Foreword

Substance use and abuse is widespread around the world. There are clear cultural differences between countries and sometimes even within the same country regarding the use and abuse of substances. Various cultural and social factors play an important role in defining and treating patterns of substance abuse. Reasons for substance use and abuse vary from genetic, social, and psychological. Depending upon the degree of abuse and recognition of the patterns of abuse, help may be sought from a number of sources. Cultures and societies dictate how resources are allocated and how people are encouraged to use certain pathways into care. Identifying the unmet needs and mental health gap in the field of substance use and abuse is the first crucial step.

This reference text – a significant output from the International Society of Addiction Medicine – meets the aims of the Society. These aims are eminently laudable as they recognize the role of physicians in treating and managing addictions. The key challenges remaining include policy differences across countries and how these must be addressed. Furthermore, training of all health professionals in recognizing physical and psychiatric problems associated with substance abuse is a must. Depending upon human and financial resources, perhaps a tiered approach may be indicated. Physicians in partnership with others have a significant role to play in a public mental health agenda. Substance abuse – varying from tobacco to drugs, prescribed or otherwise – is a major challenge in the field of public mental health. The editors have done a sterling job in bringing together over 250 authors from a rich global background to have shared their expertise and experiences. This volume provides an excellent introduction at an international level to epidemiology, biological, social, and psychological interventions and recognition of medical consequences and comorbidities. The editors deserve our congratulations on a job well done.

President, World Psychiatric Association

The past decade has witnessed disturbing growth in the prevalence and diversity of substance use problems throughout the world. First considered a "US problem" and later a problem "of the Western world," substance abuse and addiction are now clearly world-wide problems producing dramatically greater loss of life, morbidity, and costs than virtually any other health condition.

Perhaps because addictions have been so prevalent and serious in the USA for the past 40 years, over 80 % of published clinical research on addiction to alcohol and other drugs of abuse has been done by the USA and other English-speaking investigators. But this body of work has at best only partially informed our understanding of how to prevent and treat addiction. This is because so many factors that contribute to susceptibility to initial substance use; transition from voluntary use to uncontrolled addiction; and to treatment entry, adherence, and effectiveness are determined as much by environmental, family, and interpersonal forces as they are by genetics and metabolism. These factors vary substantially across countries and cultures. Thus, world understanding about how to prevent, intervene early, and treat addiction will require far more diverse study.

In this context, the *ISAM Textbook of Addiction Treatment*, with its broad and diverse contributions representing 265 scientists and 30 countries, is a timely and welcome addition to worldwide understanding on how to intervene and treat addictions. In particular, the *Textbook* introduces a wide range of new perspectives on the development of substance use disorders and a number of previously unreported interventions to reduce the prevalence, severity, and associated harms from substance abuse and addiction.

To be sure this *Textbook* will not resolve decades-long controversies in optimal prevention, intervention, and treatment responses, there is still too little information and too many preexisting views to yet achieve consensus. But this *Textbook* signals something that has frankly been lacking in US-dominated research and treatment of addiction: a willingness to incorporate, evaluate, and include effective *new* approaches, methods, and tools. It is clear that no country, profession, or theory can claim adequate success in preventing or treating addiction to justify the all-too-common political, financial, and even scientific resistance to new methods.

If there is a need to reduce diversity, it is in our methods of diagnosing substance use disorders, in articulating common goals of treatment, and in adopting common measures and methods for evaluating treatment access, adherence, and effectiveness. These kinds of consensus standards should help this still-developing field of public and clinical health to identify and agree upon effective

new interventions. This is an obvious and needed role for the *International Society of Addiction Medicine* and should be a natural outgrowth of continued international collaboration and sharing of results through venues such as this *Textbook*.

Office of National Drug Control Policy
USA

The initiative to write a textbook addressing the global aspects of addiction, whether prevalence, types, and methods of abuse or different management approaches, is unique and welcome. The chapters are comprehensive to deal with all psychosocial–biological aspects of addiction. Psychoactive substance use poses a significant threat to the health, social, and economic fabric of families, communities, and nations. The extent of worldwide psychoactive substance use is estimated at 2 billion alcohol users, 1.3 billion smokers, and 185 million drug users.

In an initial estimate of factors responsible for the global burden of disease, tobacco, alcohol, and illicit drugs contributed together 12.4 % of all deaths worldwide in the year 2000. Looking at the percentage of total years of life lost due to these substances, it has been estimated that they account for 8.9 %.

The level of economic development in countries also plays an important role. The burden from psychoactive substance use is higher in developed countries than especially in high-mortality developing countries. The sex ratio for the attributable deaths of psychoactive substance use varies from 80 % male for tobacco and illicit drug use to 90 % for alcohol. With regard to DALYs, it is between 77 % and 85 % for all substances. The largest proportion of DALYs is on males in developed countries, where psychoactive substance use accounts for 33.4 % of all DALYs (WHO Website).

WHO seeks to promote the concept of health for all through its strategy of reducing the incidence and prevalence of psychoactive substance use and providing the best available evidence on the management of substance-related problems. The achievement of this goal is designed to lead to reductions in the demand for psychoactive substances and to reduce the health and social problems associated with such use.

The debate that we are criminalizing cannabis while decriminalizing alcohol and tobacco in spite of their higher disease burden is controversial (Okasha 2008). The use of replacement therapy in addiction in developed countries may be unavailable in emerging countries. What are the alternatives? We have contradictory feedback from different countries. I believe this book will enlighten those working in the mental health of addiction in different developed, emerging, or developing countries to comprehend the complexity of the problem of addiction and the necessity to use flexible programs according to the norms, culture, and economy of the country.

Preface: What Does an International Perspective Bring?

The International Society of Addiction Medicine (ISAM) was founded in Palm Springs in 1999. From the onset, the elements of its main mission were

- *Advancement of the knowledge of addiction as a treatable disease*
- *Recognition that physicians worldwide have a major role to play in the management of addiction*
- *Enhancement of the credibility of the physician's role*
- *Emphasis of the importance of educational activities*
- *Establishment of consensus documents and practice guidelines*

To implement this mission, the Society has organized an annual meeting ever since. This major gathering has also been supplemented on a few occasions with regional meetings. The Society also cosponsors the journal *Substance Abuse*. To pursue the mission, an International Certification in Addiction Medicine was created in 2005 and has been administered annually on a total of 15 occasions.

In seeking reference texts to create the examination questions for the Certification, it became evident that the three or four excellent multiauthored textbooks available in English all originated from the USA, with an occasional contribution from an author from another country. These books are heavily centered on data arising from an American context and culture. We decided that a textbook with a broader authorship representation was required as well as a search for data originating from across the world. Mindful of the fact that authors would potentially have different degrees of English proficiency, we divided the scope of our chapters into overview, focused, and sidebar chapters for case studies. International strategies to address substance abuse have traditionally favored control of the supply of drugs rather than reduction of the demand for their use. This textbook aims to describe the multifaceted options available for culturally sensitive strategies prioritizing demand reduction.

This international textbook is divided into 12 sections, resulting from the collaborative efforts over 3 years of some 265 contributors from 30 countries. These sections outline the components of an international perspective.

A broader understanding of epidemiology, etiology, and prevention

The prevalence of drug intake is determined not only by individual stress factors but also regional and larger-scale cultural patterns of drug consumption, social role models, as well as legal requirements and prohibitions.

A common sequence is for the onset of substance abuse to be largely influenced by cultural factors; environmental and social factors are important in the transition to hazardous consumption, while neurobiological and other risk factors become more salient in the transition to substance use disorder.

The genetic and epigenetic components of the heritability of addiction also point to cross-population differences in risk susceptibility across large samples. These considerations consequently inform the spectrum of applied prevention strategies.

An appreciation of the arduous search for a common language as well as means of detection and intervention

A historical review of the concept of substance use and its disorders illustrates differences in international perspectives and challenges in achieving a universal taxonomy. Currently, the recent aggregation of the concept of dependence with that of substance abuse in the latest DSM-5 is in contrast with the efforts of the ICD10 review to retain "hazardous use" as a separate entity. This new DSM-5 spectrum, largely based on questionnaire data, will require further clinical validation.

While there is consensus about the benefits of screening and brief intervention strategies, the selection of optimal screening instruments, laboratory detection methods, and brief intervention techniques is the subject of an international effort to assess cross-cultural validity as well as investigate cost-effective laboratory tests and intervention strategies to accommodate the world's range of financial and practice resources.

The global facets of drug abuse and the current and future of biological approaches

The differential availability of traditional drugs such as alcohol, tobacco, opioids, and cannabis along with newer drugs such as cocaine, amphetamines, hallucinogens, sedatives, and anabolic steroids is evident across the global stage and brings insights into the origins of abuse. Furthermore, our shrinking world is more and more subject to epidemics of new products sweeping from one continent to the next. The trend is for laboratory-manufactured chemicals to replace plant-derived drugs. The latest surge of crystal methamphetamine is now followed by the emergence of synthetic cannabinoids; the creation of these new drugs will unfortunately continue.

Advances in neurosciences have so far yielded about a dozen drug-specific medications, and access to this small number is further limited by conservative national policies, economic constraints, and lack of clinicians' expertise. The good news is that there is also mounting evidence of efficacy from a number of diverse complementary options such as acupuncture, biologics, transcranial magnetic stimulation, nutrients, phytomedicines, and mind-body treatments. The evidence for these approaches originates from around the globe, where some of these techniques derive from a long-standing acculturation.

Behavioral approaches and the balance of fidelity and adaptation

Globally, behavioral approaches are a major element of treatment. Over the last 50 years, these therapies have evolved from generic advice-giving and confrontational strategies to more sophisticated, evidence-based techniques aimed at improving retention in treatment and positive reinforcement of change. Behavioral approaches are either directed at the individual or at groups, couples, families, and communities.

Not all such approaches have been evaluated to the same extent, with the major effort directed at the investigation of Motivational Interviewing, Cognitive Behavioral Therapy, and Contingency Management.

Challenges in the international dissemination of these approaches include the significant effort required for the transfer of knowledge and skills as well as the need to balance the evidence-based principles and methods of the approach with the adaptation needed to incorporate new cultural contexts and values in a translated language. Like in the biological approaches, innovative techniques continue to be created and are at various stages of investigation.

Social therapies and their accessibility

Faced with the difficulties in abating, if not ending, the disease of addiction, a diverse group of socially grounded therapies have sprung worldwide. Approaches have included peer-led movements with no formal affiliation such as the 12-step programs which are spanning most of the globe. Other peer-led programs have evolved as institutions regulated by governments such as therapeutic communities. These approaches are not identical worldwide but have nevertheless many similarities. A major advantage of these approaches has been their cost-effectiveness rendering them accessible to a range of economic capabilities.

The second advantage has been their adaptability to social institutions as diverse as the workplace, the justice system, or the residential treatment programs. These approaches have gained widespread acceptance particularly in developing countries.

The diverse elements of a systems approach

A community treatment system requires a comprehensive network of different approaches, services, and participants. A public health perspective stresses connections among services. These services share concepts of different indications and rules for patient pathways through treatment phases following a stepped care model.

The network, in addition to formal therapeutic regimes, includes low-threshold approaches through outreach activities and harm reduction interventions. The resources and priorities will of course differ between developing and developed countries. A comprehensive network remains a work in progress with continuous adaptations. An overall drug policy document should reflect political support to provide adequate and sustainable resources.

A system must include continuous monitoring and evaluation. The education and training of staff must be informed by the results of the evaluation. Stakeholders are to be involved in the priority setting as well as ethical and legal considerations.

What constitutes a behavioral addiction?

Over the last 30 years, an increasing range of behaviors have been recognized as susceptible to develop from excessive engagement to a habitual or compulsive pattern. In addition to the investigation of common biological and psychological underpinnings, an international perspective highlights the difference between the required quasiuniversal use of a medium like the Internet and the susceptibility to develop an Internet addiction along sociocultural differences. The same applies to the meeting of basic needs such as food, sex, or exercise and their evolution into

compulsive behaviors. Leisure activities such as gambling and videogames may also follow the same pathway. Ever-increasing access to services, products, and credit may accelerate this course.

Other insights are arising from the study of behavioral addictions as windows into human nature without the effects of substances. A model of addiction is emerging, depending less on "harm-based" negative consequences which are subject to ever-changing cultural values and judgment calls and more on the presence of such concepts as craving, loss of control, impulsivity, compulsion, mood dysregulation, and/or cognitive distortions.

Differences in treatment seeking patterns, treatment approaches, and settings as well as goals of treatment are highlighted in an international comparative analysis.

The recognition of medical consequences and comorbidities

The principles of assessment and management of the medical consequences of drug use ought not to be different around the world, and yet morbidity and mortality rates of drug users vary markedly due to differences in the general health status of the population, access to health care, and rates of treatment uptake and dropout. An estimated one-third of the global population is living with one or more bacterial or viral infections. Nutrition is important, and nutritional disorders impact on recovery from other co-occurring illnesses. The availability and acceptability of simple preventive measures like the use of a condom significantly affect the rate of sexually transmitted infections. The medical consequences of drug use interact in each country with the general level of hygiene as well as availability of preventive and treatment resources. While the management of acute disorders is the main focus of health resources in developing countries, chronic disorders including chronic pain become the major concern in developed countries, and substance use plays an important role in the course of both these acute and chronic disorders.

The co-occurring care of substance use and psychiatric disorders and system change

While the recognition of medical comorbidities has not resulted in an overall health system change, a reorganization is occurring in the addiction and mental health fields. Since the 1950s, the recognition of the co-occurrence of substance use and psychiatric disorders and its impact on the delivery of services has evolved. In most developed countries, the addiction field struggled to establish its own system of delivery of care based on the need to treat otherwise unrecognized or marginalized individuals with addictive disorders. In the United States, NIDA and NIAAA as separate research institutes led the building of a scientific knowledge foundation for our field. Worldwide, various degrees of separation remained in existence with many countries maintaining the addiction services under the umbrella of mental health.

For the last 30 years, increased recognition of the high prevalence of individuals with co-occurring disorders has resulted in a replanning of the coordination between addiction and other mental health services and in some cases integration of both systems. Based on improved empirical evidence in both fields, this renewed coordination is leading to enhanced attention to the neurobiological interface as well as pharmacological and psychotherapeutic combined options. The redesign of

optimal systems of care as well as related workforce training is ongoing. Diagnostic-based approaches now integrate the treatment of substance use and other psychiatric disorders.

The dilemmas of special populations

The challenge of prioritizing special groups for further recognition is a daunting one, and there is no international consensus. Our own selection included women, addressing half of humanity as well as the elderly soon to become a quarter of humanity. The LGBT group provided an example of the impact of significant stigmatization. Much attention has been directed at the care of physicians and other health care providers as an example of evidenced excellent outcome when well-defined workplace strategies are in place. Our last two groups involved the "displaced" populations either through conflicts or disasters; internationally, these groups are in the millions!

Perhaps a common feature of these groups is a sense that their fit within the general system of care may not be optimal, and there is demonstrated evidence that some of their needs may be better met wholly or partly in distinct pathways of care.

Meeting the needs of our youth

Contrary to the previously listed groups, there is international consensus that the youth of the world deserve their own care. Much is to be gained by a focused system for young people who use drugs. They face the higher risk of initiating substance use. This initiation is determined by a multitude of risk factors in different developmental contexts, some of it originating from parental chronic substance use.

Adolescence is also a critical period where protective factors can also modify the pathways to substance use. The earlier the intervention during that period, the more chance there may be of a successful outcome including the prevention of chronicity and the reduction of the risk of suicide. Knowledge of the impact of both risk and protective factors can also optimize preventive strategies.

The engagement of a young person who is often vulnerable and even marginalized may require the involvement of multiple systems along with repeated assessments. Greater specificity in treatment choice that is developmentally appropriate such as CBT and MET along with family-based interventions have been demonstrated to provide the most consistent gains. Barriers to involvement must also be addressed such as stigma, safety, transportation, and family commitment.

Educating, training, and sustaining our workforce

The education, training, and sustenance of an appropriate workforce are critical to the survival of our field. A range of pioneering efforts is available. They are based on an increasingly consensual framework of identified competencies recognized by specialty associations as well as a number of universities through a master's degree.

Recognition of these competencies is facilitated through diverse pathways such as an American Board Examination, an International Certification (ISAM), and a number of diploma degrees. The knowledge base is accessible through a number of Open Access literature repositories or educational activities such as the Treatnet program. Fellowships in research training are available through NIDA, and a number of travel fellowships to conferences are offered.

Concerning the recognition of a specialty status, there is no "one size fits all" model. This journey must adapt to local educational and licensing requirements that govern the national practices of medicine.

Beyond training, the recruitment of an adequate workforce must take into consideration the provision of attractive career paths countering stigma as well as adequate remuneration and working conditions.

In conclusion, as no country has so far been able to eradicate the misuse of substances or control excessive behaviors, pooling the international experience is warranted. A global scanning of the options allows us to forecast potentially promising approaches. Considering the world experience, we are also reminded of the dictum "Absence of evidence may not necessarily mean evidence of absence." It may just be that the evidence has yet not been unearthed and our current investigations are still not sensitive enough.

Andreas Heinz and Nady el-Guebaly

Basic Sciences and Clinical Foundations: An Introduction

1

Andreas Heinz and Nady el-Guebaly

Abstract

We here introduce the section "Basic Scienes and Clinical Foundations". In this section we will adress the social, cultural, and regional as well as the neurobiological and genetic aspects of addiction. The foundational section of this international textbook on addiction treatment aims to provide an apt prologue to the topic. This section includes chapters on neurobiology, a thorough review of the neurotoxic and neuroadaptive consequences of chronic drug intake with a focus on alcohol. A chapter on genetics presents the heritability of addiction and its genetic and epigenetic components; another chapter presents the international epidemiological aspects of addiction with a focus on the findings of the Global Burden of Disease study. Another focus is on sociocultural dimensions, thus two chapters present roles of socio-environmental factors in diagnosis and treatment and their impact on the patient-clinician interpersonal dynamics as well as interaction with the family, intimate social networks, community at large, and policy makers. Moreover, we show cultural factors, i.e., the shared beliefs, norms, and patterns of behaviors. The social patterning of psychoactive drug use differs as to whether it is medicinal, regular, intermittent, or addictive. Finally, two other chapters focus on the prevention applications of the

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment: International Perspectives*, DOI 10.1007/978-88-470-5322-9_148,

components discussed with review of the international experience. In conclusion, this foundational section provides an informative basic science review of current knowledge. As this is the first section of this textbook the aim is to demonstrate the basic sciences and clinical foundations; and to reflect the commonalties and differences of broad global and international perspectives.

Drug use and dependence is one of the leading causes of disability and suffering particularly in adolescence and younger adults (Gore et al. 2011). Addictive disorders also contribute to a substantial percentage of interpersonal violence, partly due to the direct effect of drugs of abuse such as alcohol (Heinz et al. 2011) and partly due to social consequences of illicit drug abuse (Macleod et al. 2004; Nutt et al. 2007; Toumbourou et al. 2007). In this section, we will discuss the social, cultural, and regional as well as the neurobiological and genetic aspects of addiction. The appreciation of this term has evolved. In 1976, Griffith Edwards suggested to focus on key aspects of drug dependence, namely, tolerance to drug effects developing with its chronic (ab)use and withdrawal symptoms appearing when chronic drug use is suddenly intermittent (Edwards and Gross 1976). He suggested replacing the term "addiction," as more likely to stigmatize patients because it points to strong drug urges and the allegedly impaired ability to control such desires. Edwards instead proposed to focus on the "somatic" aspects of the addictive disorders, most notably tolerance and withdrawal. However, tolerance also develops to nonaddictive drugs such as β-blockers, which are used as antihypertensive medication, and withdrawal symptoms emerging as a sign of impaired cerebral homoeostasis can appear when β-blocker consumption is suddenly stopped (Karachalios et al. 2005). Therefore, current textbooks of addictive disorders often tend to emphasize the craving for the drug of abuse and the impaired ability to control the consumption of this drug in spite of its adverse effects as key aspects of addictive disorders (American Psychiatric Association and DSM-5 Task Force 2013).

Craving, loss of control, and consumption despite negative consequences have often been labeled as the "psychological" symptoms of an addictive disorder, while tolerance development and withdrawal symptoms have been called "somatic" signs of the disease; however, in our view, this distinction between psychological and somatic symptoms of addictive disorders should no longer be supported, as both withdrawal symptoms and craving for the drug of abuse have cerebral correlates. Tolerance development is associated with neuroadaptations within affected neurotransmitter systems, and withdrawal symptoms result from an imbalance between central excitatory and inhibitory neurotransmitters, causing an overshoot of autonomic nervous system responses (Hughes 2009). Craving in turn might be attributable to dysfunctions of motivational systems including dopaminergic neurotransmission in the ventral striatum (Heinz 2002; Everitt et al. 2008). Furthermore, current theories of addictive behavior emphasize a gradual shift from goal-directed, reward-seeking behavior towards automatic drug intake, a concept that has previously been promoted by Tiffany and Carter (1998) with respect to nicotine dependence and that has currently gained a lot of behavioral as well as neurobiological support

in animal experiments and human studies focusing on chronic drug intakes (Everitt and Robbins 2005). These considerations show that far from being limited to either the psychological or somatic domain, all key aspects of addictive disorders such as tolerance development, withdrawal symptoms, drug craving, and impaired control of drug use are associated with central nervous system correlates and neuroadaptations.

Modern theories of psychiatric disorders integrate subjectively reported symptoms such as craving or urges to consume a drug with behavioral variables such as acute or habitual drug intake and their respective neurobiological correlates (e.g., activation of the ventral or dorsal striatum and the respectively associated frontocortical-striatal-thalamic loops (Chen et al. 2011; Goldstein and Volkow 2011; Peters et al. 2011)). Moreover, neurobiological research has often pointed to the intimate interaction between social stress effects and the development and maintenance of drug addiction (Heinz et al. 2011; Hinckers et al. 2006). For example, exposure to developmentally early social isolation stress in nonhuman primates promotes excessive alcohol intake, and the degree to which such social effects impact on the neurobiological correlates of addiction is modulated by genetic variability (Barr et al. 2003; Fahlke et al. 2000; Heinz et al. 2011; Higley et al. 1991).

Beyond individual social stress factors, regional and large-scale cultural patterns of drug consumption, legal requirements, and prohibitions as well as complex social role models all contribute to the prevalence of drug intake (el-Guebaly et al. 2002; Rehm et al. 2003). Also, modern cosmopolitan societies need to consider the effects of different explanatory models of addictive disorders. For example, we and others have observed that it may not suffice to translate information material to prevent the development of addictive disorders because the concept, the terms, and the general understanding of addictive behavior can vary substantially between persons and cultures and misunderstandings can only be avoided if local and linguistic concepts of "normal" and "harmful" drug use are known (Penka et al. 2008; Vardar et al. 2012).

