in the pathogenesis and clinical course of alcohol dependence, but some studies have highlighted that the onset of ASPD characteristics preceded that of alcohol addiction by approximately 4 years, and this finding suggests that in patients with ASPD, alcohol dependence might be a secondary syndrome (Bahlmann et al. 2002). In a more recent study from the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) in terms of alcohol consumption behavior, the young antisocial subtype significantly reduced their risk drinking days between NESARC study Wave 1 and Wave 2 (in this second wave, interview was conducted approximately 3 years later) (Moss et al. 2010).

Few studies have investigated the combined association between ASPD and alcoholism in relation to neuropsychological function. Alcohol-dependent patients with ASPD exhibit decision-making deficits and personality traits characterized by impulsive and antisocial tendencies that are more pronounced than alcohol-dependent patients without ASPD (Miranda et al. 2009). Another study that examined the influence of ASPD symptoms and alcoholism on tests sensitive to frontal brain deficits found that alcoholism and ASPD were significant predictors of frontal system and affective abnormalities suggesting that the combination of alcoholism and ASPD leads to greater deficits than the sum of each (Oscar-Berman et al. 2009).

124.2.6.2 ASPD and Stimulant Drug Addiction

Research tells us that symptoms or traits of ASPD, such as deficits in executive function and response regulation, as well as anxious-impulsive personality traits, may represent endophenotypes associated with the risk of developing cocaine and amphetamine dependence (Ersche et al. 2012b). Recent research found abnormalities in frontostriatal brain systems implicated in self-control in both stimulant-dependent individuals and their biological siblings with no history of chronic drug abuse. These findings support the idea of an underlying neurocognitive endophenotype for stimulant drug addiction (Ersche et al. 2012a).

A commonly held perception is that cocaine use is more highly associated with antisocial behavior than cannabis use, although a comparison of ASPD rates among individuals seeking treatment for cocaine and cannabis dependence did not reveal significant differences between the two groups of patients (Mariani et al. 2008).

It is suggested that neural structures implicated in psychopathic pathology also include the amygdala and orbitofrontal cortex (OFC). One feature associated with

psychopathy is substance misuse. This could contribute to apparent impairments. SUD could reflect the lifestyle of the individual with psychopathy where substance misuse has interacted with the fundamental pathology to produce additional OFC pathology (Blair 2003). However, frontal systems dysfunction is present prior to stimulant-abuse onset (Winhusen et al. 2013).

Young adults under treatment with SUD and comorbid ASPD do not necessarily have poorer retention or worse substance use outcomes compared with SUD young adults who do not have ASPD, when treated according to a well-defined behavioral therapy protocol (Easton et al. 2012).

124.3 Conclusion

Although significant advances have been made over the past several decades in the development of effective research for addictions and personality disorders, they remain a substantial public health problem. The development of new neuroscientific methodologies to assess brain structure and function provides an exciting opportunity to apply these tools in order to understand and improve treatments.

Clinicians should have increased expectations that a patient with a SUD may have a co-occurring pathological personality trait or disorder. The consistent findings on the association of schizotypal, antisocial, and borderline personality traits or disorders with persistent SUD indicate the importance of these disorders and their neurobiological basis in understanding the course and treatment of SUD.

Understanding the neurobiological mechanisms by which certain personality traits may provide vulnerability to or resilience against SUD would help to develop strategies for SUD prevention.

Future research may enable the neurobiological link between personality traits and addiction to different substances of abuse to be understood.

From a dimensional perspective, we must consider personality traits and their combination with other syndromic disorders (such as ADHD) along with SUD, in an effort to define clinical phenotypes that should guide more individualized treatment.

It is necessary to search for a diagnosis of personality disorders and traits in patients with SUD and this dual diagnosis should not distract us from simultaneously starting vigorous treatment for both psychopathological manifestations.

Overview of International Issues in Comorbidity

125

Pedro Ruiz and Ihsan M. Salloum

Contents

125.1 Introduction

The role and concept of "comorbidity" has radically changed in the field of substance abuse in recent years. No longer the concept of comorbidity as two independent or parallel factors playing a role within each other in the presence of substance abuse condition is considered the prevailing factor in the understanding and conceptualization of "substance abuse" or "addictive disorders." Actually, in recent years we have observed the opposite, that is, the existence of etiological factors, which are part of medical illnesses or conditions that intrinsically relate to addiction and/or substances of abuse.

This new concept is currently known and internationally accepted as "dual diagnosis." Within this new conceptualization of substance abuse disorders and

dual diagnosis, a series of factors are currently perceived as determinant conditions vis-à-vis substance abuse and dependence. Among these factors we need to include (1) genetic factors, (2) neurobiological factors, (3) psychological factors, (4) behavioral aspects, and (5) sociocultural components.

125.2 Comorbidity Issues

125.2.1 Determinants of Substance Abuse and Dependence

Within this context, we need to address the following factors:

125.2.1.1 Genetic Factors

In alcoholism, genetic factors have been found to play a big role based on family, twin and adoption studies (Nguyen et al. 2011). We must emphasize, however, that alcoholism has been found to also play a key role as a comorbidity factor in other psychiatric disorders, such as depression, bipolar disorder, antisocial personality disorder, conduct disorder, and attention deficit hyperactivity disorder. Attempts are also currently made to categorize alcoholism into clinical phenotypes or subgroups based on factors such as family history of alcohol dependence, age of onset of the disorder, clinical symptoms, and personality traits (Nguyen et al. 2011).

Similarly, attempts have also been made to associate genetic influences vis-à-vis the use and abuse of tobacco and other drug dependencies such as cocaine and other stimulants, opioids, and cannabis (Nguyen et al. 2011). These attempts are also based on family, twin, and adoption studies. In this context, the dopaminergic and the serotonergic systems have been implicated in tobacco dependence and nicotine increases in the central nervous system. The cytochrome P450 enzyme system has also been implicated in the metabolism of drugs and other xenobiotic agents. In this context, the majority of nicotine is metabolized by the CYP2A6 into cotinine (Nguyen et al. 2011). In general, twin studies have demonstrated that genetic factors play a big role in the transition from drug initial use and drug dependence. In some studies, it has also been found that personality variables such as "sensation seeking" play an important role in the prediction of both substance abuse and dependence.

With respect to cocaine and other stimulants, it has been advanced that personality traits such as impulsivity and novelty seeking, as well as an individual response to stress, may be a contributing factor to cocaine addiction (Nguyen et al. 2011). Opiates, including morphine and codeine are drugs that originate from opium; all opioids are composed of substances with morphine. Oral opioid abuse in the United States has increased from 2002 to 2004. It has been found no poor metabolizers in a sample of opioid – dependent cases, thus suggesting that CYP2D6 defective genotypes may provide pharmacogenetics protection against developing opioid dependence (Nguyen et al. 2011).

Cannabinoids such as marijuana is the most commonly used illicit drug in the United States, accounting for 75 % of all illicit drug use. Family studies have indicated that the use, abuse, and dependence of cannabis tend to aggregate in

families (Nguyen et al. 2011). It looks that there is a relationship between the use of cannabis and the development of nicotine dependence and also the subsequent use of hard drugs. There is also increased evidence that the endogenous cannabinoid system plays a major role in the brain's reward pathways. Obviously, genetic factors play a big role in the risk for development of substance use disorders.

The role of genetic factors underlying certain comorbid conditions has also been reported. Emerging evidence suggest overlapping vulnerabilities with common genetic factors predisposing individuals to both substance use and mental disorders or to increasing the risk of having a second disorder once the first appears. For example, variations in the catechol-*O*-methyltransferase gene regulating the enzyme that breaks down dopamine confer vulnerability for developing schizophrenia in adulthood for those who were exposed to cannabis in adolescence (Caspi et al. 2005). Common genetic risk has been reported for several co-occurring psychiatric disorders such as of major depression, nicotine dependence and conduct disorders and antisocial personality disorder (Fu et al. 2007), bipolar disorder and alcoholism (Yasseen et al. 2010), or alcohol dependence and comorbid drug dependence (Dick et al. 2007).