Our textbook addresses all the above named aspects of addiction. The foundational section of this international textbook on addiction treatment aims to provide an apt prologue to the topic. It consequently includes articles on the burden of disease, the cultural as well as genetic aspects of addictive disorders, and the neurobiology of addiction and also on the resulting strategies for prevention and treatment of drug use and dependence.

The first chapter on neurobiology by Sebold and Garbusow is a thorough review of the neurotoxic and neuroadaptive consequences of chronic drug intake with a focus on alcohol (▶ Chap. 2, "Neurobiology of Addiction"). Dispositional factors such as the level of response to alcohol and early social deprivation are reviewed. The stimulatory and sedative effects of acute alcohol consumption are then outlined, followed by a discussion of the animal and human studies underpinning the concept of a reward system and the important differentiation between the experiences of "liking" and "wanting." The chapter concludes with an analysis of the consequences of chronic alcohol consumption as well as insights for new pharmacological treatment.

The second chapter on genetics by Dr. Rutter presents a complementary perspective to the first one (▶ Chap. 3, "The Genetics of Addiction: A Global Problem with Global Opportunities"). An introduction reviews the heritability of addiction and its genetic and epigenetic components, including the startling finding that our genetic individuality resides in 0.4 % (about 12 million) of the nucleotides in the DNA sequence. The examples provided are derived from cross-population analyses of nicotine dependence, thus providing an insightful window into our second "legal" drug. The chapter concludes with a futuristic perspective on the implications of genetics for treatment and the emergence of pharmacogenetics.

The third chapter by Dr. Rehm et al. presents the international epidemiological aspects of addiction with a focus on the findings of the Global Burden of Disease study (▶ Chap. 4, "Burden of Disease: The Epidemiological Aspects of Addiction"). Regional differences are compared. A sequence emerges whereby the onset of substance abuse is largely influenced by cultural factors; environmental and social factors are important in the transition to hazardous consumption, while neurobiological and other risk factors become more salient in the transition to substance use disorder. A striking example of the relative importance of these factors is presented in a case vignette about the rapid changing patterns of use in Georgia since gaining its independence and the relaxation of state control, by Drs. Kirtadze and Otiashvili. The public health impact of intravenous and polysubstance drug use and a resulting epidemic of infectious diseases are leading to a contemplation of much needed drug policy reforms.

An international textbook ought to pay particular attention to sociocultural dimensions. Consequently, the next two chapters present two complementary perspectives on this topic. Dr. Westermeyer presents a theoretical analysis of the roles of socio-environmental factors in diagnosis and treatment and their significant impact on the patient-clinician interpersonal dynamics as well as interaction with the family, intimate social networks, community at large, and policy makers. A list of recommendations for positive governmental actions is included.

Dr. Room in the next chapter focuses on the cultural factors, i.e., the shared beliefs, norms, and patterns of behaviors. The social patterning of psychoactive drug use differs as to whether it is medicinal, regular, intermittent, or addictive. The handling of alcohol and drug problems often changes over time, for example, from a judicial to a health problem. The chapter concludes with Alcoholics Anonymous as an example of core practices worldwide but also local cultural adaptations. A description of Japanese support groups is provided in Section V on "▶ Social Therapies and Treatment Settings: An Introduction".

The last two chapters focus on the prevention applications of the components previously discussed with review of the international experience. Drs. Burkhart and Simon from the European Monitoring Centre for Drugs and Drug Addiction first describe a logical frame for prevention and assessment of its effectiveness. The basics of several prevention strategies are then described including mass media campaigns and environmental prevention. The benefits and limitations of different targets of the preventative efforts range from the population at large to vulnerable groups to family-based prevention and indicated prevention for individuals.

The second part by the same authors discusses the important regional and cultural aspects of prevention. Societal values influence student and adolescent behaviors as well as parenting practices. Again, an international perspective is presented as to recent developments and trends in preventative measures. Examples of the previously described strategies in different regions of the world and their relative acceptance are described along with resulting lessons about successful transfer and adaptation of the experience between continents and countries.

In conclusion, we hope this foundational section provides an informative basic science review of current knowledge. Due to the different scientific backgrounds involved, several "Glossaries of Terms" are included. The first section of this textbook aims to reflect the commonalties and differences of broad global and international perspectives as salient determinants of management strategies.

Contents

Abstract

Chronic drug intake (including alcohol) has profound neurotoxic and neuroadaptive consequences on neurotransmitter systems and brain circuitries that are strongly involved in learning and memory. Neuroadaptive alterations within these systems can contribute to addiction development and maintenance. Current brain-imaging studies identified neural correlates of behavioral processes that play a key role in addiction, such as cue-induced craving or automatic action tendencies. Such neurobiological findings reflect neuroadaptations to

chronic drug intake, to further environmental as well as genetic factors and serve as dispositional factors for the maintenance of addictive behavior patterns. In this chapter, we describe neurobiological theories of addiction development and maintenance with a focus on motivational alterations and their neurobiological correlates as revealed by current neuroimaging studies in alcohol dependence. We discuss findings that assess alterations in reward anticipation and processing and their respective effects on learning mechanisms that are known to be implied in alcohol dependence. A better understanding of neural processes directly associated with the development and maintenance of addiction can help to improve prevention programs as well as therapeutic and specifically pharmacological interventions in the treatment of addicted patients.

2.1 Introduction

The dependence syndrome is characterized by cognitive and physiological phenomena after repeated substance intake including continuous drug intake despite the knowledge of its negative consequences in order to reduce physiological and psychological withdrawal symptoms. Further symptoms are a high priority given to drug use, the development of tolerance towards the specific drug effects, a strong desire to take the drug, and the inability to stop or control the drug intake or the amount of the consumed drug (International Classification of Diseases, 10th revision (ICD-10); Dilling et al. 2011). According to *The Global status report on alcohol and health* (2011a), the World Health Organization (WHO) described a prevalence of 4 % of alcohol use disorders worldwide with more than 2.5 million people dying annually due to the consequences of hazardous alcohol intake, which as a causal factor exceeds global death rates caused by HIV/AIDS or tuberculosis (WHO 2011a). Regarding nicotine dependence as another common substance use disorder, there are currently more than one billion tobacco users (WHO 2011b), and about five million deaths are caused by direct tobacco smoking (WHO 2012), pointing to the serious physiological harm of tobacco consumption. However, both alcohol and nicotine dependence as common use disorders of legal and socially accepted substances do not only cause severe somatic effects, but also have profound social, economic, and psychological impact on the dependent individuals and society. Since up to 85 % of the patients suffering from alcohol dependence and up to 80 % of smokers relapse after detoxification, respectively smoking cessation (Boothby and Doering 2005; Zhou et al. 2009), strong effort has been made to investigate the underlying pathophysiological mechanisms in the development and maintenance of substance use disorders and to identify their neurobiological substrates. By using brain imaging techniques, neural correlates of processes have been identified that are assumed to be involved in relapse, such as craving or cue-induced, automatic drug intake (Beck et al. 2012; Tiffany 1990). The goal of such studies is to shed light on the neurobiology of drug addiction as well as to provide new options for specific behavioral and pharmacological interventions. For instance, neuroimaging studies that predict relapses in detoxified patients based on neural activation pattern have potential clinical implications: Programs treating addiction might use information about neural correlates of relapse prediction in order to assess patients who have a high risk of relapse to higher levels of care. In this chapter, we will illustrate neurobiological theories of addiction development and maintenance. We will focus on the neurobiology of alcohol dependence and describe excitatory and sedative effects and their neurobiological substrates of acute alcohol intake. We will describe neuroadaptive effects of excessive chronic alcohol consumption and present neuroimaging studies that discovered alterations in neurotransmitter systems and their impact on functional neural activity in alcohol dependence.

2.2 Neurobiological Factors for the Development and Maintenance of Alcohol Dependence

2.2.1 Dispositional Factors for the Development of Alcohol Dependence

Several risk factors for the development of alcohol dependence have been reported in the literature including the influence of genes and environment (Ehlers and Gizer 2013; Zimmermann et al. 2007). We will focus on key mechanisms identified in animal experiments and human studies.

2.2.1.1 Level of Response to Alcohol

One dispositional factor that has been discussed in the literature is the individual response to alcohol: individuals with a low level of response to alcohol, i.e., who consume and need higher amounts of alcohol to experience any stimulating effect and who experience sedative effects only after higher doses of alcohol, tend to use alcohol excessively and seem therefore to be at a higher risk of developing alcohol dependence (Paulus et al. 2012; Schuckit 2000; Schuckit and Smith 2000, 2006). Thus, low sensitivity towards the effects of ethanol predicts future heavy alcohol consumption (Schuckit et al. 2009b) and alcohol-related problems (Schuckit et al. 2009a). This endophenotype represents a genetically influenced trait with a heritability rate of 40–60 % and can be observed more often in subjects with a positive versus negative family history of alcoholism (Paulus et al. 2012), pointing further to a close gene-environment association. Concerning the neurobiological correlates of this trait, human studies using functional magnetic resonance imaging (fMRI) reported that the neural processing of cognitive demands (Paulus et al. 2006; Schuckit et al. 2012; Tapert et al. 2004b; Trim et al. 2010) and emotional stimuli (Paulus et al. 2012) is affected by the individual level of response to alcohol: increased brain activations mostly in the frontal gyrus and cingulate gyrus during trials with emotional faces or demanding – high working memory load – trials (required for usual performance) were associated with a low level of response to alcohol in healthy adolescents (Tapert et al. 2004b) and in young adults (Paulus et al. 2006, 2012; Schuckit et al. 2012; Trim et al. 2010). This may reflect the need of compensatory brain activation for adequate processing of contextual information which has also been observed in alcohol-dependent patients compared to healthy volunteers (Pfefferbaum et al. 2001; Vollstädt-Klein et al. 2010a). Further, alcohol challenge studies reported that in contrast to subjects with a high level response to alcohol, moderate doses of alcohol attenuate this "default" hyperactivity in individuals with low sensitivity to alcohol without affecting their performance (Paulus et al. 2006, 2012; Schuckit et al. 2012; Trim et al. 2010), assuming that after drinking those individuals adapt a more efficient processing, i.e., less effort in suppressing irrelevant information (Paulus et al. 2006; Trim et al. 2010).

Also concerning the genetic influence on alcohol sensitivity, candidate genes encoding the enzymes alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH), which are involved in the metabolism of alcohol, also interact with the

amount of alcohol consumption and thus the risk of developing alcohol dependence (Birley et al. 2009; Frank et al. 2011; Hurley and Edenberg 2012). When alcohol is metabolized, acetaldehyde is produced as the first intermediate product by ADH (Spanagel 2009). Acetaldehyde is assumed to be responsible for some short- and middle-term consequences of excessive alcohol intake such as the feeling of "hangovers" due to its own harmful effects to the body. Primarily in East Asian population, protective ADH variations occur resulting in rapid accumulation of acetaldehyde, which triggers an unpleased "flush" reaction including erythema (redness of the skin) of parts or, in some cases, the entire body and therefore often results in less alcohol consumption (Hurley and Edenberg 2012). Thus, variations in the ADH genes influence alcohol sensitivity, i.e., the acute effects of alcohol consumption (Birley et al. 2009; Chen et al. 2009; Hurley and Edenberg 2012; Whitfield 1994). Altogether, these studies suggest that less negative and aversive effects of acute alcohol consumption are associated with more intake and a higher risk to develop alcohol dependence (Heinz et al. 2001; Schuckit and Smith 1996).

2.2.1.2 Early Social Deprivation

People suffering from psychiatric disorders are often limited in their social interactions; on the other hand, environmental factors (such as social deprivation early in life, isolation or abandonment) can increase the risk to develop psychiatric disorders including drug dependence (Heinz et al. 2011; Meyer-Lindenberg and Tost 2012; Pruessner et al. 2004). Experiencing social stress activates effector systems such as the hypothalamic-pituitary-adrenal (HPA) axis and can sensitize the mesolimbic dopamine system (Heinz 2002; Meyer-Lindenberg and Tost 2012; Pruessner et al. 2004). For example, in nonhuman primates, Nader et al. (2006) observed in a study using positron emission tomography (PET) that low social status was associated with higher (potentially stress-induced) dopaminergic concentrations in the extracellular space (reflected a radioligand binding to dopaminergic D2 receptors) and with increased cocaine intake.

Furthermore, it was demonstrated that in primates, early social deprivation, which induces stress, leads to serotonergic dysfunction, which was associated with high levels of aggression, a low level of response to acute alcohol intoxication and higher alcohol intake (Heinz et al. 1998a). Young primates who were separated from their mother in early infancy displayed a lower level of serotonin turnover, a higher availability of serotonin transporters (5-HTT) and lower level of response to alcohol. In this study, the 5-HTT increase appears to have been a consequence of stress-induced reduction of the turnover of serotonin (Heinz et al. 2000). A high level of 5-HTT availability may also be due to genetic variation (Lesch et al. 1996) and may thus affect alcohol intake: In line with this assumption, Hinckers et al. (2006) observed that subjects with a genetic disposition for a high availability of 5-HTT displayed low alcohol sensitivity which was correlated with higher alcohol consumption in adolescents.

Moreover, rodent studies showed that social isolation during a critical period of adolescence enhances the glutamatergic N-methyl-D-aspartate (NMDA) receptors

in the ventral tegmental area (VTA) (Whitaker et al. 2013). The VTA is the center of origin of striatal dopaminergic projections and is thus significantly involved in reward-based learning as well as in the development of dependent behavior. In these socially isolated rats, Whitaker et al. (2013) observed an increased learning rate for drug-associated stimuli, which was more resistant to extinction, suggesting that NMDA receptor plasticity is one mechanism though which the vulnerability of drug dependence is adjusted during a critical period in adolescence (Whitaker et al. 2013).

2.2.2 Effects of Acute Alcohol Consumption

It is assumed that moderate acute alcohol intake is linked to consequences such as stress reduction and relaxation via the sedating effect of alcohol (Zimmermann et al. 2007), physiological excitation (improved performance on motor, cognitive, and information-processing tests), a decrease of negative mood states (like anxiety and depression), increased talkativeness, as well as feelings of euphoria and increased sociability (Ekman et al. 1963; Gilman et al. 2008; Williams 1966). The ability of alcohol to reinforce its acute intake increases the probability of repeated alcohol consumption and thus is a key condition for developing excessive intake (Heinz et al. 2012).

Since ethanol passes the blood-brain barrier quickly after alcohol consumption, several neurotransmitter systems are affected by acute alcohol consumption (Charlet et al. 2013; Lindenmeyer 2001): Here, enhancing and stimulating effects as well as inhibitory effects of ethanol are mediated by the time course of the respective activation of dopaminergic, serontoninergic, opioidergic, gamma-aminobutyric acid (GABA)ergic, and glutamatergic neurotransmission, modulating the individual vulnerability to develop alcohol dependence.

2.2.2.1 Stimulatory Effects of Acute Alcohol Consumption

Ethanol acts as a stimulant via its excitatory effects on the central nervous system (CNS), which can be perceived as rewarding. Conscious affective experiences of alcohol consumption have, e.g., been documented by Williams (1966), who reported a decreased negative affective status (less anxiety and less depression) after the intake of low levels of ethanol in healthy volunteers. Moreover, positive effects on the behavioral level like increased talkativeness, elation, happiness, euphoria, relaxation, stress reduction, and increased sociability and anxiolytic effects have been reported (Duka et al. 1998; Ekman et al. 1963; Gilman et al. 2008). Gilman et al. (2008) measured the rewarding and anxiolytic effects of alcohol using fMRI in social drinkers receiving ethanol injection. The authors observed that alcohol activated the dopaminergic striatal reward system which correlated with higher self-ratings of intoxication, regardless of presenting threatening or nonthreatening emotional stimuli to the participants, (Gilman et al. 2008). The authors suggested that this anxiolytic effect of alcohol may affect the ability of decision-making after alcohol consumption, thus subjects may underestimate

dangerous situations. The experience of strong stimulating effects of ethanol on the one hand and low sedative or aversive effects on the other hand was associated with a higher risk for increased alcohol consumption and the development of alcohol-related problems (Holdstock et al. 2000; Newlin and Thomson 1990).

Serotonergic neurotransmission is assumed to be involved in mediating the acute effects of alcohol as well as modulating aggressive behavior and negative mood states (Bushman and Cooper 1990; Heinz et al. 2001) and in a low response to alcohol. Serotonin hereby, e.g., interacts with dopaminergic neurotransmission, which plays a key role in integrating motivational and motor functions (Heinz et al. 2001, 2003; Knutson et al. 1998; Robbins et al. 1989). Serotonergic neurotransmission seems to play a key role in the development rather than the maintenance of alcohol dependence: in a study by LeMarquand et al. (1994), serotonergic uptake inhibitor like citalopram and fluoxetine decreased alcohol intake in moderate social drinkers. However, studies of selective serotonergic reuptake inhibitors (SSRIs) do not clearly support their effectiveness in alcohol treatment (Garbutt et al. 1999; Kiefer and Mann 2005). This may be due to the fact that anxiety and depression, which correlate with 5-HT dysfunction after detoxification (Heinz et al. 1998b), do not predict relapse during the first month of abstinence. Rather, anxious subjects tend to be more cautious and to avoid harm, and depression only predicts relapse if persisting for a long time after detoxification (Heinz et al. 2001).

2.2.2.2 Sedative Effects of Acute Alcohol Consumption

With increasing doses of alcohol consumption, sedative effects of ethanol occur (Martin et al. 1993). These inhibitory alcohol effects could be associated with negative mood states and the subjective experience of a hangover (Nagoshi and Wilson 1989). In comparison to the stimulatory effects that reflect the rewarding aspects of alcohol consumption and reinforce alcohol intake, sedative and unpleasant effects may thus tend to decrease alcohol use (Ray et al. 2009; Schuckit and Smith 1996). Here, high amounts of alcohol inhibit/interfere with glutamatergic neurotransmission (Carlson and Lydic 1976; Cohen et al. 1997). It has been hypothesized that sedative effects induced by ethanol reflect a generally lower activity of the cerebral cortex (Hendler et al. 2013). For example, a PET study by De Wit et al. (1990) revealed that glucose metabolism after acute consumption of ethanol is decreased in the whole brain, particularly at higher doses. Furthermore, brain regions associated to specific behavioral impairments induced by alcohol intake have been identified. For example, impaired motor coordination, which was associated with reduced functioning of the cerebellum (Hanchar et al. 2005); PFC impairment was associated with impairments in executive cognitive functions, including planning, verbal fluency, memory and complex motor control in healthy control receiving different doses of alcohol (Peterson et al. 1990), as well as cognitive flexibility, information processing speed, and planning and problem solving in patients suffering from alcohol dependence (Zorko et al. 2004).

Consumption of high doses of ethanol appears to be particularly relevant in adolescence, because this life span is a critical period of cortical development which can be disrupted by alcohol intake (Crews et al. 2007). Interestingly, animal

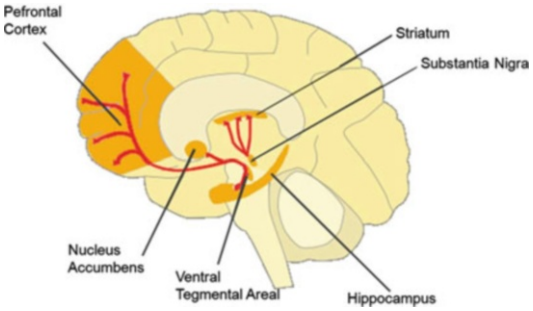

Fig. 2.1 The dopaminergic mesocorticolimbic circuit: the VTA, ventral striatum, including the nucleus accumbens (NAcc), dorsal striatum, the amygdala, frontal and limbic circuits. Key regions of the so-called neural "reward system"

studies show that adolescence is a period with a decreased sensitivity to the sedative effects of acute alcohol consumption, with adolescents showing substantially less acute alcohol sensitivity (Silveri and Spear 1998). Monti et al. (2005) observed that adolescent as well as alcohol-preferring rats show low sedative effects of alcohol, comparable to humans at risk for developing an alcohol dependence (Schuckit and Smith 1996). Critically, this may entice adolescents to binge drink, although, they are more vulnerable than adults to neurotoxicity induced by ethanol (Crews et al. 2000; Monti et al. 2005). Crews et al. (2000) described binge drinking-induced brain damages in adolescent rats in frontal and temporal cortical regions, while adult rats showed no binge drinking-induced alterations in these areas. In line with this, De Bellis et al. (2005) observed in a human study using magnetic resonance imaging (MRI) a smaller PFC in subjects with an adolescent-onset-alcohol use disorder. Here, a smaller PFC correlated with a higher number of drinks per drinking episode and a higher number of drinks per maximum drinking episode (De Bellis et al. 2005).

2.2.3 Addiction and the Reward System

2.2.3.1 Disentangling "Liking" from "Wanting"

Key regions of the so-called brain "reward system" are innervated by dopaminergic neurons ascending from the ventral tegmental area (VTA) and substantia nigra via the ventral (including the nucleus accumbens (NAcc)), and the dorsal striatum, and the amygdala to frontal and limbic circuits (Ikemoto 2007) (see Fig. 2.1). All drugs of abuse have in common that their intake leads to increased dopaminergic neurotransmission in the ventral striatum and the NAcc (Di Chiara and Imperato 1988). As natural or primary (like food, sex, or sleep) and secondary reinforcers (like money) also elicit dopaminergic release, it was initially suggested that dopamine mediates reward and causes hedonic feelings (Wise 1982). Thus, the mesocorticolimbic circuit has often been termed as the neural "reward system." However, this assumption was challenged by studies that demonstrated symptoms of apathy instead of anhedonia in subjects who received pharmacological blockage of dopaminergic neurotransmission such as neuroleptics (Acquas et al. 1989;

Heinz 2002). It was therefore suggested that dopamine mediates motivational behavior towards reward instead of consummatory pleasure – therefore functions as a neural correlate of "wanting" instead of "liking" (Berridge 2009). It is generally assumed that "liking" (experience of pleasure) on the neurobiological level is associated, e.g., with the opioidergic neurotransmitter system, and on a neuroanatomic level with activity within the NAcc and the ventral pallidum (Le Merrer et al. 2009). Evidence for a functional role of the opioidergic system in mediating hedonic effects of reward comes from human studies and animal experiments: Animal studies using mu receptor knockout mice showed decreased food intake (Papaleo et al. 2007) and insensitivity toward the hedonic effects of morphine (Matthes et al. 1996). In accordance with this, nalmefene – a μ-opiate receptor antagonist decreases subjective pleasantness of palatable foods in humans (Yeomans and Wright 1991). Besides food reward, the opioid system further seems to mediate hedonic and affective value of drug reward, including alcohol consumption. Thus, it was shown that a genetic variation of the μ-opiate receptors is associated with more intense response to alcohol (Ehlers et al. 2008) and with alcohol craving (Heinz et al. 2005a). Moreover, naltrexone, a μ-opiate receptor antagonist that is administered for craving reduction in addiction treatment is assumed to block the hedonic effect of alcohol, thus reducing relapse rates and alcohol intake in alcohol-dependent patients. Thus, the opioidergic system is assumed to serve as a neural correlate of "liking" and may therefore mediate positive emotions, such as pleasure, hedonism, or reward when drugs are consumed. Dopamine, on the other hand, appears to play a key role in mediating "wanting," thus signaling behavioral significance and triggering motivation. Evidence for this comes from studies that demonstrated increased dopaminergic neurotransmission when reward occurs unexpectedly or when it is greater than expected, thus signaling salience and consequently motivates the individual to strive toward the reward (Schultz 1998).

2.2.3.2 Dopamine in Mediating Learning Effects

Dopaminergic firing increases when reward-predicting cues appear, thus mediating reward anticipation and reinforcement learning. Primarily, Schultz (1998) demonstrated a shift in phasic dopaminergic activity from the received reward to the reward-predicting cue, as soon as subjects have learned the contingency between the reward and the stimulus. However, learning via dopaminergic transmission is also established when experiences other than reward were paired with a previous neutral cue: For example, phasic dips in dopaminergic activity were observed when an outcome is worse than expected (Schultz 1998; see Fig. 2.2). Indeed, there is accumulating evidence that intact dopaminergic transmission is essential for extinction learning, for instance, for the deletion of conditioned responses to stimuli that are no longer associated with reward (Quirk and Mueller 2008). Drugs of abuse elicit dopaminergic neurotransmission to a greater extent and to a more immediate effect (Goldstein 2001) than natural, biologically essential (primary) rewards (Heinz et al. 2012). Moreover, compared to natural reinforcers, the effect of drugs on dopaminergic release does not seem to habituate (Di Chiara and Bassareo 2007),

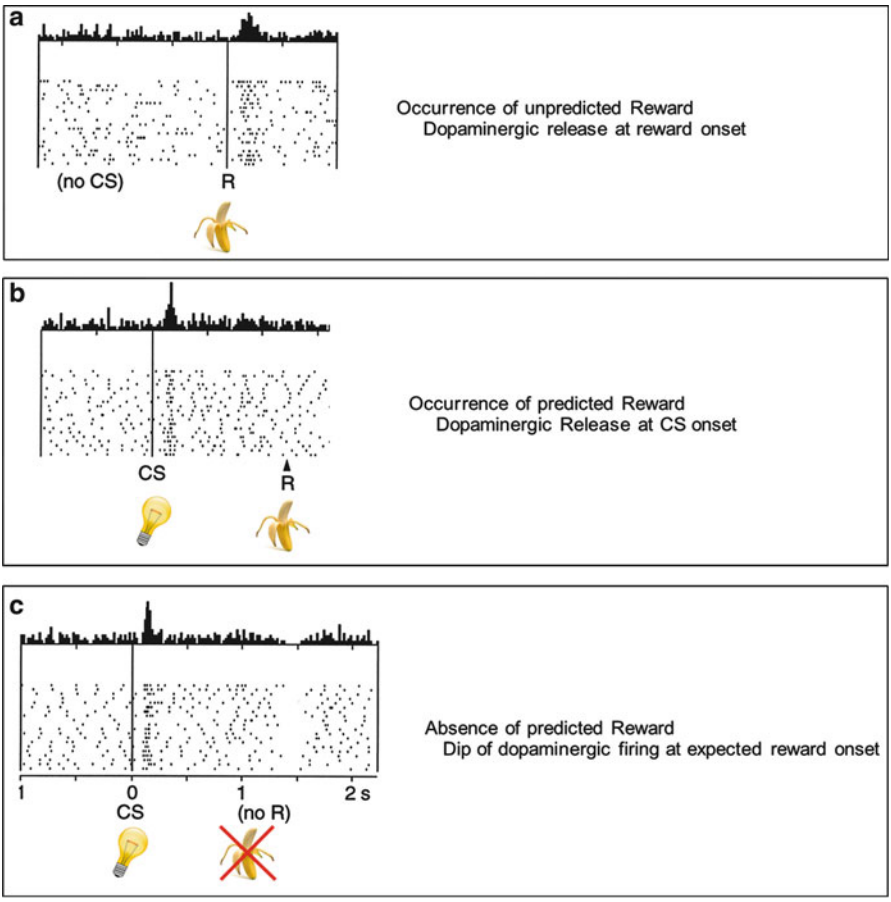

Fig. 2.2 (**a**) Burst of dopaminergic firing in occurrence of an unpredicted reward (R) at reward onset (positive prediction error). (**b**) After pavlovian conditioning: burst of dopaminergic firing not at reward but at conditioned stimulus (CS) onset. (**c**) No reward: Dip of dopaminergic firing at expected reward onset (negative prediction error) (Adapted from Schultz (1998))

because the pharmacological effect of the drug itself causes a persistent dopaminergic release in the striatum (Wise and Rompre 1989). Furthermore, in animals (Paulson and Robinson 1995), repeated administration of drugs fosters augmented dopamine release. This phenomenon – commonly termed as sensitization – was also confirmed to some degree in humans (Boileau et al. 2006). Thus, repeated administration of addictive drugs might cause a hypersensitive dopaminergic system. Moreover, it has been suggested that in addiction, dopamine is released by formerly neutral cues that have predicted drug intake previously (Heinz 2002). Several animal studies demonstrated that in addiction drug-associated stimuli activate dopamine release in the medial prefrontal cortex and the ventral striatum (Bassareo et al. 2007; Dayas et al. 2007; Di Chiara 2002; Shalev et al. 2002). These findings have been extended to

humans, as it was demonstrated that the expectation of amphetamine effects also elicits an increased dopaminergic transmission (Boileau et al. 2007). Crucially, these dopaminergic releases might signal increased salience of specific drug-associated stimuli and thus potentially capture and hold the individual's attention (Robinson and Berridge 1993). In alcohol dependence, external stimuli of visual or olfactory modality, such as the sight of an alcohol bottle in the supermarket or the smell of it in a pub might serve as such predicting cues.

2.2.3.3 Incentive Salience Theory of Addiction

The adaptation of phasic dopaminergic signals over the course of learning appears to reflect the assignment of value to cues (Flagel et al. 2011). Thus, in addiction it has been proposed that environmental stimuli, which have repeatedly been paired with drugs, acquire incentive salience as a result of pavlovian learning (Robinson and Berridge 2008). More precisely, it is assumed that these drug-associated stimuli can become "motivational magnets" as they attract attention and guide approach behavior (Berridge 2009). Indeed, when intravenous cocaine administration is reliably and repeatedly paired with an external cue (illuminated lever), rats approach the illuminated lever more likely and with increasing rapidity, so the cue now became a conditioned stimulus representing the cocaine reward (Uslaner et al. 2006). Moreover, an increase of alcohol consumption has been observed in the presence of stimuli that have formerly been presented during alcohol intake (Corbit and Janak 2007; Glasner et al. 2005). The attribution of incentive salience to drug-associated stimuli is thought to be closely linked to the observation that addicted subjects show significant reactions to drug-related stimuli even when no drug is administered, a phenomenon commonly referred to as cue-reactivity (Carter and Tiffany 1999).

Cue-induced activity in addiction has been demonstrated to exist on a variety of physiological levels including changes in heart rate, sweat gland activity, skin temperature, and functional brain activity (Carter and Tiffany 1999). These physiological changes are assumed to reflect automatic conditioned responses that are not under conscious control. Studies using stimuli that are presented below conscious threshold demonstrated these "automatic" physiological responses to drug-related cues. In a neuroimaging study conducted by Childress et al. (2008), cocaine-addicted patients displayed increased limbic activation when confronted with cocaine-related pictures for only 33 ms. Further cue-induced neural reactions towards drug-related context have been assessed with different neuroimaging techniques: heavy but not light drinkers displayed increased neurophysiological activity in frontal regions in the electroencephalogram (EEG) when watching alcohol-related cues for only 500 ms (Herrmann et al. 2001). Furthermore, Petit et al. (2012) demonstrated in a recent study that when confronted with alcohol cues, heavy social drinkers displayed poorer inhibitory ability in a visual Go/No-Go task: here a response is claimed in the Go condition and should be inhibited in the No-Go condition announced by a specific signal, respectively. Another study assessed neural activation patterns using fMRI during the presentation of pictures of alcoholic drinks and neutral cues to heavy and light social drinkers and observed

a heightened alcohol cue-induced neural activation of the dorsal striatum in heavy social drinkers, while light social drinkers showed increased activation in the ventral striatum and prefrontal "cortical control" regions (Vollstädt-Klein et al. 2010a). As the authors suggested, this may indicate resilient neural patterns preventing the light social drinkers from the development of alcohol dependence (Vollstädt-Klein et al. 2010b). In accordance with this, in a recent study conducted by Beck et al. (2012), patients prospectively remaining abstinent displayed intact ventral striatal activation when confronted with alcohol cues, while patients who prospectively relapsed did not.

Increased physiological cue-reactivity was also reported in relation to consciously experienced cue-reactivity, as indicated by self-reported measurements that assess increased craving or the desire for a particular substance of abuse (Schulze and Jones 2000; Vollstädt-Klein et al. 2010a). Interestingly, a study investigating the response of light, heavy social drinkers and alcohol-dependent patients to alcohol-related cues reported different effects on craving associated with the content of the alcohol cues used: while pictures displaying solely alcoholic beverages induced more craving in the patient group, complex social scenes with alcoholic beverages were more likely to elicit craving in the group of heavy social drinkers, referring to a shift of the rewarding aspects and positive expectations of drinking in a social context in social drinkers towards the habitual motivated aspects of alcohol itself in alcohol-dependent patients (Lee et al. 2006). However, it has been demonstrated that subjective and physiological cue-reactivity can be dissociated, as physiological cue-induced responses in addiction resemble responses elicited by affectively positive stimuli, albeit subjects deny conscious feelings of pleasure (Heinz et al. 2003; Mucha et al. 2000).

2.2.3.4 Habitual Drug Seeking

Whereas the incentive salience theory suggests that in addiction, drug-associated cues become motivationally highly attractive and therefore "wanted," Tiffany's theory of addiction suggests that drug consumption reflects a habitual responding that is controlled by automatically initiated action schemata (Tiffany 1990). Thus, in addiction, drug-associated stimuli might not elicit a positive affective or motivational state that results in drug-seeking behavior. Rather, according to Tiffany's theory in addiction, drug consumption happens to occur in a habitual fashion, as it might be automatically initiated mostly independent of actual reinforcer contingencies and current reward values (Stephens et al. 2010; Tiffany 1990). Theoretical arguments for habits as a key role in drug addiction were based on the observation that drug consumption in addiction seems to be fast and efficient, initiated and completed without intention, difficult to impede in the presence of triggering stimuli, effortless, and conducted in the absence of awareness (Tiffany 1990). Further evidence for habitual drug consumption comes from clinical observations of addicted patients: many relapses happen to occur without any preceding urges to consume drugs or conscious craving (Tiffany 1990). According to their "transition to habit" theory, Everitt and Robbins (2005) suggested that addiction reflects the

endpoint of a series of transitions: from initial drug intake that causes hedonic feelings (liking) to a stage when substance use becomes habitual (wanting) and ultimately to a loss of control that is characterized by compulsive drug seeking and intake. Habitual drug consumption is assumed to be disentangled from anticipatory drug effects. Evidence for this comes from animal studies: rats that have learned a specific response in order to self-administer drugs continue to perform this response even when drug delivery is suppressed (Katner et al. 1999; Katner and Weiss 1999). Thus in addiction, action selection may no longer be guided by outcome expectancy, but rather be driven by external sensory information that elicits pavlovian-conditioned responses. The standard test of habitual action selection is the demonstration that sensory-specific devaluation or revaluation of rewards has no immediate effect on choice behavior. In the devaluation design the value of a specific reward is decreased, for instance, by associating it with sickness, whereas in the revaluation design, the value of the reward is increased, for instance, by determining to experience the reward in a state of deprivation. Crucially, neither devaluation nor revaluation of a stimulus alters choice behavior on that stimulus, when action selection is habitual. This has been supported by studies demonstrating that unlimited access to alcohol fosters ethanol consumption in rats, which is insensitive to quinine, which has a bitter taste and is thus not rewarding (Hopf et al. 2010; Wolffgramm and Heyne 1995). Crucially, it has been demonstrated that responding for ethanol becomes insensitive to devaluation at a stage when responding for food reward is still sensitive to devaluation, indicating that the shift from goal to stimulus-directed consumption is more rapid for alcohol than for natural rewards (Dickinson et al. 2002).

On the neural level "wanting" might be mediated by the ventral striatum and the state of habitual intake by the dorsal striatum. Thus the development of an addiction might be mediated by a transformation from goal-directed to stimulus-driven, automatic behavior, which is assumed to be accompanied by a shift of ventral to dorsal striatal activity. Animal studies seem to confirm this contention: once substance use becomes habitual, drug-associated stimuli foster release of dopamine in the dorsal striatum (Balleine et al. 2007; Corbit et al. 2012; Ito et al. 2002; Wong et al. 2006). However the translation of observations in animals excessively trained to perform lever presses for food or drugs, which finally habitize, to human behavior, which can be consciously reflected and verbalized, is controversial. Existing studies in humans have demonstrated that smoking cessation in nicotine-dependent subjects increases motivation for tobacco smoke (Madden and Bickel 1999; Perkins et al. 1996), indicating goal-directed responses in nicotine dependence. However, as these tests were not conducted in extinction, the effect of deprivation might have been mediated by the experience of an increased reward value in the deprivation state rather than the altered reward value of the expectancy (Stephens et al. 2010).

Also compulsions and obsessions as in obsessive compulsive disorder (OCD) do hardly resemble habitual intake (Schoofs and Heinz 2013). Therefore, the role of habitual vs. goal-directed drug intake in humans in addiction remains to be explored.

2.2.4 Consequences of Chronic Alcohol Consumption

2.2.4.1 Cue-Reactivity

Physiological and subjectively experienced cue-reactivity has been suggested to play an important role in addiction maintenance and relapse. More precisely, in addiction it is assumed that drug-associated stimuli signal upcoming reward and thus prompt drug-seeking behavior (Robinson and Berridge 1993). This evidence has been generated from a number of studies using fMRI in order to investigate neural correlates of cue-reactivity. These studies have shown that substance-dependent subjects display increased activation of several core regions of the mesolimbic pathway, when confronted with drug-associated stimuli. This finding has been reported in various substance dependencies, including heroin (Yang et al. 2009; Zijlstra et al. 2009), cocaine (Volkow et al. 2006), alcohol (Beck et al. 2012; Grüsser et al. 2004; Schacht et al. 2013; Tapert et al. 2004b; Wrase et al. 2007), cannabis (Filbey et al. 2009), and nicotine dependence (Bühler et al. 2010; David et al. 2005). Although these studies suggest substantial overlap between neural structures implicated in cue-reactivity, the identified brain structures considerably vary between studies, depending on the experimental design of the study (duration of stimulus presentation, block design vs. event-related design), cue-modality (visual, olfactory, gustatory), and state of the subjects (detoxified patients or actively drinking, treatment seeking vs. no treatment seeking patients) (Heinz et al. 2010; Yalachkov et al. 2012). Brain regions which have reliably been identified in different cue-reactivity fMRI studies include the anterior cingulate cortex (ACC), the medial prefrontal cortex (mPFC), the ventral and dorsal striatum and the orbitofrontal cortex (OFC), the dorsolateral prefrontal cortex (dlPFC), and the amygdala (Charlet et al. 2013, see Table 2.1). Several neuroimaging studies also reported correlations between cue-induced hyperactivity in the mesolimbic circuit and self-reports of craving in substance-dependent patients, suggesting that cue-related neural activation of reward-associated brain regions may be associated with the motivation to consume drugs and therefore with prospective relapse. In alcohol dependence, a positive correlation between craving and cue-induced neural activity was found in the subcallosal gyrus (Tapert et al. 2004a), the ventral striatum, the orbitofrontal cortex, and the anterior cingulate cortex (Myrick et al. 2004). As the assessment of craving is limited by the fact that it relies on individuals' ability to accurately rate and report their own desire for the substance, some studies add more objective relapse indicators, such as days of abstinence in a given observation period following brain imaging assessment. Here, cue-induced activity in the ventral putamen/striatum (Braus et al. 2001) and the medial prefrontal cortex (Grüsser et al. 2004) predicted relapse in detoxified alcohol-dependent patients within a follow-up period of 3 months. A recent study by Beck et al. (2012) observed that functional connectivity patterns differ between prospective relapsers and abstainers from alcohol: while subsequent relapsers displayed increased neural activation in the medial prefrontal cortex during the presentation of alcohol-associated versus neutral stimuli, subsequent abstainers activated midbrain regions, such as the ventral tegmental area including the subthalamic nucleus and showed increased functional connectivity between the

Table 2.1 Core regions activated by alcohol-related stimuli in imaging studies using cue-reactivity paradigms

Brain structure	Function	Study	Study design of cue reactivity paradigm
Anterior cingulate cortex (ACC)	Performance monitoring and error detection, encoding of motivational salient stimuli	Tapert et al. (2003)	Alcohol-related vs. nonalcohol pictures

midbrain, amygdala, and the orbitofrontal cortex. This observation may suggest that (preserved) integrity of a circuit that is implicated in the processing of aversive aspects and the danger of alcohol intake may represent a resilience factor against relapse (Beck et al. 2012).

2.2.4.2 Neuroadaptive Dopaminergic Changes

Chronic alcohol intake has been demonstrated to be associated with profound neuro-adaptive and neurotoxic effects on dopaminergic, GABAergic, serotonergic, and glutamatergic neurotransmission. For instance, alcohol-dependent patients display low levels of dopamine synthesis and release as well as an decreased availability of D2 receptors (DRD2) in the ventral striatum (Heinz et al. 2004, 2005b; Volkow et al. 1996). A positive correlation between the reduction of DRD2 and lifetime alcohol intake (Heinz et al. 1996) suggests that these neuroadaptive alterations might be due to excessive alcohol consumption rather than genetically prerequisites. The extent to which DRD2 and dopamine synthesis are decreased was correlated with self-reported craving for alcohol, which predicted relapse (Heinz et al. 2005b). In accordance with the observation that up to 70 % of all placebo-treated alcohol-dependent patients relapsed within the first 12 weeks after detoxification (Boothby and Doering 2005), it has been demonstrated that the described alterations in the dopaminergic neurotransmission recover within the first days to weeks after detoxification (Heinz et al. 2005b). Thus, it has been suggested that in early phases of abstinence, the described neuroadaptive changes of dopaminergic neurotransmission cause the individual to strive for particularly strong activators of the downregulated dopaminergic system such as drugs or drug-associated stimuli, which are effective enough to elicit a substantial dopaminergic

response in spite of the generally reduced neurotransmission. This is in line with the finding that the degree of striatal downregulation of DRD2 in alcohol dependence is associated with the extent of drug-cue-induced activation in the medial prefrontal cortex and the anterior cingulate and with the severity of alcohol craving (Heinz et al. 2004). It has been suggested that the bias towards high dopaminergic stimulatory drugs can bias choices against weaker primary and secondary reinforcers such as food, money, or social interactions. A current study of Kienast et al. (2013), who combined PET and fMRI, further suggests a failure of dopamine-modulated emotion processing of aversive stimuli in alcohol-dependent patients. Here, no association was found between dopamine synthesis in the amygdala and functional activation in the amygdala and ACC elicited by aversive emotional stimuli in recently detoxified alcohol-dependent patients, while such correlations were observed in healthy volunteers (Kienast et al. 2008). Furthermore, the patients displayed impaired functional connectivity between the amygdala and the ACC while viewing the aversive cues, which may contribute to increased trait anxiety due to malfunctional corticolimbic neuromodulation. Negative mood states, such as high anxiety, can lead to an increased relapse risk especially in late abstinence (Kienast et al. 2013).

Dopaminergic dysfunction may primarily interfere with learning of new conditional stimuli and contexts that predict nondrug reward. Indeed a study demonstrated impairments in learning from nondrug-related rewards in alcohol dependence (Park et al. 2010), which correlated with craving for (well-learned non-explicit) alcohol intake. The shift of natural reward processing to preferential drug-related reward processing has been metaphorically described as a "hijacking of the reward system," which was substantiated by several studies using a Monetary Incentive Delay task (MID, Knutson et al. 2001). For example, it was shown that alcohol-dependent subjects compared to healthy controls displayed a decrease in ventral striatum activity during expectation of monetary gains but an increased activation in the same region when confronted with drug cues (Beck et al. 2009; Wrase et al. 2007). Activity in the ventral striatum elicited by drug cues was correlated with self-reports of craving (Wrase et al. 2007). These findings are in line with other studies suggesting an essential role for the ventral striatum in relapse prediction. For instance, the degree of ventral striatal activity elicited by drug-associated stimuli presentation was associated with time until relapse (Braus et al. 2001) and the amount of prospectively consumed alcohol (Grüsser et al. 2004), suggesting that the ventral striatum plays a role not only in the acquisition but also in the maintenance of alcohol dependence. In accordance with the assumption of a hijacked reward system, it has been suggested that strong neural responses to rewarding, nondrug-related stimuli might serve as a potential protective brain mechanisms against relapse. Indeed, it was demonstrated that increased ventral striatal responses to affectively positive connoted pictures were related to more subsequent abstinent days and less prospective alcohol intake (Heinz et al. 2007). Furthermore, Charlet et al. (2013) observed heightened neural responses to emotionally negative facial stimuli in the ACC, which also predicted better treatment outcome (days of abstinence and days of binge drinking) in

a 6-month follow-up period in detoxified alcohol-dependent patients. Since the anterior cingulate cortex is involved in the adequate attribution of people's intentions as well as in error monitoring and emotion control, the integrity of this specific brain area might thus represent one resilience factor protecting patients from relapse despite stressful social situations (Charlet et al. 2013).