125.2.1.2 Neurobiological Factors

It has been clearly demonstrated that drug addiction is a relapsing disorder categorized by compulsive use of drugs, the inability to control drug intake, and its continued use despite associated negative consequences (Schmidt et al. 2011). The recent focus on the complex neurochemical, biochemical, and structural changes in the brain has shown an impact in the five major classes of drugs; they are as follows: psychostimulants, opiates, ethanol, cannabinoids, and nicotine. Despite the fact that different classes of abused drugs have different mechanisms of actions, there are major similarities among them insofar as the brain circuits modifications observed via repeated exposure to these drugs. The limbic nuclei, including the amygdala, hippocampus, and medial prefrontal cortex send major glutamatergic efferent projections to the nucleus accumbens. The reinforcing effects of all drugs of abuse and due to actions in the limbic system, a circuit of nuclei that is responsible for the influence of motivational, emotional, contextual, and affective information and behavior. Currently, there are overwhelming evidence that demonstrate that increased dopamine neurotransmission contributes to the reinforcing effects of psychostimulants, opiates, ethanol, cannabinoids, and nicotine.

Psychostimulants, despite its different mechanisms of action, increase extracellular levels of dopamine, serotonin, and norepinephrine in the nervous system. It looks, based on animal studies, that enhanced dopamine transmission in the nucleus accumbens is important for the initiation and maintenance of psychostimulants self-administration behavior. Although increased norepinephrine transmission may be involved in the discriminative stimulus effect of cocaine, it does not appear to play a significant role in cocaine reinforcement. Likewise, the role of serotonin vis-à-vis cocaine reinforcement remains unclear. With respect to glutamate, it looks that altered glutamate transmission contributes substantially to cocaine-induced neuronal and behavior plasticity.

Ethanol produces numerous excitatory and inhibitory neurotransmitter systems in the brain, which result in mood elevation, sedative, anxiolytic, and ataxic effects. Marijuana remains one of the most widely abused drugs in the United States. The psychoactive effects of marijuana include euphoria, enhanced sensory perception, increased appetite, analgesia, disrupted cognitive functioning, anxiety, paranoia, and at higher doses, sedation. Stimulation of nicotine acetylcholine receptors in the central nervous system is responsible for the diverse psychoactive effects of nicotine, including mood elevation, decrease anxiety, increased arousal, improved attentiveness, decreased appetite, muscle relation, and cognitive enhancement.

Similar brain regions, such as those involving stress, dopamine, and GABAergic and glutamatergic brain circuitries among others, are also involved in other psychiatric disorders including schizophrenia, mood disorders, or nicotine dependence (Volkow 2004; Moran et al. 2012).

125.2.1.3 Psychosocial Factors

While psychological and social factors can contribute to the development and maintenance of substance abuse and dependence across the lifespan for many individuals, it remains that other individuals often do not develop these disorders, even when facing similar circumstances and biologies (Shoptaw 2011). Once substance use disorders are established, accompanying neural changes and conditioned behaviors ascend in importance, with the roles of psychological and social factors having less impact in maintaining substance abuse or dependence.

Individuals with substance abuse or dependence often complain they have an "addictive personality." This popular term has, however, little empirical support; by contrast, research into long-standing psychological and personality "traits" shared by individuals with substance abuse or dependence shows a good deal of support for common characteristics, specifically: sensation seeking, delay discounting, and other components of impulsivity. In general, persons with antisocial personality disorder are two-and-one half times more likely than those without antisocial personality disorder to also meet the criteria for drug abuse and dependence after controlling for demographics characteristics and other psychiatric diagnoses. Also, individuals who met criteria for any personality disorder are 1.8 and 3.3 times more likely to be comorbid for drug abuse or drug dependence. Individuals with bipolar illness represent an important group who face genetic, neurobiologic, and environmental factors that can contribute to a high prevalence of comorbid substance abuse and dependence disorders. Epidemiological studies have repeated documented bipolar disorder with the highest rate of substance use disorders compared to any other axis I psychiatric disorder. They are more likely to have the mixed and rapid cycling subtype, which responds less to lithium therapy and has high rates of other comorbid psychiatric and medical disorders (Salloum et al. 2005, 2008).