2.2.4.3 Neuroanatomical Alterations

Alcohol as a neurotoxic substance causes widespread neural alterations when chronically consumed: up to 70 % of alcohol-dependent patients show alcohol-associated brain atrophy, i.e., tissue loss of grey and white matter, ventricular enlargement, and sulci widening (Carlen et al. 1978; Oscar-Berman and Marinkovic 2007; Schroth et al. 1988). Morphometric studies investigating brain volume changes in alcohol dependence found that this atrophy affects frontal, temporal, and parieto-occipital regions but also the hippocampus, the corpora mamillaria, as well as the cerebellum, with the most marked atrophic changes within the white and grey matter of the frontal lobe (Kril et al. 1997; Moselhy et al. 2001). In particular, volume deficits of frontal and parieto-occipital regions appear to be clinically relevant, since these changes were reported to be predictive of an earlier return to any alcohol use and the risk of relapse (Beck et al. 2012; Rando et al. 2011). These atrophic changes might lead to impairments of working memory and executive functioning, thus possibly reducing long-term action planning and inhibition of short-term reward-directed behavior (e.g., alcohol intake) (D'Esposito et al. 1995; Watanabe 1996). However, the precise pathophysiological mechanism of alcohol-associated brain atrophy is not fully understood; possibly, a hyperglutamatergic state during alcohol withdrawal leads to a calcium influx via activation of glutamatergic NMDA receptors and thereby initiates cytotoxic cascades (Tsai et al. 1995). Furthermore, alcohol withdrawal was reported to activate the HPA axis, resulting in elevated cortisol concentrations (Heinz et al. 2003). Cortisol concentrations in turn were associated with reduced 5-HTT availability in the brain stem, which also contributed to increased severity of depression in early abstinence (Heinz et al. 2003). Interestingly, these neuropathological changes seem to be partially reversible, because regenerations of brain volume during short-term alcohol abstinence were described in alcohol-dependent patients (Agartz et al. 2003; Bendszus et al. 2001).

2.2.4.4 Alcohol Tolerance and Withdrawal

Chronic substance use results in different neuroadaptive changes in the brain, leading to tolerance towards the acute effects of the substance and causing withdrawal symptoms when substance use is suddenly stopped. This neuroadaptation seems to be essential for the maintenance of homeostasis between excitatory and inhibitory functions in the brain and counteracts the (mostly inhibitory) acute effects of the drug of abuse (Koob and Le Moal 1997). As a consequence of these alterations, a reduction or cessation of substance use may lead to a severe disturbance of homeostasis, which can clinically manifest as psychovegetative withdrawal symptoms or epileptic seizures. Both development of tolerance and

withdrawal symptoms seem to be related to drug activation of GABAergic as well as inhibition of glutamatergic neurotransmission (Krystal et al. 2006; Tsai et al. 1995). GABA represents the main inhibitory neurotransmitter in the human brain and is involved in rapid information processing in cortical and subcortical areas. While acute alcohol consumption induces activation of inhibitory GABA-A receptors, leading to sedation after intake of large amounts of ethanol, chronic alcohol consumption seems to result in an increased tolerance for acute alcohol effects due to a systematic downregulation of GABA-A receptors. Long-lasting GABA-A receptor changes have been found in alcohol-dependent patients after several weeks of alcohol abstinence and even may persist long during further abstinence (Abi-Dargham et al. 1998). Regarding psychovegetative withdrawal symptoms, neuroadaptive changes within the glutamatergic system appear to result from chronic alcohol-induced antagonism of glutamatergic NMDA receptors. Indeed, a compensatory upregulation of glutamatergic NMDA receptors as a consequence of chronic alcohol intake has been observed (Ward et al. 2009). In case of reduction or cessation of alcohol consumption, the excitatory neurotransmitter glutamate then can activate an elevated number of NMDA receptors (Glue and Nutt 1990). This process can cause dysbalances between inhibitory and excitatory functioning with a predominance of excitation, which may result in epileptic seizures and disinhibition of noradrenergic neurons at the locus coeruleus, resulting in, e.g., vegetative withdrawal symptoms (Engberg and Hajos 1992).

2.2.5 Pharmaco-fMRI: New Insights of Pharmacological Treatment

Albeit treatment of drug-associated harm with drug substitution has been proven to be a very successful option in opiate addiction (Mattick et al. 2009), in alcohol addiction, treatment with substitutive psychoactive compounds (such as γ- Hydroxybutyric Acid, GHB) is prohibited in many countries, due to limited responder rates in GHB therapy (Maremmani et al. 2011). Instead, in many European countries, drugs potentially counteracting alcohol-associated neuroadaptations such as naltrexone or acamprosate are temporarily applied for relapse prevention. Even though Cochrane Reviews have demonstrated significant effectiveness of both pharmacological treatments (Relative Risk reduction of naltrexone (0.83) and acamprosate (0.86) compared to no medication) (Rösner et al. 2010a, b), the exact mechanisms by which acamprosate and naltrexone decrease alcohol ingestion and relapse rates in alcohol-dependent patients are yet to be explored. The application of neuroimaging techniques in pharmacologically treated alcohol-dependent patients is useful in predicting which medication helps to prevent relapse. For example, elevated levels of μ-opioid receptors have been observed in the ventral striatum of some detoxified alcohol-dependent patients (Heinz et al. 2005a) and are targeted by naltrexone, which blocks μ-opioid receptors.

A combination of fMRI and pharmacological treatment (Pharmaco-fMRI) allows to investigate how and where a specific pharmacological drug acts in the central nervous system. For example, a study conducted by Myrick et al. (2008)

demonstrated that naltrexone treatment produces significant reduction of cue-induced activity in the ventral striatum in alcohol-dependent subjects (Myrick et al. 2008). Notably, these changes in neural activity were additionally related to decreases in cue-induced craving, indicating a close link between pharmacological effects of naltrexone, striatal activation, and pharmacological craving modulation. Cue-elicited reduction in ventral striatal activation in detoxified alcohol-dependent patients under naltrexone has also been demonstrated by (Mann et al. 2011). Schacht et al. (2013) further suggested that the reduction of cue-induced activation in the OFC and the ventral striatum under naltrexone depends on genetic variations of the μ-opioid receptor gene and dopamine transponder gene, indicating that polymorphic variations in both genes should be considered in studies investigating the effect of naltrexone on reward processing. Further studies were conducted in order to assess the effectiveness of acamprosate. Acamprosate is assumed to reduce neuronal hyperexcitability, which may be responsible for acute alcohol withdrawal on the level of both excitatory glutamate and inhibitory GABA neurotransmitter pathways (Courtyn et al. 2001). In a study by Langosch et al. (2012), acamprosate treatment resulted in a significant reduction of cue-induced activity in the striatum and in the posterior cingulate in alcohol-dependent patients. However, this effect might not be solely due to the pharmacological treatment, as placebo treatment had a comparable effect on neural cue-induced activity. In fact, all patients from the study by Langosch received psychotherapy, indicating that this non-pharmacological treatment might have reduced neural cue-reactivity.

Besides naltrexone and acamprosate, alternative pharmacological treatments have been suggested to reduce craving and relapse rates in alcohol-dependent patients. One example for a new pharmacological treatment is baclofen, a GABA-B receptor agonist, which has raised attention since case reports and first clinical studies suggested its effectiveness in the treatment of alcohol-dependent patients (Addolorato et al. 2007; Ameisen 2005). A recent pharmaco-fMRI study has demonstrated that a single dose of baclofen diminishes resting state activity in limbic structures in nicotine-dependent patients (Franklin et al. 2012); baclofen application had previously significantly reduced the number of cigarettes smoked per day in nicotine-dependent subjects (Franklin et al. 2009). The authors of these studies hypothesized that baclofen might diminish the "limbic" substrate that is hyperresponsive to drugs and drug cues (Franklin et al. 2012).

2.3 Conclusion

Altogether neurochemical effects of acute alcohol intake are perceived as rewarding and therefore reinforce drug intake via pavlovian conditioning. These learning mechanisms appear to underlie a shift from occasional alcohol consumption to habitual intake (Heinz et al. 2009). Neuroadaptive alterations (particularly within the so-called reward system) are related to craving and increased processing of alcohol cues (Heinz et al. 2004). Thus, neurobiological

consequences of excessive alcohol intake are in accordance with the clinical observation (Tiffany 1990) that many alcohol-dependent patients find it particularly difficult to abstain from habitual consumption patterns and relapse after detoxification, despite high individual motivation to remain abstinent. Neuroimaging studies help to gain a better understanding of the neurobiological correlates of craving and motivation for alcohol intake, which can help to develop criteria for selective use of anti-craving medication. Furthermore, longitudinal and multimodal imaging studies might help to identify predispositional neurobiological markers for a high relapse risk and thus to offer patients their required higher intensity of treatment.

Glossary of Terms

Action-outcome/Goal-directed Learning Instrumental actions that are acquired through response-outcome associations. Goal-directed actions are performed with the intention of obtaining the goal. Goal-directed actions are sensitive to devaluation/revaluation.

Devaluation A psychological design for the assessment of stimulus-triggered (habitual) responding. Animals are trained to perform two responses, one for each of two different rewards. One reward is then devalued by associating it with bad taste (via quinine), sickness (lithium chloride), or satiety (via pre-feeding). When given the opportunity to perform the instrumental responses again in extinction, the responses for the devalued reward should be selectively diminished, in case actions are controlled by outcome expectancy. Instead, when actions are stimulus-driven (thus habitual), actions for the devalued reward should not be altered.

Incentive A stimulus that promotes approach to a reward as a result of predictive associations with this reward. Incentives serve as motivational devices as they facilitate and energize behavior that has been associated with the reward. Incentives may acquire activational properties, which amplify the incentive properties of other incentive stimuli that occur concurrently, but are not necessarily related to the reward.

Liking Emotional affective value of reward that has hedonic impact and causes feelings of pleasure. In addiction research, self-reported measure of hedonia has been used as a proxy for liking.

Pavlovian conditioning (Classical conditioning) Associative learning, in which the conditioned stimulus (CS), comes to signal the occurrence of a second stimulus, the unconditioned stimulus (US), which elicits conditioned responses.

Reinforcer A stimulus that increases the probability of a desired response. In contrast to incentives, reinforcers elicit responding on the basis of their contingency with actions (instrumental conditioning).

Revaluation A psychological design for the assessment of stimulus-triggered (habitual) responding. The procedure is the same as in the devaluation procedure, except that the value of the (e.g., food) reward is increased, for example, by food deprivation of the animal. When actions are controlled by outcome expectancy, the selection of the revalued stimuli should be selectively increased. However, when actions are stimulus-driven (thus habitual), selection of the revalued reward should not be altered.

Reward A class of unconditioned motivational stimuli, which elicit pleasure and hedonic feelings that can act as positive reinforcers.

Sensitization A phenomenon that describes progressive amplification of responses after repeated administrations of a specific stimulus. Repeated administration of drugs may cause an enhancement of a directly elicited drug effect, i.e., sensitization. In animals, locomotor activity often functions as a measure for sensitization.

Stimulus-Response/Habitual Learning Instrumental responses that are acquired through the association of actions with stimuli. Habitual actions thus reflect the execution of stimulus-response associations. Habitual actions are enabled by particular stimulus configurations and thus insensitive to devaluation/revaluation. Habitual behavior comprises features of automaticity such as speed, autonomy, lack of control, and absence of conscious awareness.

Wanting Motivational value of reward that has decision utility. In addiction research, craving for the positive effects of drugs have been used as a proxy for wanting.

The Genetics of Addiction: A Global Problem with Global Opportunities

3

Contents

Abstract

Drug addiction is a chronic, relapsing brain disease characterized by compulsive drug seeking, craving, loss of self-control, and impaired decision making (National Institute on Drug Abuse NIDA – Drugs, brains, and behavior: the science of addiction. National Institutes of Health, U.S. Department of Health and Human Services, Washington, DC, 2010). Drug addiction persists in spite of many harmful physical and social consequences and cuts across geography, class, ethnicity, occupation, age, gender, and history. The science of genetics offers one approach to understanding individual differences in a complex disease like addiction. Genes provide a scaffold for normal development, for learning, and for pathophysiology. But genes do not act in isolation of other processes and genes alone do not cause addiction. Genes act within the environments of the cell, of the body, and of the world beyond the individual. Indeed, new

discoveries in epigenetics demonstrate the reality by which environmental factors and exposures can regulate the activity of the gene. Addiction results from the interactive effects among multiple genes, acting in multiple environments and across multiple stages of development. This review, while focused on recent discoveries in genetics, argues that the global problem of addiction is best viewed through a prism that reflects the combined influences of genes, environment, development, and culture.

3.1 Introduction

The United Nations Office on Drugs and Crime (UNODC) serves as a warehouse for statistics about drug abuse. It reports that illicit drug users are found in every country, and drug abuse is among the top 20 risk factors associated with adverse health outcomes. On a global scale, the abuse of drugs is staggering: In 2012, out of a worldwide population estimated to be about 4.5 billion people aged 15–64 years, as many as 300 million used illicit drugs at least once in the past 12 months, 38 million were problem drug users, and 16 million were injection drug users, a primary vector for transmission of HIV and other infections (World Drug Report 2012).

To control the use of drugs, societies around the world employ a variety of approaches, from prohibition to criminalization, from "zero tolerance" to legalization. Marijuana is a good illustration of changing attitudes and differing approaches across the globe. As of this writing, the status within the United States, for example, is that 22 states and the District of Columbia allow the use of marijuana for medical purposes, while two states have recently (2012) legalized personal use. Coincidently, the 2012 Monitoring the Future Survey showed that regular marijuana use is on the rise in 8th, 10th, and 12th graders, with 6.5 % of 12 graders reporting daily/nearly daily use (Johnston et al. 2013). The survey also reports an increasing perception that marijuana is not harmful. Whether these laws and attitudes will promote addiction to marijuana or increase other negative consequences of abuse remains to be seen, but there is reason for concern. We know, for example, that the risk of addiction nearly doubles for those who start using in their teenage years, and it increases as well among daily users. Furthermore, the legalization of marijuana for recreational uses might spur competition among growers who could produce varying potencies across marijuana strains, leading to the possibility of higher addiction rates, as well as increased incidence of psychotic symptoms that are likely to appear in genetically vulnerable initiators (Tosato et al. 2013). There is an experiment of sorts in progress in the United States, and the full consequences of these approaches are unknown.

Alcohol and tobacco are the most widely used drugs globally and together account for high rates of mortality and morbidity. Alcohol dependence causes about 2.5 million deaths/year by exacerbating a variety of diseases in addition to alcoholism, including epilepsy, heart disease, cirrhosis, and cancer. The largest

killer, however, is smoking tobacco with nicotine as the major constituent responsible for addiction among smokers (Rehm et al. 2006; Mokdad et al. 2004; Henningfield et al. 1985), accounting for about 6 million deaths/year largely by causing cancer, heart disease, stroke, and respiratory disease. In the United States, approximately 435,000 deaths are attributed to tobacco, 85,000 deaths to alcohol, and about 17,000 due to illicit drug use, totaling about 537,000 US deaths per year due to addiction (Mokdad et al. 2004). The economic burden of drug abuse approaches 2 % of gross domestic product in some countries (World Drug Report 2012).

For some historical perspective on the number of deaths associated with drug abuse, consider that 20 million people died in the 4 years of World War I, some five million deaths per year. Similarly, World War II was fought over the course of 6 years, with a death toll of about 60 million, some 10 million per year. Tobacco, alcohol, and illicit drug use together contribute to an annual death toll of about 8.75 million, a figure that has been relatively constant over the last decade. With no end in sight, the global problem of addiction is clear. Given time, drug use and addiction will yoke the young, drain the health of the user, distort global economics, and penetrate political landscapes. Building the armament of biological knowledge is a critical piece in helping those affected.

3.2 Genetics of Addiction

3.2.1 Is Addiction Heritable?

We frequently observe that addiction runs in families. In addition to their genetic makeup, family members also tend to share environments as well as exposure to various environmental risk factors. Moreover, individuals may be affected differently by exposure to the same environment in ways that contribute to risk for disease. Fortunately, addiction is not an inevitable outcome of drug use. In fact, most people who initiate substance use recreationally do not become addicted. However, approximately 10 % of recreational users do become abusers, resulting from a cascade of brain changes that undermine the person's self-control and ability to resist intense impulses to take drugs (Leshner 1997; Kasanetz et al. 2010). Thus, a major challenge is to understand why some individuals are vulnerable to addiction whereas others are less so.

Genetics, the study of patterns of inheritance of given traits as they are passed down from parent to offspring, has made significant contributions to our understanding of addiction at both the population level and the molecular level. For decades, twin, adoption, and population studies from around the globe have demonstrated that the offspring of parents addicted to drugs are at increased risk of becoming addicted themselves (Dick 2011). Further studies using inbred strains of rodents or induced mutations in mice confirm the heritability of addiction. Of course, just as not everyone who takes drugs becomes addicted, not everyone born to drug-addicted

parents becomes addicted. Heritability studies agree that the proportion of phenotypic variance (i.e., addiction) attributable to genetic factors is in the range of 40–60 %, which leaves a similar proportion attributable to environmental factors.

It bears repeating that complex phenotypes like addiction are the result of complex interactions among genes and environments. Understanding the role of environmental influences on addiction can help home in on the genes that may be missed by genetic studies that ignore those factors (Hamza et al. 2011). Leveraging cultural patterns with appropriate study designs could be powerful for uncovering genetic risk and furthering our ability to educate, inform, prevent, and treat addiction. In the sections that follow, five key areas of addiction genetics are highlighted: phenotype; genetics and epigenetics; gene by environment interactions and prevention; neurobiology; and treatment and pharmacogenomics. Addressing these areas is critical for building the scientific foundation to tackle the global problems of addiction.

3.2.2 The Phenotype

To identify valid, meaningful genetic and environmental predictors of addiction, it is essential to define the phenotype of interest with as much precision as possible (Rice et al. 2001). Drug addiction is a conglomeration of various factors – compulsive drug seeking, craving, loss of self-control, and impaired decision making (National Institute on Drug Abuse – NIDA 2010). Ultimately, the successful identification and utility of specific genes, their biological pathways, and other etiological processes hinge on precise phenotypic definitions. An understanding of how such phenotypes are influenced and molded by environmental factors, developmental course, and other individual characteristics is a necessity.

Drug addiction is dynamic and characterized by cyclical patterns of harmful drug use, withdrawal, and relapse. It is further complicated by the involvement of multiple substances as well as cognitive, emotional, and social disruption in addition to the observable behavior patterns. Are these multiple disruptions merely consequences of drug abuse or do they suggest an underlying vulnerability as well? It has been hypothesized, for example (Palmgreen et al. 2007), that drug abuse is a consequence of sensation-seeking, impaired decision making, or weak executive control, all of which are functions of the frontal lobes of the brain, which in turn are gene regulated.

An important consideration in genetics research is defining an appropriate control group for comparing to the cases under study. Depending on the study design, addiction phenotypes can prove tricky. For example, one may want to identify genetic factors in highly dependent cases compared to controls. Using "never exposed" controls will produce very different results than if the controls have been carefully chosen to include those who have been exposed to some defined amount of substance use, but did not become addicted.

Differences in culture, religion, and laws sometimes can be exploited to delineate genetic factors that may be informative for improving addiction prevention and treatment. On a population level, those societal differences can be considered as

"macrophenotypes." Macrophenotyping allows the use of statistics and demographics for a given population without knowing the specific phenotypes of its individuals (Table 3.1). For example, the legal drinking age differs across the globe. Some Islamic nations prohibit drinking alcohol at any age. In other countries, the minimum age for consuming alcohol legally differs from the age when it can be purchased legally. Thus, laws and religious practices governing alcohol use serve to produce a macrophenotype. The age of legal smoking also differs somewhat from one country to the next. A recent survey of three billion individuals in 16 countries found that 48.6 % of men and 11.3 % of women were tobacco users, a macrophenotype defined by gender (Giovino et al. 2012). In Nigeria, smoking is illegal in public, and the macrophenotype shows that the death rates due to smoking are the lowest globally (7.1 %). The anti-smoking culture in Nigeria is a powerful environmental constraint on smoking in the population. Those who nevertheless initiate smoking, therefore, might be genetically vulnerable to continue smoking and also have more difficulty quitting. Thus, an environmental constraint – cultural prohibition in this case – leads to a hypothesis that there may be rare but penetrant genetic variants that reside in Nigerian smokers. The most replicated genetic variants associated with nicotine dependence have been in the nicotinic acetylcholine subunit receptor genetic regions on chromosome 15 (see below). According to the International HapMap Project and the 1000 Genomes Project (see below), the variant primarily associated with smoking dependence is nonexistent in the Yoruba (Nigerian) population, rare in Americans of African ancestry, and common in Americans of European ancestry (Fig. 3.1). This raises the possibility that genetic variants in Nigerian smokers could illuminate new drug targets for smoking cessation and lead to better treatment and intervention approaches.

3.2.3 Genetics and Epigenetics

At the molecular level, genetic approaches examine the structure and function of DNA and how genetic variation affects the expression of the genetic information. The hope of understanding the molecular basis of drug addiction and other complex phenotypes is driven, in part, by the remarkable progress that has been made in the field of genetics during the past decade. The year 2013 marks the tenth anniversary of the sequencing of the human genome. As a result, we know that humans share approximately 99.6 % of the three billion nucleotides of DNA sequence. Our genetic individuality lies in the remaining 0.4 % (approximately 12 million) nucleotides that comprise genetic differences largely represented by single-nucleotide polymorphisms (SNPs), copy number variations, as well as small insertions and deletions that are scattered across the genome. SNPs are the most well-studied variations and are generally benign with unknown consequence, but some may account for trait differences that alone, or in combination, contribute to disease (Barreiro et al. 2008). Approximately six million SNPs are quite common with allele frequencies greater than 10 % in the population. Others are of moderate frequency (1–10 %), and many are rare (<1 %).

Table 3.1 Alcohol, cigarette, and drug use macrophenotypes across the HapMap countries. Ranges were determined for all countries (bottom row) and then assigned a colored quartile (low, medium-low, medium-high, and high). HapMap countries represent four populations that have genotype and haplotype data in the public domain available for download: Ibadan, Nigeria (YRI); US residents of northern and Western European ancestry (CEU); Tokyo, Japan (JPT); and Han Chinese individuals from Beijing, China (CHB). Countries in the Northern Europe and Western Europe regions are separated for purposes of illustrating the macrophenotypes

HapMap country		Purchase age for alcohol	Alcohol consumption L/capita/year	Alcohol death rates per 100,000	Purchase age for smoking	Number of cigarettes per adult per year	Percentage of All deaths attributed to Smoking in the year 2000	Drug use death rates per 100, 000

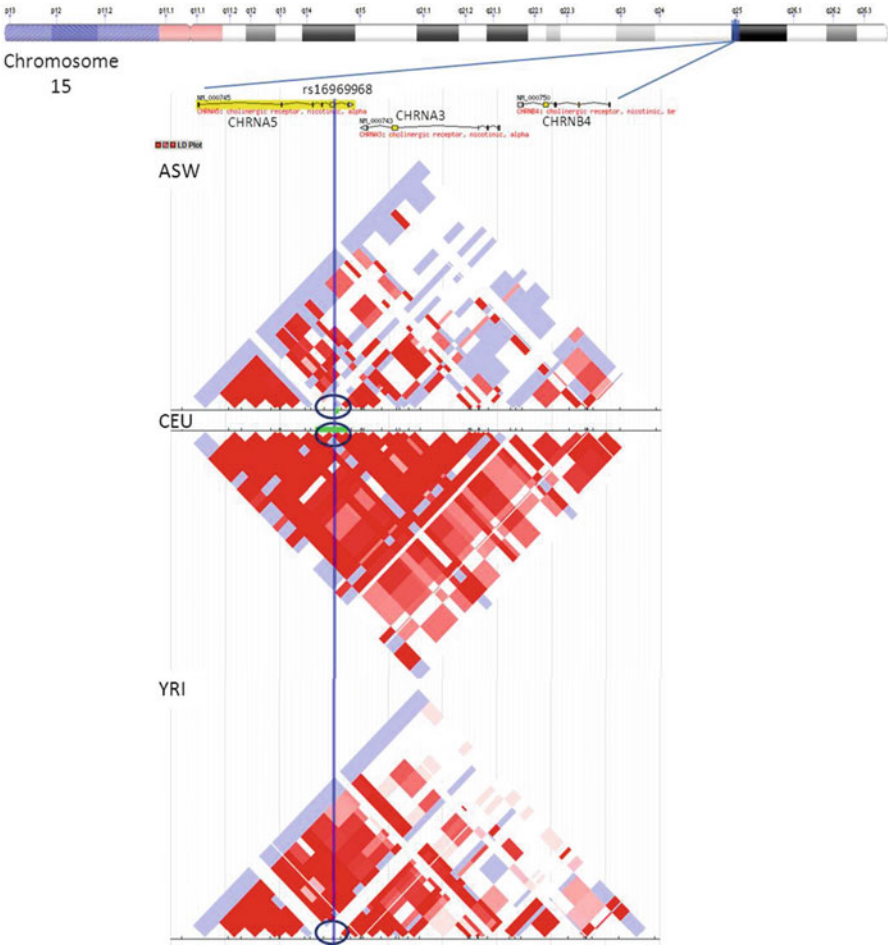

Fig. 3.1 Linkage disequilibrium (*LD*) plots for the CHRNA5/A3/B4 region on chromosome 15. The orientation of the CHRNA5, CHRNA3, and CHRNB4 genes is shown as the expanded section underneath the full chromosome 15 map (*top*). The vertical *blue line* represents the rs6969968 SNP and intersects the LD plots from the following populations: Southwestern US residents with African ancestry (ASW; *top*), US residents with European ancestry (CEU; *middle*), and Ibadan, Nigeria (YRI; *bottom*). The *green line* within the *blue circles* indicates the region of LD. Note the high LD in the CEU population (*long green line*), the very low LD in the ASW population (*short green line*), and the lack of LD in the YRI population (no *green line*). The LD plots were generated using the HapMap Data Phase III/release #2, February 09 on NCBI B36 assembly, dbSNP b126:chr15: 76,640,000 to 76,730,000 (http://hapmap.ncbi.nlm.nih.gov/cgi-perl/gbrowse/hapmap3r2_B36/)

Progress in the field of genetics during the past 20 years has come through conceptual insights and technological breakthroughs that have produced powerful approaches for rapid and robust screening of millions of known SNPs. Two key discoveries revolutionized the field. The first was the recognition that the genome had specific regions with higher recombination rates, the so-called recombination

hot spots. The second was the finding that the genome is organized into block-like structures or haplotypes that can be "tagged" by SNPs.

Recombination hot spots exploit how the process of inheritance relies on the basic molecular structure of DNA, rather than on the sequence variation in it. This has great implications on the nonrandom patterns of DNA sequence variation along chromosomes, which, in turn, can be used to reveal useful DNA sequence variation that contributes to disease (Hey 2004). Linkage disequilibrium (LD) describes the nonrandom association of alleles at adjacent locations on the chromosome, or loci. The farther apart two loci are, the more likely they are to recombine. Genomes with low LD are older, where there has been a longer period of time for recombination events to occur (haplotypes are shorter and made up of fewer SNPs), such as seen in the African populations. On the other hand, populations with higher LD are the newer populations such as the European Americans and isolated populations such as the Ashkenazi Jews (Shifman et al. 2003).

The second discovery was that these LD block structures acted as fingerprints for geneticists who could use them to identify correlated SNPs across the genome (Altshuler et al. 2008; Trifanova et al. 2012). In other words, one or a few SNPs could represent an entire haplotype (because of the high rate of LD), which meant that rather than screening the entire SNP collection across the genome, only a subset of proxy SNPs – or TagSNPs – needs to be screened without loss of information. From this concept, the NIH International HapMap Project was launched to describe the common patterns of 3.5 million SNPs across populations (The International HapMap Consortium 2005, 2007). The HapMap Project has been an invaluable tool for SNP genotyping platform improvements and for helping to discern the importance of genetic association loci for complex diseases. Subsequently, the 1000 Genomes Project was launched with the goal of characterizing 95 % of genetic variation accessible by high-throughput sequencing technologies and that have 1 % or greater allele frequency in each of five major population groups, including Europe, East Asia, South Asia, West Africa, and the Americas (The 1000 Genomes Project Consortium 2010, 2012). Together, these represent the most extensive collections of human genomic diversity to date and provide a necessary piece to the puzzle for understanding how genetic diversity impacts disease. The HapMap and 1000 Genomes data were intended to be a resource used for identifying and cataloging genetic similarities and differences in humans, and therefore, these datasets do not have phenotypic information. However, as illustrated in Table 3.1, they may be useful for initial macrophenotypic assessment, to then apply to standard case control studies for the purposes of associated genotypes to phenotypes.

The structure of LD in distinct genomic sites, such as those we know or suspect to be associated with addiction, is of interest. The LD structure defines the boundary of a given region. The more population structures one can access (e.g., through HapMap), the better and narrower those boundaries are defined (Fig. 3.1). A narrow region is central to this approach because once an initial SNP has been associated with a disease phenotype, it represents much more of the genetic variation than just that SNP alone. The importance of the sequence

contained within these regions then becomes the analytic quest, and finding the genetic variation within that LD block that has functional significance is the next step in understanding the inherited component of addiction susceptibility. Replication is imperative; candidate SNPs that have been evaluated repeatedly across ethnicities and in a variety of association study settings will help to isolate those variants more likely to show functional effects (Saccone et al. 2008).

Genome-wide association (GWA) studies have been the cost-effective approach of choice for discovering important genetic regions in complex diseases. The GWA approach is built on the notion that common alleles predispose to common disease. Current GWA genotyping platforms include common SNPs derived from haplotype information to allow for genotyping the most SNP content across ethnicities. However, the genomic coverage for the GWA genotyping platforms was not selected for specific hypotheses; thus, it is important to understand the coverage a genotyping array provides (Saccone et al. 2009b) and to replicate and verify any and all findings. Most GWA studies to date – about 75 % of them – have been performed in populations of European descent. Of those that examine non-European populations, the numbers of individuals represented within them are predominantly from European descent (Rosenberg et al. 2010). As non-European populations become accessible for GWA analysis on a variety of traits, it will be possible to test the generalizability of the GWA findings from European populations to others. Cross-population contrast mapping (Saccone et al. 2008; Helgason et al. 2007; Liu et al. 2012) compares genotype frequencies at the associated SNP and the correlated SNPs within the haplotype to define the genetic architecture for both populations at that locus (Rotimi and Jorde 2010; Saccone et al. 2008; Zaitlen and Eskin 2010). This approach relies on the assumption that biological mechanisms underlying a given disease are shared across populations, despite the differences in allele frequencies.

A good example of this approach comes from nicotine dependence studies. In 2007, a group of scientists from both the public and private sectors embarked on a small GWA study ($n \sim 2{,}000$) for nicotine dependence that compared nicotine-dependent individuals ("cases") with exposed (must have smoked at least 100 cigarettes during lifetime), but not addicted, controls (Bierut et al.). The cases and controls were of European American descent and their genotypes were compared across 2.2 million SNPs. From the final analyses (Bierut et al. 2007; Saccone et al. 2007), several SNPs were identified in the nicotinic subunit receptor genes that had not been well studied previously. These genes are in a cluster on chromosome 15, CHRNA5 (alpha 5), CHRNA3 (alpha 3), and CHRNB4 (beta 4), referred to here as the CHRNA5/B4/A3 cluster. Previous work using pharmacological methods had identified CHRNA4 and CHRNB2 as the main culprits involved in smoking dependence, which have been the primary targets for smoking cessation medications. The GWA study data, however, has broadened the scope to other nicotinic subunit receptors in the larger nicotinic subunit receptor family. The SNP that was most interesting was rs16969968 because it represented a change from a conserved aspartic acid at position 398 to an asparagine (D398N) within the CHRNA5 receptor subunit (Bierut et al. 2008).

At the nucleotide level, the A allele of the SNP is the risk allele, and the G allele is the ancestral, or common, allele (Fig. 3.1). The fact that this SNP was in the part of the gene that encoded the protein and that it was conserved across species added impetus to studies seeking to replicate the finding and examine the functional consequences of the SNP.

As one of the most replicated findings in complex disease genetics, however, it remained unclear if it would withstand cross-population analyses. This region has high linkage disequilibrium in European ancestry populations, making it difficult to differentiate correlation from causation. It turns out that the frequency of rs16969968 varies widely across 39 different populations (Cann et al. 2002). Ultimately, a meta-analysis for nicotine dependence in tens of thousands of samples of European ancestry confirmed the CHRNA5/B4/A3 cluster association (Thorgeirsson et al. 2010; Tobacco and Genetics Consortium 2010; Liu et al. 2010). In populations of European and Middle Eastern origin, the frequency of the A allele was around 40 %, whereas it was uncommon or absent in East Asian, Native American, and African and African American populations (Fig. 3.1 and Bierut et al. 2008; Saccone et al. 2009). Although the rs16969968 risk variant is a strong association, it only explains a small amount of variance (Berrettini and Doyle 2012). Others have used GWA meta-analysis as a way to identify other loci involved in smoking dependence in European ancestry populations (Thorgeirsson et al. 2010) and in African American populations (David et al. 2012) and have found additional variants of interest, although not as strong. Genome sequencing methods are needed to look for potential rare variations with large effects that are missed by the GWA platforms that have been employed to date.

Because the genetic architecture of the CHRNA5/B4/A3 cluster varies across populations, comparing associations across diverse populations with differing genetic architectures can help refine the region of association and point to variants more likely to have functional relevance (Rotimi and Jorde 2010; Saccone et al. 2008; Zaitlen and Eskin 2010). Multiple genome-wide and targeted association studies now have revealed significant associations between nicotine dependence and variants in the CHRNA5/A3/B4 cluster in subjects of European origin and Asian (Li et al. 2010) and African American ancestry ($n = 32{,}587$), which extends the involvement of this specific gene cluster across all three populations, narrowing the region of association (Chen et al. 2012b). Of the variants tested, only rs16969968 was associated with smoking in these three populations and was a marker of a larger "high risk" haplotype. The consistently observed association of rs16969968 with heavy smoking across multiple populations, combined with its known biological significance, suggests that rs16969968 is most likely a functional variant that alters risk for heavy smoking. Implications of this work will be explored in subsequent sections.

The molecular intersection where the environment meets the genes happens at the epigenome and is worth mentioning here. Epigenomics is the study of functional, and sometimes heritable, changes in the regulation of gene activity and expression that are not dependent on gene sequence (Chadwick 2012).

Although each cell type in the human body effectively contains the same genetic information, epigenetic regulatory mechanisms enable pluripotent stem cells to give rise to the diversity of differentiated cell types (e.g., skin cells, liver cells, or neurons).

Genome function and cellular phenotypes are influenced by DNA methylation, along with histone modifications, which account for associated proteins that activate or repress the genome function in a context-dependent manner (Bernstein et al. 2010). Chromatin is the combination of DNA wrapped around histone proteins (called nucleosomes) and associated with DNA-binding factors, accessory complexes, and noncoding RNAs. Chromatin structure allows the tightly packed DNA to fit into the nuclei, yet it retains the ability to react dynamically to the specific gene expression needs of the cell. In states of activity, DNA is loosely packaged so that specific genes are readily accessed by the transcription machinery and "turned on." In states of inactivity, DNA is wrapped around the histones and "turned off" by structural proteins that ensure the chromatin-containing genes are tightly packed and inaccessible to the transcriptional machinery. This "winding" and "unwinding" of chromatin occurs through chemical modifications such as methylation and acetylation on the histone proteins or to the DNA itself (e.g., DNA methylation or hydroxymethylation) that take their cues from elsewhere, whether that be from the cellular, social, or even historical environment. There have been several human studies indicating that ancestral environments can dictate the physiology and behavior of descendants (Kaati et al. 2002).

A 2004 seminal report demonstrated the concept that parenting and early environmental exposures (e.g., exposures to the gamete, fetus, or offspring) or experiences influence risk for later life pathologies, and these can be unequivocally linked to epigenetic changes (Weaver et al. 2004; Johnstone and Baylin 2010). In rats, maternal behaviors such as licking and grooming can epigenetically "program" stress responses in the pups that are stably maintained in adulthood. The research demonstrated that offspring of mothers displaying high levels of maternal care showed different DNA methylation patterns in the brain's stress pathways and exhibited fewer anxiety-like behaviors compared to offspring of mothers displaying low-level maternal care, resulting in pups with higher anxiety-like behaviors. Interestingly, the researchers went on to demonstrate that the effects were reversed in cross-fostering experiments (Weaver et al. 2004).

Similarly, exposure to drugs of abuse also may have epigenetic influences that affect the offspring (Kendler et al. 2012). In a recent study, male rat offspring, but not female rats, sired by cocaine-exposed males were slower to acquire cocaine self-administration and maintained lower rates of responding for cocaine than in offspring sired by unexposed males. The investigators went on to show that the effects were likely due to increased acetylated histone H3 with brain-derived neurotrophic factor promoter regions in the sperm of sires that self-administered cocaine (Vassoler et al. 2013). Taken together, these examples indicate the pervasive influence of environmental factors that regulate epigenetic mechanisms and that these influences may not only affect cellular events, but they may affect cellular events that take place in our children and grandchildren.

Not unlike the HapMap and the 1000 Genomes Projects that came before it, the NIH Roadmap Epigenomics Program and the International Human Epigenome Consortium (IHEC) are developing atlases of the epigenomic landscape of a variety of cell types (Chadwick 2012). Scientists have been collecting data to generate maps of the epigenomic landscape of a variety of tissue types, but there has been little done to date looking at individual differences and their effects on epigenomic programming. With the epigenomic maps at hand, it will be possible to understand influences of drugs of abuse, stress, and diet on epigenetics and then to consider how environmental context and culture can affect the epigenome as well. While genetic variation is more tractable to screen, epigenetic variation may lead to more effective treatment approaches since the mechanisms may be more malleable than our DNA.

3.2.4 Gene × Environment Interactions and Prevention

An understanding of addiction genetics will improve our ability to predict who is at risk for drug addiction and who is not. With improved predictive validity, prevention efforts can be focused on those at high risk. To reiterate a point made earlier, vulnerability to drug addiction is the result of multiple genes interacting with one another (epistasis or G × G interactions), genes interacting with environments (G × E), and genes interacting with environment and stage of development (G × E × D). Although challenging and costly, research employing designs and analyses that enable the study of these interactions is critical to our progress. There are statistical models available that enable us to characterize such complex interactions (Neale et al. 2006). Structural equation modeling, for example, allows variables that are not measured directly (i.e., latent factors) to be incorporated. This is an important consideration for addiction phenotypes since not everyone will try substances of abuse, let alone become addicted. Moreover, replicating complex designs is itself a challenge and can be approached in two general ways. Direct replications are those which use the same statistical model on the same outcome variable, genetic variant, and environmental factor as was done for an original finding. Indirect replications seek to replicate the general finding but use different variables (Duncan and Keller 2011).

As an obvious example of G × E interaction, consider that the CHRNA5/B4/A3 cluster associated with nicotine dependence will be penetrant only if the person is exposed to tobacco. This example provides a straightforward explanation for why one person who has the risk variant may become dependent on tobacco and smoke upwards of 30 cigarettes/day, while another person who does not have the risk variant may try a cigarette and never use tobacco products again (Duncan and Keller 2011). Indeed, much of the success in decreasing smoking prevalence, for example, has been realized through well-supported environmental and educational methods. Trends for smoking have declined since 1970, but have plateaued since 1990. This suggests that these strategies alone are not as effective in current smokers, indicating that current smokers and many future smokers

may be a more genetically at-risk population. Nearly 90 % of smokers who try to quit relapse within a year, with the majority relapsing within a week (National Institute on Drug Abuse 2012). Therefore, treatment and prevention interventions for substance abuse disorders and other complex diseases will have maximum public health benefit when multifaceted approaches incorporating the genetic, biological, and environmental determinants are employed (Merikangas et al. 1998).

A recent example of G × E × D interaction comes from two independent reports (Weiss et al. 2008; Hartz et al. 2012) demonstrating a strong association between CHRNA5/A3/B4 variants and increased severity of nicotine dependence in early-onset smoking. The study extends the original association by separating the heavy smokers into two groups, those with "early onset" of daily smoking at or before age 16 and those with "late onset" on or after age 17. The association was seen in subjects who began daily smoking at or before the age of 16, thus identifying a period of exposure vulnerability that may contribute to nicotine dependence later in life. This report demonstrates a clear interaction among genes, environment and development where the confluence of factors increases the likelihood of nicotine dependence. It also supports other evidence that people who use addictive substances before age 18 are six times more likely to develop a substance use disorder than those who do not start using until they are 21 or older (CASA 2011).

Other environments influence addiction behaviors, too. Partner smoking is a risk factor for smoking (Sutton 1993). Among women who quit smoking during pregnancy, the strongest predictor of relapse was having a partner who smoked. Another study found relapse rates four times as high for individuals living with smokers, compared to those who did not (Kahn et al. 2002), and women may be more vulnerable to spousal influences than men (Homish and Leonard 2005).

Another study found that individuals with the rs16969968 risk allele who received low parental monitoring were at increased risk for nicotine dependence (Chen et al. 2009). Counterintuitively, peer smoking had a substantially lower effect on nicotine dependence among those with the high-risk rs16969968 genotype than among those with lower-risk genotypes (Johnson et al. 2010). This research highlights the possibility that those with high genetic risks may be more or less affected by intervention strategies based upon familial and/or social contexts. G × E influences such as these examples vary widely across cultures, and understanding these types of environmental influences can be of great help in developing robust prevention and intervention strategies that can be tailored to individuals.

3.2.5 Neurobiology

One of the problems of drug abuse is its ability to "hijack" the brain's reward system. Drug users will go to great lengths to seek a high. The discovery of gene variants that confer vulnerability to addiction promises to improve our

understanding of the neural processes responsible for addictive behaviors. Repeated exposure to some drugs results in enhanced responses to the drug (i.e., sensitization) and is a hallmark of addiction. Through repeated exposure, there is an enhancement of dopamine release across the rewarding centers of the brain (nucleus accumbens, ventral tegmental area, and the frontal cortex), resulting in reinforcement of drug taking. Neurobiological studies examining nicotine self-administration in animal models support the notion that CHRNA5 acts as a "gate" for nicotine intake, but not necessarily by acting to enhance the reward pathway, but rather by abolishing an aversive circuit through the medial habenula and interpenduncular nucleus (IPN; Fowler and Kenny 2012). Gene expression studies in mice show that the CHRNA5/A3/B4 genes are expressed in the habenular/IPN regions, unlike the more global expression of other nicotinic subunit receptors (Fig. 3.2 and Changeux 2010). In animals where the CHRNA5 gene has been knocked out, the "gate" is missing and self-administration of nicotine increases. Additionally, virus-induced expression of the CHRNA5-subunit-risk allele in the medial habenula-IPN nucleus of the rat resulted in reduced aversion to nicotine and, consequently, greater consumption of the drug (Fowler et al. 2011). Together, these findings provide neurobiological confirmation for what is seen in human genetics of nicotine dependence in that the heaviest smokers generally have the associated risk allele. Of course, so far these studies are not completely analogous inasmuch as knocking out the CHRNA5 gene in mice is not the same as a single nucleotide difference at the rs16969968 variant allele in humans, but trends pointing in the same direction are encouraging.

Another genetic variant, A118G in the human mu opioid receptor gene (MOR), has been associated with opioid, alcohol, and other drug addictions and with the need for higher morphine doses to achieve adequate analgesia in those who have this allele. Recent work using animal- and human-cultured cell lines found that the asparagine (G allele) reduced N-linked glycosylation more than the aspartic acid (A allele) form (Huang et al. 2012). This difference in glycosylation status causes protein instability and may account for the reduction of the MOR protein in certain brain regions. Other work has examined this gene variant's effects on dopamine release after tobacco smoking. One study shows that carriers of the G allele had more dopamine release in response to smoking than homozygous A-allele carriers. In addition, plasma cortisol levels were lower in G-allele carriers. These studies are consistent with literature on the association of MOR A118G with drug abuse and stress, yet continued research is needed to explore the implications of these findings to link these mechanisms to drug abusing behaviors.