Major depression is also a concomitant factor vis-à-vis alcohol and drug abuse and dependence. Actually, depressed individuals seek out substance use to mediate depressed feelings and thoughts. In general, persons in the general population who suffer from major depression, dysthymia, generalized anxiety disorder or panic disorder concurrent with problems drug use are more likely than those who do not

have these conditions to initiate and use prescribed opioids, presumably to minimize uncomfortable psychological states from those disorders. The presence of major depression with comorbid alcoholism and addictions is characterized by higher severity of symptoms (Salloum et al. 1995; Salloum and Jones 2008), with remarkably higher frequency of suicidal behavior compared to either major depression alone or alcoholism alone (Cornelius et al. 1995; Salloum et al. 1995). Depression and comorbid cocaine dependence has been noted to have high frequency of suicidal behavior and lethality symptoms (Salloum et al. 1996; Cornelius et al. 1998).

Individuals with schizophrenia have one of the highest rates of comorbidities with substance use disorders. Hallucinogens and stimulants can produce experiences similar to schizophrenia in nonpsychotic individuals. Anxiety disorders and substance abuse disorders co-occur at substantial rates. Links between posttraumatic stress disorders (PTSD) and substance abuse tend to be common. Impairments in inhibiting cognitive impulses are linked to using substances of abuse. Adult individuals with attention deficit hyperactivity disorder (ADHD) tend to also have substance use disorders. Among individuals with substance abuse and dependence, a large percentage of them also experience comorbid violence and aggression. Violence and aggression that occurs within the context of a close interpersonal relationship frequently co-occurs with abuse of alcohol or other drugs.

Childhood adversities, including parental substance abuse, family violence, physical sexual abuse, and poverty, have also been present among persons who suffer from substance abuse and dependence. Life stressors can also induce certain individuals to use tobacco, alcohol, or other drugs as a way of reducing psychological discomfort. It should also be noted that individuals who have strong social attachments to their families tend to suffer less from substance abuse or dependence.

125.2.1.4 Behavioral Factors

Much of human behavior is maintained and modifiable by its consequences through the process of operant conditioning; under this process, some consequences of behavior, called reinforces, increase the probability that a person will respect a behavior in the future. Reinforcement is deeply involved in shaping much of human behavior, from simple activities like walking and riding a bicycle to complex behaviors like writing, conversing, an extensive body of experimental research suggests that the external pattern of behavior that no call drug addiction, is also operant behavior that is maintained by its consequences (Silverman et al. 2011).

Early laboratory research in nonhuman subjects has provided strong evidence that drug addiction can be viewed as operant behavior maintained by drug reinforcement. Laboratory models of drug addiction in nonhumans provide a unique and rich service of information on the nature of drug addiction and the variables that affect it. Experimental studies in nonhumans and humans have also provided thorough analyses of the roles of basic elements of operant conditioning in drug self-administration. Reinforcement plays a major role in this regard; this has been demonstrated with cocaine, opiates, alcohol, benzodiazepines, nicotine, and marijuana among others. The role of "discriminative stimulus" is also a good example of certain environmental events that could lead to drug seeking and drug use.

In summary via laboratory and clinical research efforts we have strong evidence that drug addiction can be operant behavior that is maintained and modifiable by its consequences.

125.2.1.5 Sociocultural Factors

Mankind's relationship with substances served socially desired functions. Drugs were used as medicine, in the performance of rituals and religious functions, and as recreation. Sociocultural factors affect individuals either through several small group effects or through the larger social environment. Each of these factors and their implications may have both risk and protective properties; that is, they are part of the etiology as well as prevention and treatment of substance abuse and many psychiatric disorders. In this regard, during the last decade, the focus of research has moved from the investigation of a series of sociocultural factors in isolation to a study of their relevance and interdependence, as well as their links with genetic influences. In this context, society, culture, ethnicity, and race play a major role in the substance use and abuse, as well as their implications with respect to addiction at large in society (el-Guebaly and Ruiz 2011).

Social groups and the microenvironment effects may protect or facilitate an individual's drug use through one or several of social communities such as "the family unit and parenting," "peer group," "schools," "workplace," "social network systems and support," and "group identification and deviancy."

Larger social structures and/or macroenvironment can also play a protective role and/or facilitate drug use, among them neighborhood disorganization; adverse socioeconomic conditions; environmental availability via access, acquisition and distribution of drugs; cultural influences, acculturation process, and media; and/or worldwide electronic information. These previously mentioned sociocultural variables have significant implications in every aspect of the management of the spectrum of the substance use disorders; for instance, sociocultural variations may affect the meaningfulness of the diagnostic categories in the substance use disorders, and the importance of fully assessing an individual's psychosocial and environmental problem that may affect the diagnosis, treatment, and prognosis, via social preventive strategies that could help people to be inoculated against the social pressures precipitating drug trial and experimentation through social coalition building. Likewise, high-profile media campaigners against drug use and abuse; additionally, via prevention effects on a global scale such as the WHO Framework Convention on Tobacco Control"; also, through the use of social treatment strategies via family therapy, group therapy, network therapy, therapeutic community strategies, sober living homes, twelve step programs, employee assistance programs (EAPS), prison settings, as well as other treatment strategies directed to the treatment and prevention strategies.

125.2.1.6 Associated Medical Factors

Within the context of licit and illicit use of substances and drugs, we have to take into consideration the most common medical factors and/or associated conditions with this use and abuse of substances. Among them are the maternal and neonatal

complications of alcohol and other drugs (Kaltenbank and Jones 2011). The public's concern and the subsequent behavioral and medical research on the effects of prenatal exposure to substances is grounded in the concept that disturbances during the development in utero are a direct result if these substances altering the psychical and/or nervous systems of the child. Among the drugs considered capable of negatively impacting the children of abused mothers, we find alcohol, opioids, cocaine, amphetamines, inhalants, toluene, gasoline, marijuana, nicotine/tobacco, benzodiazepines, and hallucinogens, such as PCP.

These have also been excellent reports related to the medical complications resulting from drug use and dependence (Lee et al. 2011). In this context, the critical issue is to provide excellent care of drug users with medical conditions. Overlapping symptoms and syndromes, adherence to treatment, prevention of complications, the use of injection drug use, overdoses, sexual risk behavior, immunizations, and confluent risks and associated outcomes on drug addicts who also suffer from cardiovascular disease and/or cancer; alcoholic pancreatitis; liver disease and viral hepatitis; sexually transmitted diseases such as syphilis, gonorrhea and chlamydia, genital herpes, human papilloma virus, and trichomoniasis; skin and soft-tissue infections; infective endocarditis; tuberculosis; pneumonia; chronic lung disease; pulmonary complications of crack cocaine use, drug use, and neurologic disease; and other types of medical complications all play a major role in dealing with the medical complications of drug use and dependence (Lee et al. 2011).

Likewise, psychiatric complications of HIV-1 infection and drug abuse has led to 60 million drug abuser individuals having gotten infected with HIV-1 worldwide of which 42 million are still living with the infection (Goforth et al. 2011). The introduction of zidovudine (AZT) and later of the highly active antiretroviral therapy (HAART) has helped to decrease both the mortality and the incidence of AIDS (Goforth et al. 2011). Additionally, not only the type of psychiatric disorders related to HIV infection but also psychosocial issues such as abuse; risk-taking behavior; adherence to CART; and central nervous system involvement such as delirium, dementia, sleep disorders, psychosis and anxiety, as well as myopathies and pain with respect to the peripheral nervous systems involvement can all play a major role related to psychiatric complications of HIV-1 infection and drug abuse. Examples of neuropsychiatric infections and malignancies associated with HIV infections are atypical aseptic meningitis, cytomegalovirus (CMV) encephalitis, herpes simplex virus encephalitis, candidiasis, varicella zoster virus encephalitis, liposarcoma, and many others.