Drug addiction is comorbid with many psychiatric conditions, such as depression, anxiety, and schizophrenia (Buckley et al. 2009). The high prevalence of cigarette smoking among schizophrenics suggests the hypothesis that addictive behavior and schizophrenia may rely upon shared neurocircuitry. For instance, approximately 90 % of people with schizophrenia smoke and use nicotine as a mechanism of self-medication to increase cognition (Chambers et al. 2001). Schizophrenics may have underlying genetic differences in regions of the brain that are similar to those seen in long-term substance users, but without the prior drug exposure. This example

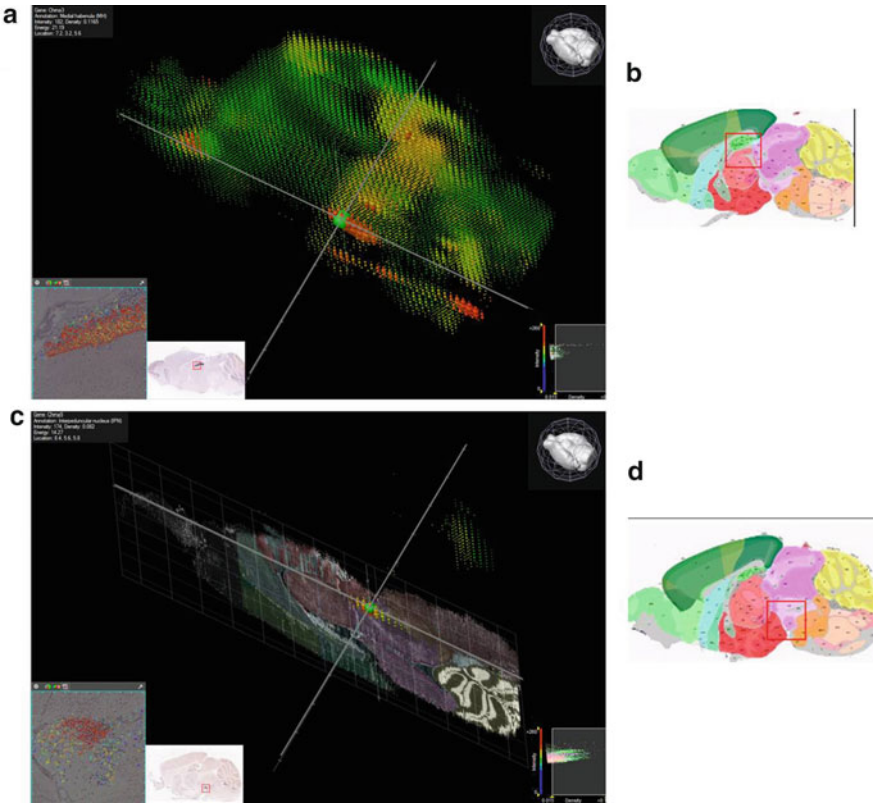

Fig. 3.2 Gene expression of CHRNA5/A3 in the medial habenula-interpenduncular nucleus (*IPN*). Gene expression data were obtained using the Allen Mouse Brain Atlas, released March 7, 2013: http://www.brain-map.org/. (Panel **A**): Gene expression of CHRNA3 in the medial habenula (*MH*). The orientation of the brain image is shown in the circular image on the *upper right*. The scale of intensity is shown on the *bottom right*. The axis crosses at the medial habenula and the gene expression is shown in the *bottom left*, adjacent to the in situ hybridization (*ISH*) image. (Panel **B**): Mouse brain anatomy map of selected region for CHRNA3 expression. *Panel C*: Gene expression pattern of CHRNA5 in the IPN. The axis crosses at the IPN and the gene expression is shown at the *bottom left*, adjacent to the ISH image. (Panel **D**): Mouse brain anatomy map of selected region for CHRNA5 expression

highlights the importance of studying the genetics of substance use and schizophrenia as distinct and as comorbid disorders. Additional studies have demonstrated novel associations between other gene variants in the CHRNA5/B4/A3 cluster with various smoking-related phenotypes, such as nicotine dependence symptoms, nicotine tolerance, smoking initiation, and comorbid conditions (e.g., regular drinking and depression), with these vulnerabilities being heightened in early-onset smokers. Once a gene variant is discovered and validated, a systematic analysis of the functional role that a gene variant plays can be undertaken.

3.2.6 From Treatment to Pharmacogenetics

Elucidating the genetic and neurobiological basis of addiction, from gene expression to the neural networks that mediate drug seeking and drug taking, eventually will enable scientists to translate knowledge into new treatments directed at specific targets in the brain or to treatment approaches that can be individualized for each patient (i.e., pharmacogenomics). Drawing a precise molecular portrait of addiction is challenging, but every new finding provides an unprecedented opportunity to identify and investigate new potential pharmacological targets or explore and exploit their clinical utility. For example, recent research has solved the crystal structure of the four opioid receptors (Wu et al. 2012; Thompson et al. 2012; Granier et al. 2012; Manglik et al. 2012). Although the opiate receptor has been studied for decades, the availability of its structure now provides a molecular framework for structure-based discovery of new medications with targeted pharmacological properties (Thompson et al. 2012). Understanding how these potent ligands work in the context of their effects on receptors with known genetic variation (e.g., the A118G variant mentioned previously) will enable medicinal chemists to design medications to maximize their therapeutic efficacy while minimizing their adverse side effects and abuse liability.

Genetic variation is the key to explaining individual differences in the way that drugs are distributed and metabolized. Pharmacogenetics/pharmacogenomics is the study of how genetic variation among individuals affects their capacity to metabolize drugs (pharmacokinetics) and the drugs' effects on the individuals (pharmacodynamics) (Rutter 2006; Belle and Singh 2008). There is significant variability in response to drugs of abuse, and pharmacogenetics provides relevant crossover concepts that tailor a person's genetic makeup to a drug treatment that provides the best "match."

Investment in genetics is bearing fruit for the development of treatment options for substance dependence. The A118G mu-opioid receptor polymorphism has been shown to be associated with therapeutic response to naltrexone treatment for alcohol dependence (Chamorro et al. 2012). This pharmacogenetic finding has important implications for targeted treatment of alcoholism in individuals with the 118G variant (Chamorro et al. 2012; Kranzler and Edenberg 2010). Recent meta-analysis on the A118G SNP of OPRM1 shows that naltrexone-treated patients carrying the G allele have lower relapse rates when compared to those homozygous for the A allele (Chamorro et al. 2012). The frequency of the G allele differs across populations; in Caucasians, it ranges from 15 % to 25 %, and in Asians, it is ~60 %. The potential impact of genetic screening prior to treatment in these ethnicities warrants consideration. Clinicians and patients may benefit from knowing that people homozygous for the A allele are not likely to respond to naltrexone.

A similar case can be made for pharmacogenetics of smoking. Nearly half of the people who smoke want to stop; however, most attempts fail, whereby only about 10 % of individuals achieve abstinence for 6 months or more (Ramoni et al. 2009). And, nicotine dependence contributes to the failure rate, with more highly dependent smokers having greater difficulty quitting – and staying abstinent

(John et al. 2004; Xian et al. 2005). There is growing evidence that interactions between smoker characteristics, medications, and quit success may help personalize the handful of medications that can be prescribed to a given smoker.

Cytochrome P450 (CYP) 2A6 is largely responsible for metabolizing nicotine to cotinine, and CYP2A6 genotypes contribute to variable metabolism rates that are seen across ethnicities (Nakajima et al. 2006) and even gender (Lee et al. 2012; Mwenifumbo and Tyndale 2007). Genetic variation in the CYP2A6 gene can increase or decrease the pharmacokinetics of the enzyme activity through altering the protein's expression level or its structure and function. Further studies show that the rate of nicotine metabolism predicts which smokers will be more successful at quitting with bupropion (Patterson et al. 2008) or nicotine replacement therapy (Malaiyandi et al. 2006; Schnoll et al. 2009). In the highly dependent smokers, a combination therapy is most beneficial (Loh et al. 2012).

In addition to the pharmacokinetic gene variations, pharmacodynamic gene differences are also important. The nicotinic subunit receptor B2 has been implicated in smoking cessation (Conti et al. 2008), as have the CHRNA5/B4/A3 cluster variants – although less robustly associated with cessation outcomes than with measures of smoking quantity. However, those that do show an association have shown that the same genetic risk variants that contribute to smoking quantity and nicotine dependence also predict smoking cessation (Chen et al. 2012). Carriers of the high-risk CHRNA5/A3/B4 haplotype were three times more likely to respond to smoking cessation medications, making this haplotype of interest for personalized cessation therapies. A series of randomized clinical trials grouped by smoking cessation therapy (NRT, varenicline, bupropion, and placebo) examined the association of CHRNA5/B4/A3 cluster variants with abstinence at the end of treatment and at 6 months after the quit date. In this study, treatment-seeking smokers with the CHRNA5/A3/B4-risk alleles (compared to those without) were less likely to achieve abstinence at 6 months if prescribed placebo, but more likely to achieve 6-month abstinence with treatment (Bergen et al. 2013).

Clinical trials assessing the joint effects of both the pharmacokinetic gene variations (CYP2A6) and the pharmacodynamics gene variations (CHRNA5 and others) are needed. Early investigations into the feasibility, cost-effectiveness, and impact of using genetics to tailor treatments in a real-world clinical setting have been promising (McClure et al. 2013). Larger studies are needed to understand the generalizability of this type of personalized intervention for smoking cessation.

3.3 Conclusion

Addiction is a complex, diverse, and dynamic disease. Progress in understanding, preventing, and treating addiction demands a multifaceted research program requiring analytic endurance that considers the interactive influences of genes, environment, development, and culture. The scientific advances have been fueled in part by recent advances in genomics and molecular biology. The science of epigenetics has

yielded exciting findings already and promises to unlock the ages-old gene-environment conundrum.

A major challenge awaiting resolution is the translation of basic science discoveries into novel prevention strategies and effective treatment approaches. As discussed above, discoveries in genomics and neuroscience have opened up new vistas for exploration. New medications built upon scaffolds designed computationally to fit ever more precisely specified crystalline structures of brain receptors herald an era of designer treatments for addiction. And treatment approaches that capitalize on genomic information about an individual's metabolic profile signal a pharmacogenetic approach to guide medical and treatment decisions.

NIDA has made understanding the interaction among genes, environment, and development a cornerstone of its agenda. The G × E × D interaction is thorny, and research is beginning to tease apart the separate and combined effects of these factors, but there is still challenging work to be completed. Emerging areas, including systems biology, epigenetics, computational approaches, and the role of social context or culture in drug addiction will be important research priorities for funding agencies across the globe. Future gene-based analyses combined with environmental interventions have great potential to combat addiction and save lives. The opportunities offered by global approaches can strengthen these needed research programs and hasten that goal.

Glossary of Terms

Allele An alternative form of a gene that is located at a specific position on a specific chromosome

Epigenetics The study of heritable or long-term alterations in gene expression that are not caused by changes in DNA sequence

Gene A specific segment of DNA on a chromosome that is responsible for specific characteristics in an organism

Genetic variation Differences or variations in alleles of DNA segments (e.g., genes) that occur both within and across populations

Genetics The science of genes, heredity, and variation in living organisms

Genome-wide association study (GWA or GWAS) A method to examine many common genetic variations in different individuals to see if any variant is associated with a trait

Genotype An individual's collection of genes and alleles

Haplotype Combinations of alleles at adjacent locations on a chromosome that are inherited together

Heritability The proportion of observable differences in a trait within a population that is due to genetic differences

Histone A family of basic proteins that associate with DNA to pack the DNA into chromosomes

Linkage disequilibrium (LD) The nonrandom association of alleles at two or more loci

Macrophenotype Using global statistics or demographics to estimate the phenotype of a given population without knowing the specific phenotypes of individuals within that population

Nucleotide The basic building block of nucleic acids (i.e., DNA and RNA)

Pharmacogenetics Genetic differences in genes that affect an individual's response to drugs

Phenotype The observable physical or biochemical characteristics of an organism, which are influenced by both genetic makeup and environmental influences

Recombination The formation of new combinations of genes in progeny that did not occur in parents

Single-nucleotide polymorphism (SNP) A DNA sequence variation that occurs at a single nucleotide in the genome

Abstract

This chapter provides and overview of the epidemiological aspects of substance use disorders. Starting with a methodological introduction into the estimation of global burden of disease for substance use disorders, this chapter subsequently reports regional differences in prevalence of substance use disorders and the resulting attributable burden. The chapter closes with a review of the factors that impact the incidence and course of substance use disorders.

Substance use disorders have been shown to account for about 1 % of the global burden of disease in 2010, as measured in disability-adjusted life years. The underlying methodology for this estimate was restricted to dependence and excluded abuse as defined in DSM-IV or harmful use as defined in ICD-10, so the most recent global burden of disease estimates for 2010 underestimate real burden, especially for alcohol use disorders.

The burden of disease attributable to different substance use disorders varies strongly across countries. High-income countries experience greater burden from alcohol as well as from most illegal drugs. However, burden increased in the past 20 years, especially in the developing world. North African and Middle Eastern countries experience the lowest burden of alcohol use disorders, probably due to religious reasons.

A large number of factors influence the course of substance use from initiation to the development of a substance use disorder. The overall picture suggests that extra-individual, social factors as the cultural background or peer behavior predominantly influence use initiation and transition to hazardous patterns of use, whereas intraindividual factors as personality features and genes become more prominent in the development and possible chronification of substance use disorders.

4.1 Global Burden of Disease Associated with Substance Use Disorders

Addictions (substance use disorders), as currently defined in major classification systems (see ▶ Chap. 5, "Changing Patterns of Drug Use in Georgia: A Case Vignette"), account for a considerable amount of the global burden of disease. In the 2010 Global Burden of Disease (GBD) study, alcohol use disorders were estimated to account for almost 1 % of the global burden of disease (0.7 %; see Table 4.1 and Murray et al. 2012). Burden of disease is defined here as a summary health indicator measured in Disability Adjusted Life Years (DALYs) lost (Murray 1996), comprised of years of life lost due to premature mortality plus years of life lost to disability (Vos et al. 2012). In addition to the global burden of disease from alcohol use disorders, there is about the same amount of burden of disease from illegal drug use disorders (0.8 %; see Table 4.1 and Murray et al. 2012), plus the burden from tobacco use disorders, which was not quantified in the 2010 GBD study.

Table 4.1 Burden of disease associated with substance use disorders and with substance consumption as a risk factor (GBD 2010 study)

	DALYs* in 1,000s					DALYs* per 100,000 persons				
	1990	95 % CI*	2010	95 % CI*	Delta*	1990	95 % CI*	2010	95 % CI*	Delta*
Disease categories										
Alcohol UD*	13,138	(9,544–17,484)	17,656	(12,923–23,243)	34.4 %	248	(180–330)	256	(188–337)	3.4 %

All DALYs	2,497,280		2,482,260		−0.6 %	47,105		36,027		−23.5 %

* *DALYs* disability adjusted life years, *CI* confidence interval, *UD* use disorders, *Delta* percentage change between 1990 and 2010

4.1.1 Methodology of Global Burden of Disease Estimations

To understand the burden of disease estimates and their potential limitations, it is necessary to understand how they are estimated. The definition of substance use disorders used in the GBD study (Vos et al. 2012) excluded "harmful use" as defined in International Classification of Diseases 10th revision (ICD-10) (World Health Organization 1992) or "abuse" as defined in the Diagnostic and Statistical Manual of Mental Disorders (DSM) IV (American Psychiatric Association 2000). Thus, the main burden reported in Table 4.1 stems from dependence (fetal alcohol spectrum disorder is also included in this burden category). The exclusion of "harmful use" or "abuse" is important for two reasons. First, the estimates are conservative. Second, this exclusion impacts the estimates for alcohol versus drug use disorders; for alcohol contrary to drug use disorders, a large part of the disease burden is actually due to harmful use/abuse. While disability stemming from the abuse of alcohol is lower compared to dependence (Samokhvalov et al. 2010), the prevalence and incidence of alcohol abuse is higher in many countries, such as in the United States (Hasin et al. 2007; Grant et al. 2009; Kessler and Üstün 2008; Rehm et al. 2005). For disability stemming from the harmful use of alcohol, and for mortality associated with both harmful use and abuse of alcohol, there is a scarcity of good data globally; however, from the available data, and from the calculations of previous GBD studies (Rehm et al. 2004, 2009), where harmful use/abuse of alcohol was not excluded, we can conclude that a substantial underestimation of alcohol use disorders exists in the current GBD study. On the other hand, for drug use disorders, other than cannabis use disorders, the estimation methods for prevalence were often based on problem use as defined by the United Nations Office on Drugs and Crime (2012; Degenhardt and Hall 2012), which had been used for illegal drug use disorders including abuse before, and now they are used for disorders excluding abuse. Consequently, the difference between the burden of illegal drug use disorders as a disease condition and illegal drug use as a risk factor is not large (see Table 4.1); more than 80 % of the burden from illegal drugs as a risk factor derives from drug dependence.

Tobacco use disorders are a late addition to the category of substance use disorders. Only 50 years ago the World Health Organization (WHO) clearly separated the legal, habit forming drugs of alcohol and tobacco from addictive illegal drugs (World Health Organization 1957). It is now accepted that both alcohol and tobacco are addictive substances (as evidenced in the current classifications, e.g., chapter F17 of ICD-10: "Mental and Behavioural Disorders Due to Use of Tobacco"); however, in the case of tobacco, the psychiatric classification of tobacco use disorders never entered the mainstream epidemiology and burden of disease research. Thus, "tobacco use disorders" were not a disease category in the latest GBD study report nor for other burden calculations (e.g., Wittchen et al. 2011). While part of the burden of tobacco as a risk factor is due to tobacco use disorders, the exact proportion is unclear, but is likely higher than either of illegal drugs or alcohol (see Table 4.1).

Another important aspect of the interpretation of the global burden of disease numbers concerns the underlying epidemiology. The methodology underlying the estimates of the prevalence of illegal drug use disorders has already been described

(Degenhardt and Hall 2012). With respect to alcohol use disorders, prevalence was based exclusively on a systematic review of high-quality general population surveys which measured alcohol dependence using standardized measures such as the Composite International Diagnostic Interview (CIDI; first version by Robins et al. (1988); several versions currently in use, most importantly the CIDI of the World Mental Health Survey (http://www.hcp.med.harvard.edu/wmhcidi/instruments.php), the Schedules for Clinical Assessment in Neuropsychiatry (SCAN) (Wing et al. 1990) or the AUDADIS (Grant et al. 1995)). Studies in several countries under the aegis of the WHO have revealed that for alcohol dependence as well as for illegal drug dependence standardized instruments yield similar diagnoses and, subsequently, prevalence rates; for harmful use or abuse, these similarities were much less pronounced (Üstün et al. 1997; Pull et al. 1997); however, even when standardized instruments are used, prevalence can differ. For example, consider the above-mentioned CIDI for the World Mental Health Surveys. In the first years, dependence items were only asked if the respondent had at least one abuse symptom, thereby leading to a huge underestimation of dependence prevalence (Grant et al. 2007). Similarly, small changes in wording seem to be responsible for substantive changes in Dutch prevalence figures of the past decade (see Rehm et al. 2012 for comparisons).

4.1.2 Regional Differences

Globally, the years of life lost due to both disability and premature mortality (measured in DALYs) due to alcohol use disorders and drug use disorders varied greatly by geography in 2010. See Figures 4.1 and 4.2 for the age-standardized DALYs per 100,000 people caused by alcohol use disorders and drug use disorders by country in 2010, respectively.

In 2010 the burden of alcohol use disorders was highest in Eastern Europe and in Central Asia, with 1,046 and 435 DALYs per 100,000 people being caused by alcohol use disorders in Eastern Europe and Central Asia, respectively. The lowest burden of alcohol use disorders was experienced in North Africa and Middle East, with 68 DALYs per 100,000 people caused by alcohol use disorders in 2010; religion (Islam is the main religion in most countries of this region) was the main factor that influenced the magnitude of the burden of alcohol use disorders in the North Africa and Middle East region. The country that experienced the greatest burden of alcohol use disorders in 2010 was Belarus, with 1,272 DALYs per 100,000 people caused by alcohol use disorders. For comparison, the global burden of alcohol use disorders in 2010 was 256 DALYs per 100,000 people.

In 2010 the burden of drug use disorders was highest in North America (high income), Australasia, and Eastern Europe, with 676, 573, and 465 DALYs per 100,000 people caused by drug use disorders in 2010 in North America (high income), Australasia, and Eastern Europe, respectively. The largest burden of drug use disorders was observed in Equatorial Guinea and the United Arab Emirates, with 1,001 DALYs and 843 DALYs per 100,000 people, respectively, caused by drug use disorders in 2010. With respect to the burden of specific drug use disorders,

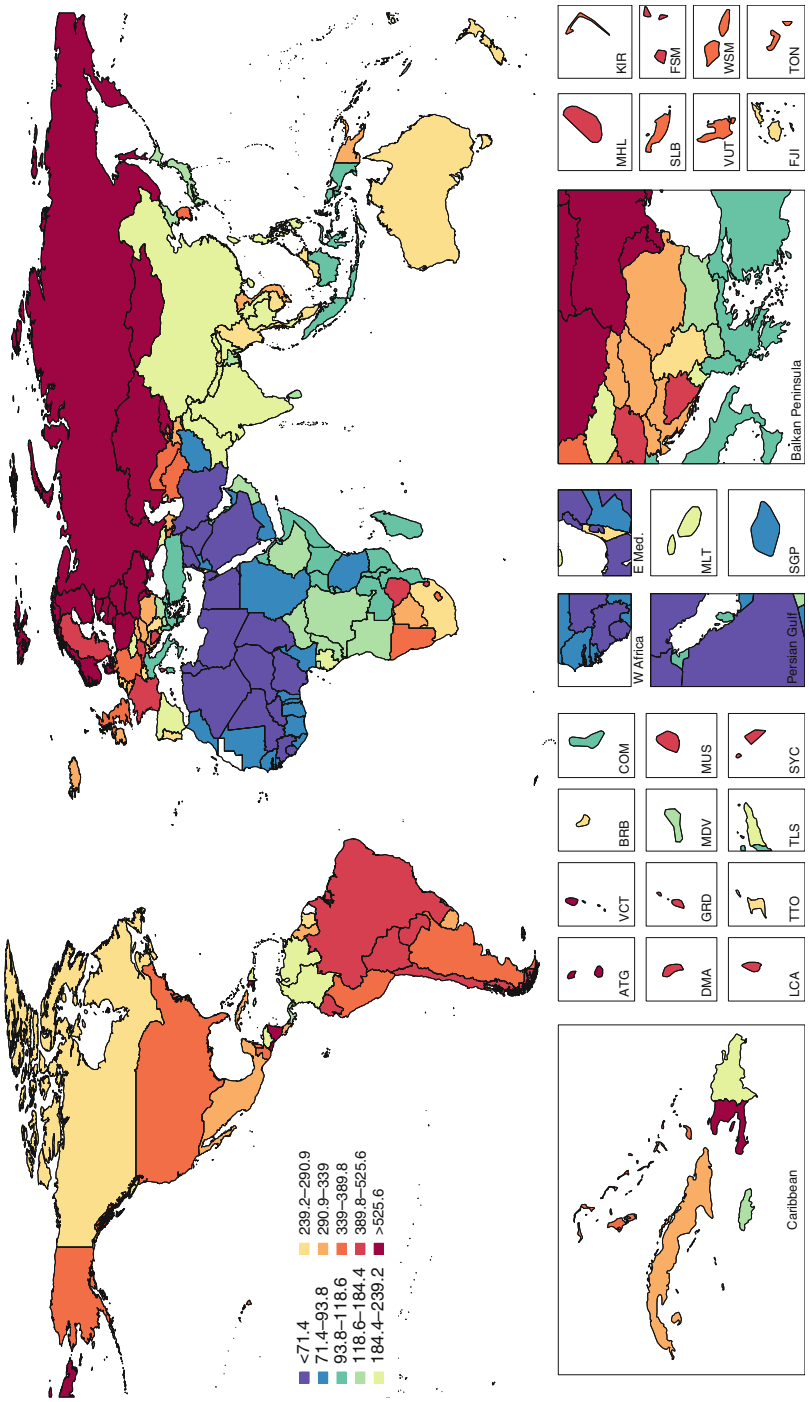

Fig. 4.1 Alcohol use disorders DALYs per 100,000 people, age-standardized, both sexes, 2010

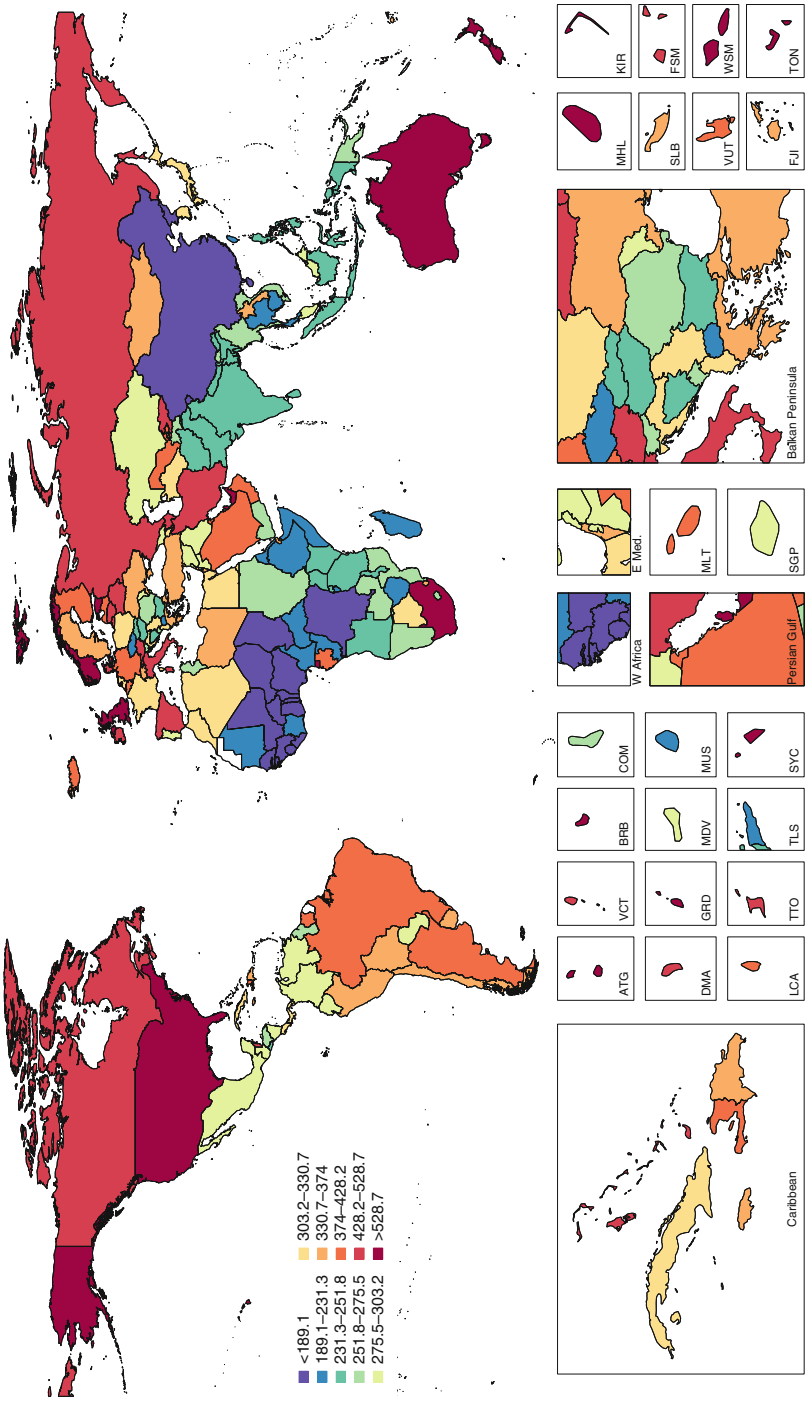

Fig. 4.2 Drug use disorders DALYs per 100,000 people, age-standardized, both sexes, 2010

opioid use disorders and cocaine use disorders were highest in North America (high income) (292 DALYs and 77 DALYs per 100,000 people for opioid and cocaine use disorders, respectively). The burden of amphetamine use disorders was highest in South East Asia (68 DALYs per 100,000 people), for cannabis use disorders it was highest in Australasia (93 DALYs per 100,000 people), and for other drug use disorders it was highest in Southern Sub-Saharan Africa (194 DALYS per 100,000 people). For comparison, the global burden of drug use disorders in 2010 was 291 DALYs per 100,000 people; opioid use disorders were responsible for 133 DALYs per 100,000 people, cocaine use disorders were responsible for 16 DALYs per 100,000 people, amphetamine use disorders were responsible for 38 DALYs per 100,000 people, cannabis use disorders were responsible for 30 DALYs per 100,000 people, and other drug use disorders were responsible for 73 DALYs per 100,000 people.

The burden of alcohol use disorders was much greater in developed countries than in developing countries, with 453 and 211 DALYs per 100,000 people caused by alcohol use disorders in 2010 in developed and in developing countries, respectively. As with the burden caused by alcohol use disorders in 2010, the burden caused by drug use disorders in 2010 was much greater in developed countries than in developing countries, with 545 DALYs per 100,000 people and 253 DALYs per 100,000 people caused by drug use disorders in 2010 in developed and in developing countries, respectively. For opioid use disorders (222 DALYs lost in developed countries per 100,000 people and 113 DALYs lost in developing countries per 100,000 people), cocaine use disorders (34 DALYs lost in developed countries per 100,000 people and 12 DALYs lost in developing countries per 100,000 people), cannabis use disorders (50 DALYs lost in developed countries per 100,000 people and 25 DALYs lost in developing countries per 100,000 people), and other drug use disorders (114 DALYs lost in developed countries per 100,000 people and 64 DALYs lost in developing countries per 100,000 people), the burden was much greater in developed countries compared to developing countries; however, with respect to amphetamine use disorders, the burden was greater in developing countries (39 DALYs per 100,000 people) compared to developed countries (34 DALYs per 100,000 people).

4.2 Transition into Substance Use Disorders

There is a history of use initiation and usually an observable pattern of hazardous use which precede substance use disorders. Generally, these observable trajectories can be approached from either a drug-centered or an individual-centered perspective (Le Moal and Koob 2007); this chapter will focus on the main individual-centered aspects and will not deal with differences between specific substances.

4.2.1 Initiation of Use

The initiation of substance use depends largely on social and environmental factors, such as cultural context, advertising, or peer influence. Worldwide *per capita*

consumption and rates of abstention differ greatly between countries (Degenhardt et al. 2008; Rehm et al. 2009; Shield et al. 2013; Degenhardt and Hall 2012). For instance, lower abstention rates from alcohol consumption are observed in high-income countries and higher abstention rates are observed in North African, Eastern Mediterranean, and South Asian countries (World Health Organization 2011); higher abstention rates are often associated with religious beliefs and with low economic wealth (Shield et al. 2011). Substance use initiation often appears in adolescence, but with some cultural and substance-specific variances (Degenhardt et al. 2008); for instance, in India and in Thailand, even though the age of initiation for alcohol consumption has declined, it remains in the 20s (Gururaj et al. 2011; National Statistics Office 2005). Across substances and cultures, women are less likely to initiate substance use (Degenhardt et al. 2008). Substance availability (Popova et al. 2009; Lipperman-Kreda et al. 2012) and advertising (Smith and Foxcroft 2009; Hanewinkel et al. 2011; Lin et al. 2012) have been shown to influence initiation of use. Beyond these influential cultural factors, the initiation of use is influenced by the individual's social network and close environment. Several studies have shown that social motives, peer or familial substance use, and normative beliefs of close peers influence initiation of substance use across different substances (Kuntsche and Mueller 2012; Galea et al. 2004; Olds et al. 2005).

4.2.2 Transition into Risky Patterns of Use and Substance Use Disorders

While most users maintain a non-risky pattern of use, some individuals will develop hazardous patterns of substance use (Swendsen and Le Moal 2011). In particular, early onset of substance use has been shown to increase the risk of later hazardous substance use across substances (Pitkanen et al. 2005; Adam et al. 2011). With respect to alcohol, recent research indicates that early drunkenness is especially associated with later hazardous patterns of alcohol consumption (Kuntsche et al. 2013). A review identifying the characteristics of people with hazardous alcohol consumption patterns in Europe (Kuntsche et al. 2004) observed that hazardous drinking patterns were more prevalent in males, adolescents, and young adults. Furthermore, the review identified other social and environmental factors, such as the predominant drinking culture, peer influences (see also Borsari and Carey 2001), parental monitoring (see also Danielsson et al. 2011), and concurrent use of other substances. Finally, the motivation for alcohol consumption seems to evolve from social motives and curiosity, predominantly as controlled use, to hazardous consumption patterns motivated by enhancement and coping (Kuntsche et al. 2005).

The factors which influence the transition from hazardous use patterns to substance use disorders are less evident. Impulsivity-related personality traits, such as sensation-seeking or the desire to be uninhibited, influence the transition from controlled use to hazardous use and from hazardous use to the development of substance use disorders (Kotov et al. 2010; Stautz and Cooper 2013). Intraindividual vulnerabilities, such as genetic factors (Le Moal and Koob 2007; Kendler et al. 2007) and comorbid

psychiatric or mental disorders (Swendsen and Le Moal 2011), can be identified as characteristics of individuals who transition to substance use disorders. In particular, high rates of incident substance use disorders have been observed, for people with prior mood, anxiety, and personality disorders (Swendsen et al. 2010).

Almost three decades ago, Khantzian (1985) developed the "self-medication hypothesis" in order to explain the development of addictive disorders where there was a prior background of mental illness or pain; this hypothesis is still discussed today (e.g., Lembke 2012). Stress and stressful and traumatic life events are also important contributors to the development of substance use disorders (Logrip et al. 2012). Adolescents and young adults show an elevated prevalence of substance use disorders in several countries, with higher rates in men (Merikangas and McClair 2012; Khan et al. 2013). There are regions of the world, however, where middle-aged men have the highest prevalence of substance use disorders (e.g., some countries in the European Union – (Rehm et al. 2005), or Russia – (Neufeld and Rehm 2013)).

4.2.3 Conclusion

The onset of substance use is largely influenced by cultural factors and often begins at a young age. It may be assumed that hazardous use precedes the transition to substance use disorders, but scientific evidence is limited in this regard. The majority of studies do not investigate the respective transitions separately, and longitudinal study designs risk missing the phase of hazardous use due to long study intervals. Furthermore, a large number of risk factors seem to exist for transitions to hazardous use and to substance use disorders. Environmental and social factors appear to be more important in the transition to hazardous consumption, whereas genetic risk factors and individual vulnerabilities appear to be more important for the transition from hazardous consumption to substance use disorders (Kendler and Prescott 2006; Tsuang et al. 1998; Vink et al. 2005; Fowler et al. 2007). Social factors play a role in

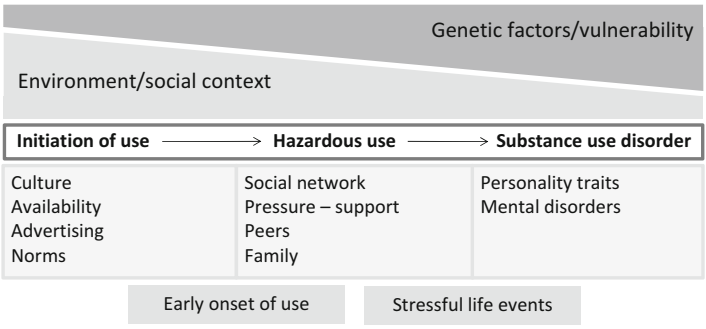

Fig. 4.3 Heuristic model of risk factors for initiation of substance use and transition to substance use disorders

the transition from hazardous consumption to substance use disorders as well, however. For example, during the Vietnam War many United States' soldiers became dependent on heroin. After returning to the United States, the majority of these heroin addictions ceased (Robins 1993; Robins and Slobodyan 2003), but in the minority of cases where the addiction persisted, family history and genetically driven vulnerabilities are considered to have played a major role. The risk factors and their differential influence on initiation and hazardous progression of substance use are summarized in Fig. 4.3.

Appendix

Definitions of scientific terms

Term	Definition
2010 Global Burden of Disease study	The largest systematic effort to describe the global distribution and causes of a wide array of major diseases, injuries, and health risk factors, and a follow-up to the 2004 Global Burden of Disease study
Age-standardized	Rates that have been adjusted to minimize the differences in age composition of a population (used when comparing rates from different populations)
Confidence interval	A range of values where there is a given probability (in this case, 95 %) that the true value (in this case, Disability Adjusted Life Years) is contained within this range of values
Delta	The percentage change in the value of a measure between two conditions (in this case, time)
Disability Adjusted Life Years	A measure of population health loss or burden of disease that takes into account years of life lost due to premature mortality and years of life lost due to disability
Burden of disease	A measure of health loss from diseases, conditions, and injuries as measured by Disability Adjusted Life Years
Incidence	The number of new cases of a disease, condition, or injury during a given period of time for a specified population
Mortality	Death
Prevalence	The number of people with a given disease, condition, or injury at any point during a given period of time (e.g., annual, lifetime, period, or point)
Systematic review	The application of search and evaluation strategies that limit bias in the assembly, critical appraisal, and synthesis of studies that are relevant to a topic
Years of life lost due to premature mortality	A measure of health loss due to premature mortality, which is calculated as an estimate of the number of years people would have lived if they had not died prematurely
Years of life lost due to disability	A measure of health loss due to disability, which was calculated in the 2010 global burden of disease study as the point prevalence of a disease, condition, or injury multiplied by a corresponding disability weight (a measure of health loss caused by a disease condition compared to total health loss (i.e., death))

Changing Patterns of Drug Use in Georgia: A Case Vignette

5

Irma Kirtadze and David Otiashvili

Contents

Abstract

In Georgia rapid economic, political, and social changes since gaining independence from the Soviet Union in 1991 and relaxation of state control have been accompanied by the scale of the illicit drug market. Drug use has become a serious public health and social issue. Heroine and buprenorphine injection epidemics of late 1990s–early 2000s were followed by the widespread abuse of home-produced injection preparations. Switching to new drugs in many instances was associated with increased risk of blood-borne infections and additional harms, such as serious neurological and psychiatric complications. Restrictive drug policy and limiting access to particular drugs were seen as solutions to country's drug problem. In addition, the system of addiction treatment was largely unprepared to provide adequate response to the changing drug use trends and often failed to meet the needs of the patients. Health-care providers might often need to engage in policy dialogue and advocate for relevant systemic reforms in order to ensure that policies, program planning, and resource allocations are meaningful, adequate, and responsive to the ever-changing needs of people affected by substance use and dependence.

5.1 Introduction

Georgia is a parlimentary republic located in the South Caucasus. The country consists of 11 regions with overall population of 4.5 million. Tbilisi, the capital of Georgia, contains the largest proportion of the population with 1,253,000 living there. Two regions of the country, Abkhazia and South Ossetia, are cut off from the rest of Georgia. These Georgian territories are sequestered as a result of internal conflicts since the early 1990s and subsequent de facto Russian Federation occupation in 2008. Approximately 288,000 persons are internally displaced in Georgia. The state language is Georgian and the main religion is Orthodox Christianity.

Georgia is a wine-producing country and consumption of alcohol is traditionally high. With almost 80 % of general population having ever used alcohol, 63.6 % admitted its last month use. Tobacco smoking was reported by 30.3 % of respondents with dramatic gender difference, 55.5 % for males vs. 4.8 % for females (Sturua et al. 2010). Marijuana is the most widely used illicit drug; however, prevalence data for general population is not available. In a recent Youth Behavioral Surveillance Survey, slightly over 10 % of students aged 15–24 admitted lifetime use of marijuana, and the highest prevalence was reported for males aged 18–24, 24 % (Dershem et al. 2012).

Georgia has experienced rapid economic, political, and social changes since gaining independence from the Soviet Union in 1991. With the relaxation of political, social, and trade control, the scale of the illicit drug market has increased and drug use has become more common. Socioeconomic transition, civil war, and ethnic conflicts, all contributed to increased illicit drug markets and drug use. In relation with injection use of illicit substances, the last two decades have been characterized by dynamic changes in drug use trends and patterns in the country. Traditional raw opium was pushed out of the drug scene by rapid introduction of heroin in mid-1990s. Heroin was later partially replaced by buprenorphine in the form of Subutex® tablets (Javakhishvili et al. 2006). Buprenorphine, which was not registered in Georgian health system until 2010, was illegally smuggled from Western Europe and occupied significant share of illicit drug market for few years. Subutex® was reported as the primary drug of dependence for 40 % of patients admitted to inpatient treatment in 2005 (Javakhishvili et al. 2006).

Since 2002 there has been a marked increase in injection use of homemade amphetamine-type stimulants (ATS) prepared from cold and cough medicines containing pseudoephedrine or phenylpropanolamine that are easily available from pharmacies without a prescription (Javakhishvili and Sturua 2009). The final injectable product of the preparation contains amphetamine and methamphetamine (street name "vint": a long-acting stimulant prepared through the reduction of pseudoephedrine) or methcathinone (street name "jeff" or "boltushka": a short-acting stimulant prepared through the oxidation of pseudoephedrine). Since 2010, the range of readily accessible homemade injectable drugs was enlarged by the so-called krokodil (desomorphine), produced from the pharmaceutical drugs containing codeine (Javakhishvili et al. 2012).

In 2011–2012 desomorphine (krokodil) and homemade ATS (vint and jeff) were leading drugs for injection in the country with significant portion of injectors using both preparations. Data from the database of Georgian Harm Reduction Network (largest provider of low-threshold services to people who inject drugs in Georgia) show that in 2012, the last month prevalence of injection use of krokodil was 42 % and the prevalence of stimulants injection was 37.5 % in a sample of 1,092 participants (40 females) of needle/syringe programs. For comparison, last month prevalence of heroin, opium, and buprenorphine injection were 31 %, 10 %, and 9 %, respectively (Georgian Harm Reduction Network 2012).

To provide a full picture of the ever-changing drugs scene, it is important to discuss the abuse of other products and over-the-counter medications that were popular for shorter periods of time and/or were characteristic to particular geographic areas of the country. In 2003 Georgia experienced an explosive abuse of a preparation produced from poppy seeds that are normally used as an ingredient for different food (confectionery manufacturing). In 2005–2008 injection use of antidepressant tianeptin (Coaxil®) was widely reported from different regions, in particular West Georgia (Javakhishvili and Sturua 2009). Finally, in 2010–2011 widespread oral consumption of anticonvulsant pregabalin (Lyrica®) was observed throughout the country.

Common features of Georgian drug scene can be described as follows: major drugs are used exclusively intravenously (no sniffing, smoking, or inhaling); daily doses of Georgian injectors are comparatively low; in most of the cases opioids are combined with benzodiazepines and other sedatives (including antihistamines with sedative effect); unstructured polydrug use is common. In the Georgian setting, benzodiazepines and other sedatives are added to opioids in order to increase the potency and duration of effect of a small dose of narcotic. In addition to the concurrent use of sedatives, the use of homemade stimulants is common. Even if polydrug use is a well-known phenomenon in the region and is confirmed by other authors (Booth et al. 2008; Kruse et al. 2009), Georgian studies indicate a scenario of even more chaotic drug use. Among other factors, the reasons for unsystematic polydrug use (mixing together opioids with other sedatives and with pseudoephedrine-based stimulants at the same time) might be the fluctuating availability of particular substances, the high price of all illegal drugs on the Georgian black market compared to local income levels, and the users' attempts to combine different drugs in order to increase the euphoric effects, potency, and duration of effect of the preparation.

Development in substance use patterns obviously depends on a complex set of contributing factors and socioeconomic context in the country. Not surprisingly, in many cases drug use trends in Georgia were shaped by policy response, legal environment, and law enforcement practice implemented at particular periods of time. It has been argued that the relatively long-lasting effect of buprenorphine injection (compared to heroin or opium) and less obvious external signs of intoxication contributed to its popularity in the Georgian drug-using setting (Otiashvili et al. 2010). Since the mid-2000s, there has been a dramatic increase in police activity aimed at random street searches and (urine) testing of people for drugs,

which, in the event of a drug being found or a drug-positive urine toxicology result, leads to harsh penalties (Otiashvili et al. 2008). Thus, buprenorphine might have attracted drug users because of its moderate clinically visible signs after its intake. Furthermore, for several years the police did not check suspects for the presence of buprenorphine in their urine, but rather concentrated on the traditional opium and heroin. This lack of detectability could in fact have added to the "attractiveness" of buprenorphine and other drugs for local drug users. Similarly, a pattern of increased homemade stimulant and homemade opioid injection followed the reduced availability of heroin and other "traditional" opioids. This was partially preconditioned by the fact that police traditionally targeted heroin and opioid markets and users switched to alternatives, which did not necessarily require involvement with illegal drug market. Again, for initial period of time, neither vint and jeff nor krokodil was properly detected through urine toxicology testing. Importantly, these alternatives were remarkably cheaper, $5–7 per single dose of vint, jeff, or krokodil, compared to $50–100 per single dose of heroine or buprenorphine.

Abuse of poppy seeds, tianeptin and pregabalin provide an additional proof of the concept described above. In all those instances, the major reason for experimenting with new preparations was drug users' attempt to self-medicate and substitute their traditional drug of abuse. Importantly, neither tianeptin nor pregabalin was identifiable through rapid urine testing, and the single dose of either preparation costs less than $10. As a policy response, all these medications, including poppy seeds, were rescheduled and put under the strictest control regime, which ultimately dramatically limited access to these preparations. Not surprisingly, drug users just went on with exploring new options.

Switching to new drugs in many instances was associated with increased risk of blood-borne infections (high frequency of injection, group character of use, sharing of paraphernalia, and risky sexual behavior) and additional harms, such as serious neurological and psychiatric complications (due to toxicity and/or insolubility of chemical ingredients used for processing the preparations) (Sikk et al. 2007). Krokodil, which received its name due to association with "crocodile eating your flesh," is probably one of the most toxic preparations injected in Georgia. Apart from quickly progressing severe neurological impairments, its use causes skin irritation and soft tissue damage. Reports provided by harm reduction and drug treatment facilities suggest that due to the fluctuating potency of the preparation, depending on the process of its refinement, krokodil injectors are at increased risk for overdoses. It is indicative that harm reduction programs in Georgia report an increased demand for naloxone.

In a country with an HIV epidemic driven by injecting drug use (56 % cumulative HIV cases attributed to IDU route (Chikovani et al. 2011b)), risks associated with the use of particular substances are of special interest. Common unsafe injection behavior among Georgian IDUs known to be sharing a cooker and dividing solution using one syringe (Chikovani et al. 2011a). In-depth analysis of drug preparation and drug division processes helps provide a meaningful explanation for these particular types of risk behavior. Buprenorphine (Subutex®) injection in Georgian setting occurs as a rule in a group of three to four people. They dissolve

one 8 mg tablet in water and then, using a large-volume syringe, divide the solution by front or back loading into smaller individual syringes (Otiashvili et al. 2010). Home preparation of both amphetamine-type stimulants (vint and jeff) and opioids (krokodil) involves using common cooker to process ingredients through often-complicated chemical refinement and using large-volume syringe to divide the final product into smaller syringes for injection (front and back loading). In both cases drug preparation is a group activity with often-predetermined division of roles and contributions (money, ingredients, space for production). Injecting stimulants from preloaded (by someone else) syringes was also reported.