Acute and chronic pain should be considered a potentially serious illness in its own right. Chronic pain is associated with mood disturbances, sleep disorder, loss of function, impaired quality of life, and caregiver burden (Portenoy 2011). There is a complex relationship between pain management and the clinical issues surrounding the problems of drug abuse, addiction, and diversion. The key role played by opioid drugs, which are both essential medical treatments and a major source of abuse, has justified the exploration of this relationship. In this context, the implications of pain assessment, the framework for interpreting the nature of the pain, the

relationship between pain and substance abuse, including its terminology such as tolerance, physical dependence, addiction, and abuse, misuse, and other related terms are crucial to understand its relationship. Finally, interpreting nonadherence behaviors in the medical context, the principles of opioid therapy are all essential for a good success on this issue, especially when dealing with patients with history of previous substance abuse.

In the context of substance use disorders, it is very important that we take into consideration the potential existence of co-occurring psychiatric disorders (Dennison 2011). For instance, use of, and withdrawal from, alcohol and other substances of abuse can cause, mimic, or mask psychiatric symptoms. The overlap of these signs and symptoms makes it difficult to accurately diagnose all conditions present. Of course, failing to diagnose any co-occurring disorder (COD) increases the likelihood that the appropriate individual's treatment needs will not be met, thus worsening the patient's prognosis. For some time, individuals with both psychiatric and substance problems have been called "dually diagnosed"; given that dually diagnosed patient are very complex based on the conceptualization of the problem or illness, many professionals prefer to call them "COD" or having "co-occurring disorders."

The World Health Organization (WHO) reports that drug interactions are a major source of morbidity and mortality. Drug interaction can also occur with the coadministration of therapeutic medications with alcohol, with other prescriptions drugs, with illegal or illicit substances, or with other pharmacological interventions that are used in the treatment of substance use disorders. In this context, we need to be aware of the mechanisms for drug interactions. Also important is the understanding of drug interactions between opioids used for the treatment of opioid dependence and other medications, drug interactions between opioids and antiretroviral medications, and interactions between opioids and medications used to treat other infectious diseases such as hepatitis C with interferon, tuberculosis with rifampicin, and with antibiotics at large. It is also essential to be aware of drug interactions between opioids and benzodiazepines and, likewise, between opioid analgesics and other medications; between stimulants and other medications and between alcohol and other medications such as benzodiazepines, bupropion, methadone, cocaine, and methylphenidate; and finally, between cigarette smoke or nicotine and other medications (Haass-Koffler and McCance-Katz 2011).

Despite the fact that in the United States there is certain discomfort with the concept of "dual diagnosis" as previously alluded to (Dennison 2011), internationally, this is not the case. In Europe, primarily in Spain and Italy, as well as in Latin America, primarily in Argentina, Colombia, and Peru, this concept of "dual diagnosis" is not only well accepted and extensively used but expanding at full speed among countries and regions of the world (Roncero et al. 2011).

Within the context of this publication, we must also underline that ethnic, racial, and cultural groups also manifest their medical illnesses, including psychiatric illnesses, within the context of their culture, tradition, beliefs, and heritage (Lewis-Fernandez et al. 2011; Munoz et al. 2007).

125.3 Conclusion

Within the field of substance abuse, the concept of "comorbidity" has greatly expanded and is better understood from a clinical point of view in recent years. In this context, the topic of "dual pathology" is greatly expanded from an international viewpoint, particularly, in countries such as Spain, Italy, Argentina, Peru, Colombia, and others.

This now conceptualized "comorbidity" has also led the field of addiction to focus on a series of determinants of substance abuse and dependence. Among them, genetic factors, neurobiological factors, behavioral factors, socioeconomic factors, and associated medical factors. Within this context the conceptualization of "comorbidity" and/or "dual pathology" has both greatly advanced in the field of substance abuse/addiction. In this chapter, we have tried to enhance its medical/clinical roles; hopefully, further attention to this area of the addiction field will lead to a better understanding of addictive behaviors and also lead to better strategies in their treatment components.