5.2 Georgia's Management Features

5.2.1 Treatment Response

To a large extent, the development of addiction treatment in Georgia has been shaped by the school of Soviet "narcology" that operated within a highly centralized and closely regulated vertical health-care system. A focus on heavy medicalization, an emphasis on administrative duties, rather than positioning themselves as care givers, and few incentives to seek major changes in the field, all have historically been characteristics of Soviet narcologists (Elovich and Drucker 2008; Latypov 2011). It was in the mid-1990s when Georgian doctors finally had an opportunity to communicate with their western counterparts, to get exposed to the notion of evidence-based medicine and to start introducing novel approaches into their practice. One of the turning points in this regard was approval of agonist medication treatment and its inclusion in the law in 2002, and the role of professional community in this process was critical. The methadone program was then launched in 2005, and buprenorphine was introduced as agonist treatment in 2010. Remarkable scale-up of agonist treatment and state support for it probably represents major achievement in a history of Georgian addiction treatment. In 2011 more than 2,300 patients received agonist medication treatment in 17 sites throughout the country (Javakhishvili et al. 2012).

It should be noted that apart from positive development with regard to agonist medication treatment, the system of addiction treatment, its institutional infrastructure, and state support were all static for the most part of the time in the last decade, and no adequate response to the changing drug use trends and needs of the clients was provided. Until 2009 no state or municipal financial support for treatment was available, and patients were paying cost of treatment out of their pockets, which significantly limited accessibility of treatment. As of 2012, no system of comprehensive treatment approach has been implemented that would utilize treatment planning, case management, and notion of continuum of care. Given the lack of systemic response, it was the doctor-narcologist who was responsible for overcoming the challenges the system was facing and exploring options available at-hand. Too often these options were very limited, in particular in relation to abuse of substances that were not commonly used in the developed world and were not

described in international literature: poppy seeds, tianeptin, buprenorphine, homemade stimulants, and krokodil.

Currently, homemade stimulants use and poly-substance use represent major challenge for the Georgian treatment system with no formalized approach adapted for any of these conditions. The systems have been largely unprepared for the ATS epidemic as service providers were focusing on opioid users and were not ready to address increased demand for managing stimulant and polydrug abuse. Another major system challenge is an absence of gender-specific services; women constitute less that 2 % of clients of drug treatment and harm reduction services. It has been suggested that both sociocultural and structural barriers impede the demand for and access to substance abuse treatment for drug-using women in Georgia (Kirtadze et al. 2013). The role of policy makers, service providers, and clinicians in removing the structural and cultural barriers is critical.

5.2.2 Policy Implications

Limiting access to particular drugs, massive searches, and arrests of drug users were seen as solutions to Georgia's drug problem. Immediate results of this approach were obvious; streets became free of people under the influence and signs of drug-related activities diminished. Thousands of drug users also ended up in prisons. These actions have had multiple, radiating, unintended consequences. For example, these actions resulted in drug users switching to more available, cheap, and largely harmful and toxic home-produced preparations and exercising more life-risky patterns of use. No evidence of reduced prevalence of drug use is available. As of 2010, there are an estimated 40,000 regular injection drug users in Georgia. Thus, the problem has not been reduced. In fact, the rate of the problem in drug use is approximately 2.5 times higher than the average European estimates (Sirbiladze 2010). Within a 4-year period, the prison population has increased fourfold (from 6,000 to 24,000), and Georgia in 2011 rated sixth in the world by per capita number of prisoners (International Centre for Prison Studies 2011). This high incarceration rate has placed economic and social burden on the families of incarcerated drug users (e.g., separating mothers and fathers from children, leaving families without economic means of support both during the incarceration and after release when drug users with incarceration histories face extreme difficulties in obtaining a job). Heavy emphasis on law enforcement measures has resulted in a disproportionate allocation of resources to programs aiming to provide health and social care to people with substance use-related problems. Countrywide, only about 6 % of those who are in need receive any kind of drug dependence treatment (2,520 out of 40,000 in 2011) (Javakhishvili et al. 2012).

Hopefully, as of the start of 2013, major policy reform was discussed; Drug Policy Coordination Council has been established and drug-related legislative initiatives have been reviewed in the Parliament. Importantly, this process has been inclusive and transparent enough and has engaged all major stakeholders: policy-makers, service providers, field experts, and representatives of affected groups. It is hoped

that newly elected government officials will be committed to recalibrate current drug policy regime and will build a system in which tolerance and care for those in need, effectiveness of interventions, and evidence-driven decision-making will be prioritized.

5.3 Conclusion

In conclusion, it is obvious that health-care professionals working in addiction treatment would benefit from gaining knowledge, skills, and, most importantly, motivation to create an emotionally and physically safe treatment environment, improve its quality, and introduce structural and procedural changes that would make treatment both attractive and accessible. Medical personnel play a critical role in exploring and utilizing approaches that are based on the best available scientific evidence and that respond to the needs of those who would ultimately benefit from it. Importantly, Georgian experience shows that clinicians might often need to engage in policy dialogue and advocate for relevant systemic reforms in order to ensure that policies, program planning, and resource allocations are meaningful, adequate, and responsive to the ever-changing needs of people affected by substance use and dependence in their respective country or region.

Abstract

Social-environmental factors serve two functions in addiction care, i.e., (Bean, Zinberg (eds) (1981) Dynamic approaches to the understanding and treatment of alcoholism. New York, The Free Press) for diagnosis, assessing the *social-environmental nature and severity* of the addiction and (Berne (1964) Games people play – the basic handbook of transactional analysis. New York, Ballantine Books) for treatment, identifying *social-environmental obstacles and resources* to recovery. In clinical settings, addicted persons may try to maintain addiction by eliciting *rescuing* or *enabling* behavior from clinicians and other parental figures; the antidote consists of adult-adult transactions aimed at *recovery*. Depending on the clinical context and phase of recovery, clinicians can choose a variety of roles vis-à-vis the addicted patient, i.e., impersonal or mechanistic *I-it* for early detoxification, formal *I-You* for diagnosis and treatment planning, and personal *I-thou* during later recovery. Ultimately, the recovering addict must achieve trust within himself/herself and regain the trust of others, through acquiring personal and social integrity. Two available social entities consist of mutual-help groups (e.g., Alcoholics Anonymous, Narcotics Anonymous) and the family. These two resources can gird the addicts in re-creating a supportive, functional *intimate social network* (ISN) – a core foundation for happy and healthy living. Clinicians' understanding of the ISN structures and functions provide a potent means for coaching addicts in recovery. In addition to clinicians, families, and mutual-help groups, communities, governments, and society at large can design environments that facilitate relapse or favor recovery. *Social-environmental obstacles* include a high prevalence of addiction and local profiteer-enablers who prey upon addicts. *Social-environmental resources* include clear norms regarding substance use, availability of timely treatment, and implementing prevention strategies. Coordinated international action can bolster local social-environmental initiatives.

6.1 Introduction

Much clinical research on addiction emphasizes the individual addict in isolation from other people. Examples include the addicted person's genes, responses to addictive substances, course of addiction over time, psychopathology, medical and psychiatric comorbidity, response to pharmacotherapies and psychotherapies, individual avenues to recovery, and causes of death. These individual-focused topics remain important and relevant. As clinicians, we often encounter the addicted person in isolation. Our professional ethics bind us to the individual patient, and various legal dictums (such as privacy and confidentiality) may seem to exclude others from the clinician-patient relationship, or at least render it difficult to include them.

This section focuses on addicted persons in social and environmental contexts. "Social" refers here broadly to anyone outside of the individual addicted person, from one other person (including clinicians) to various larger groups. These larger groups may include the family, the drinking or drugging group, the intimate

social network, the community, government, and various sociocultural and nongovernmental groups. "Environmental" incorporates all outside forces, events, and objects that act on or affect a person. The individual's relationship with the environment is dynamic: he/she interacts with the environment, is affected by the environment, and can also act on, influence, or change the environment. Related topics covered in other sections of this volume consist of Social Therapies and Treatment Settings (Sect. 5) and Systems, Approaches, Public Policies, Evaluation, and Outcome of Treatment (Sect. 6). Information provided here provides relevant background information for these subsequent sections.

6.2 The Social Context

6.2.1 The Addicted Person in Social Context

Interpersonal Psychodynamics in Addiction. The personal characteristics of the addicted person impinge on transactions with other individuals, as well as with groups. Perhaps the most common psychodynamics appearing over time in the addiction process are denial and projection. From the addicted person's perspective, these are inherently social explanations for the addiction. In brief, the addicted person initially denies that he/she is responsible for the excessive use of psychoactive substances or its consequences. Instead they blame another person or group for the addiction (e.g., family, employer, the world at large). This blaming of another comprises projection, the attribution onto others that they have produced the addicted person's failures and problems.

Some element of truth may underlie the addicted person's blaming of others, whether for the family's passing on genes that produce vulnerability, or teaching values or behaviors that foster excessive psychoactive use, or failure to intervene early upon the appearance of pathogenic psychoactive use. Despite these threads of reality, the belief that others have produced one's own behavioral problems can seriously impede one's efforts at recovery. The addicted person must take responsibility for his or her own recovery in order to work free of addiction. Blaming other persons ("my alcoholic father") or groups ("the racists," "the government") may offer some transient solace early on, but poses a profound obstacle to ultimate recovery.

Therein lies a paradox for both the clinician and the recovering addict. On one hand, the clinician's treatment and the addict's recovery converge on the notion that the addict must take responsibility for his or her own individual recovery. By the same token, clinicians' attention and recovering addicts' linkages to interpersonal and social-environmental factors encompass key steps to successful outcomes. This complex notion – personal responsibility bridging to social reintegration – does not surface suddenly to the addict's awareness. Rather it evolves gradually, growing out of experience as well as knowledge. Probably, it is best that it develops thus, since sudden awareness of one's responsibilities for recovery and the momentous tasks and time required for social reintegration could overwhelm the struggling patient, precipitating a return to addiction or even respite seeking in suicide (Bean and Zinberg 1981).

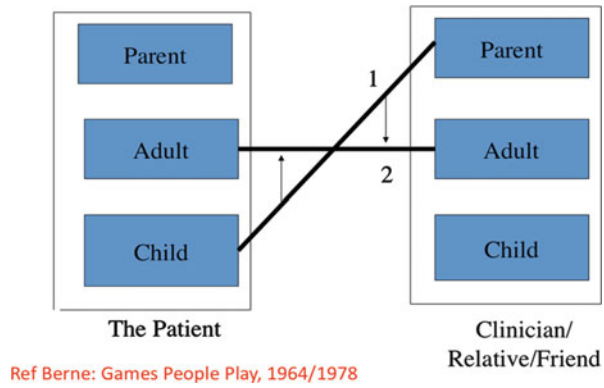

Fig. 6.1 Eric Berne's interpersonal relationship model (Transactional analysis)

6.2.2 Using Interpersonal Psychodynamics in Treatment

The actions of addicted persons in relation to others can be described using the social roles of "parent," "adult," and "child," as shown in Fig. 6.1. These parent-adult-child terms correlate loosely with the psychoanalytic terms "superego," "ego," and "id."

Addicted people sometimes assume the "child" role in relation to parental figures, such as clinicians and judges. This interpersonal strategy aims at eliciting addiction-perpetuating succor from the other person's "parent." As applied to addiction, a rescuing or enabling interaction may ensue (Berne 1964).

Rescuing entails the "parental-helper" saving the "childish-addict" from the consequences of his or her behavior. For example, a judge may let the addicted criminal off without punishment, or a clinician may repeatedly treat the addict's damaged health without attending to the addictive disorder that is causing the illnesses. *Enabling* implies that the parental figure provides resources that permit the addicted person to have the time and/or resources to continue an addiction-focused lifestyle. For example, a family member or friend may provide the addicted person with money, shelter, food, or transportation to purchase psychoactive substances and avoid social responsibilities. Both rescuing and enabling are depicted by the child-parent relationship depicted as "1" in Fig. 6.1 (Berne 1961).

Recovery requires the addicted person to act in "adult-to-adult" relationships; see relationship "2" in Fig. 6.1. This transition from child-parent to adult-adult transactions may not be easily accomplished. Clinicians can assist recovering patients and their rescuers-enablers with this often-difficult change as follows:

- Instruction regarding interpersonal roles, choices, and dynamics
- Feedback regarding "childlike" behaviors of the addicted person's part (e.g., missing or coming late to appointments, requesting prescriptions for addictive medications, requesting treatment while undermining its beneficial effects by continued addiction)
- Clinician's opting out of parental behaviors that promulgate addiction (e.g., prescribing addictive substances, providing written excuses for irresponsible or illegal behavior, undertaking or persisting in treatments rendered ineffective by addiction).

Using the paradigm described in Fig. 6.1, recreation with others tends to occur on a "child-to-child" transactional level. As recovery proceeds, the ability to recreate without recourse to alcohol-drug use poses an obstacle for many recovering persons. If their former recreation did not depend on substance use, they may simply return to their former pastimes, hobbies, or avocations. However, if their former recreation occurred in a context of substance use, they need to seek new opportunities free of substance use. Mutual-help associations and recovering groups realize this dilemma and often create recreational activities for times that favor excessive use (e.g., New Year celebrations). Clinicians should aid in this crucial aspect of recovery, since the absence of play and social "time out" from daily responsibilities can undermine an otherwise well-founded recovery.

In certain respects, clinicians can behave appropriately toward recovering patients in the "parent" role. Examples include making and conveying diagnoses, providing counsel, or prescribing medications for detoxification, craving, maintenance, or comorbid disorders. Although aimed at being therapeutic, this approach may engender childlike responses from the recovering patient (e.g., resentment, sociopathic "acting out" of negative attitudes toward the clinician or the treatment process, return to addiction). Several alternatives can aid in reducing these "parental" impediments as follows:

- Working with co-therapists who can assume a more egalitarian approach to the patient
- Assuming more the role of a "coach-trainee" than a "doctor-patient"
- Providing choices between alternative therapies, so that the patient is engaged as a codirector of treatment
- Educating the patient to the pros and cons of alternative approaches and allowing some time interval for the patient to consider the alternatives, seek other information, or obtain counsel from others before making a decision or requesting the patient to make a commitment

6.2.3 Impersonal, Formal, and Personal-Informal Relationships

Addicted persons, as well as their clinicians and other members of their social networks, can behave on several operational levels vis-à-vis the other. For purposes here, these three types of interpersonal relationships are used synonymously with I-focused typologies that have evolved over the last several decades (Farber 1956):

- Impersonal = I-it relationship
- Formal = I-you relationship
- Personal = I-thou relationship

The "I" in an I-it relationship relates to the other person in a mechanistic, largely I-centered fashion. For example, an addicted person seeking drugs from a clinician has an unshared goal with the clinician (i.e., obtaining addictive medications) as opposed to a shared goal (i.e., health seeking). Such patients may experience problems in changing their attitude toward clinicians from "naïve target" to "trusted helper." We as clinicians may act in I-it roles with unconscious patients

(e.g., administering an antagonist medication to an overdosed patient), selecting an appropriate medication for a withdrawal regimen or – in selected respects – treating a legally incarcerated or committed patient. Such impersonal or authoritarian roles also occur in other social interactions involving addicted persons (e.g., discharging an addicted employee or divorcing an addicted spouse). This type of relationship is not so much social as asocial or mechanical in its salient features. Although interactions on this level can be life saving and caring, they also carry the risk of becoming dehumanized or uncaring. Such relationship can also occur on a larger social plane, with administrators or societal leaders relating to addicted persons in a demeaning or solely economic and legal fashion (Ticho and Wnnicott 1974).

"I" in the formal I-You relationship functions in a dyadic but role-driven fashion with the other person. The relationship operates within formal social rules and cultural expectations. For example, the addicted person in a formal patient role would relate to the clinician by expressing their health-related problems and concerns forthrightly, answering the clinicians queries as they are best able, and complying with treatment recommendations. Conversely, the clinician would conduct a competent evaluation, render a reasoned assessment or diagnosis, and provide a prognosis and treatment recommendations supported by the findings. Traditions, customs, personal experience, education, professional ethics, regulations, and laws prescribe the parameters governing these formal roles. For example, social workers may act the role of housing providers for addicted persons, or police may act the role of security enforcers. As a result of negative relationships with various other people in their formal roles, addicted people can have difficulty maintaining functional relationships on this level during early recovery.

I-thou relationships include more egalitarianism and greater informality. They inevitably involve such attributes as mutual trust, commitment, and benefit. For example, the patient may ask the clinician which therapeutic alternative seems the most likely to proceed or thank the clinician after an appointment. Or the clinician may congratulate the patient for achieving a therapeutic risk or reaching a recovery milestone. These informal communications do not inactivate the formal social frame that provides the necessary boundaries to the therapeutic relationship, but they can greatly facilitate and humanize the therapeutic encounter.

The nature of the "I" relationship can change over time. For example, the clinician may take the I-it role early in a medical crisis; then change to I-You transactions during later assessment, treatment and early recovery; and finally adjust care to encompass I-thou elements during the later months and years of recovery. Slips or relapses may compel a return to an earlier mode of relating.

6.2.4 Recapturing Social Integrity

By the time they seek treatment, many addicted people can no longer rely on themselves. Clinicians hear statements like "I can no longer trust myself" or "I lie so much that I don't even know what is the truth anymore" or "I can't make even the simplest promise or commitment." Re-acquiring integrity starts with the self. To regain

integrity, addicts need to work at becoming "one" again. That is, they must have one truth, one set of values. Such constancy is difficult even for nonaddicted persons, since the variety of roles played by any one person varies so greatly. Each of us possesses slightly different personas in our relationships with parents, offspring, spouse, supervisors, co-workers, friends, old buddies from childhood, and clients. These personas if extremely diverse can pull the recovering person away from an evolving core "one-ness," or integrity, toward duplicity and relapse (Sutker et al. 1980).

Over time many people with addictive disorders lose the trust of other people. Stated differently, addicts tend to lose their trustworthiness. Without mutual trust, people are unwilling to live with addicted persons, own material goods in common with them, or exchange mutual obligations. In the absence of such commitments, the addicted person is apt to become increasingly isolated. For a time, wealth may compensate for mutual obligations, posing a greater risk for the wealthy who can hire to people to provide social support. Unfortunately, using wealth to compensate for social isolation can delay recovery efforts. To establish trust, the recovering persons must be honest, truthful, reliable, and morally upright.

Regaining the trust of others presents one of the greatest long-term challenges to the recovering addict. Depending on the duration and depth of past failures, it may take many months to years before former relatives, friends, and others can again trust the recovering addict. With some regular opportunities to regain trust, the recovering person may experience some moderate trust building within a year. Deep trust may take longer. Clinicians can support and guide the recovering person in this quest. Many recovering people expect others to impart trust after one episode, or within a week or two of abstinence. Such disappointments can reignite addiction if the patient is not prepared for it. Once prepared for the long haul, however, most recovering people can launch into the quest of regaining integrity (Westermeyer and Walzer 1975).

Perhaps one of the advantages of becoming again an integrated, trustworthy person is the paucity of people in the networks of many people early in recovery. Since they have lost so many supporters, they can start anew rebuilding on a small number of relationships. Starting simply with only a few relationships eases the task of achieving integrity.

6.3 The Addicted Person's Family

The Addicted Family. In most societies, more than half of addicted persons grew up in a family with an addicted parent. Some addicts even have two parents with an addictive disorder. Or neither parent may be addicted, but siblings, grandparents, uncles, aunts, or cousins may be addicted (Galanter 1993).

Coming from an addicted family can produce a myriad of hurdles. Addiction tends to start earlier in such circumstances. Childhood may have been fraught with stress and conflict, if the parent or parents had not recovered earlier. Role models for later adulthood, marriage, and parenting may be absent or flawed (ElGuebaly et al. 1990; Westermeyer et al. 2001).

By the same token, having an addicted family background can also impart certain advantages. Relatives may recognize the signs of addiction early on, due to their familiarity with it. Especially if familiar with recovery, they may support the addicted relative in recovery-oriented endeavors. Those seeking out recovery-oriented mutual-help groups may come from addiction-afflicted families (Westermeyer et al. 2001). In some countries, mutual-help groups for the adult children of addicts have formed.

6.3.1 Recovery Within the Family

For addicted adolescents and young adults, family therapy can be a highly effective intervention. The same is true of couple's therapy in which one partner is addicted. A key to either alternative lies in seeking a therapist familiar with addiction, recovery, and the treatment of addicted families and couples (Coviello et al. 2004).

If both members of a couple are addicted at the same time, concurrent recoveries occur only rarely. Since recoveries tend to be unique in certain respects and occur unevenly over time, partners seldom recover in the same fashion along the same time frame. This discrepancy wears on the relationship, so that maintaining the blighted relationship while trying to recover becomes nigh unmanageable. A more viable alternative may lie in recovering separately and then deciding whether the two recovered-evolved personas can create a new sobriety-based life together (O'Farrell and Cowles 1989).

Recovered persons, when single, often meet and court other recovered persons. This common, often vexing-yet-rewarding experience can serve as strong groundwork for a successful partnership. Each member shares concepts, jargon terms, and perhaps common recreations and social affiliations with the other. Plus they understand deeply the torments of loss and loneliness, and they share the long, hard trek from addiction through recovery to wellness.

6.4 The Intimate Social Network in Addiction and Recovery

6.4.1 Intimate Social Networks (ISNs)

Several typologies exist for conceptualizing "social networks," such as number of confidants or people contacted in the last week. The one utilized here developed from the work of a psychiatrist who had trained in social science (Pattison 1977). In this format, the individual is asked to name the people who are the most important to them in their current lives. Most adolescents and adults who are functioning at a reasonably comfortable level report 20–30 people, who fall naturally into four or five groups (e.g., people living together, a group of relatives living elsewhere, friends, co-workers, people who share a common interest or pastime); see Fig. 6.2. This small group differs qualitatively from the much larger number of people whom any one individual knows and can name (usually on the order of several

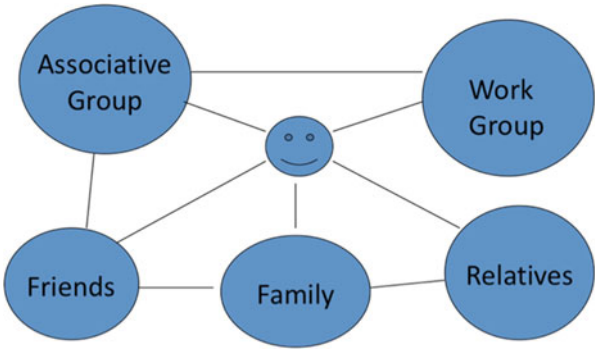

Fig. 6.2 Normal social network n = 20–30, 4–5 groups, reciprocal, 80 % connected, stable over time

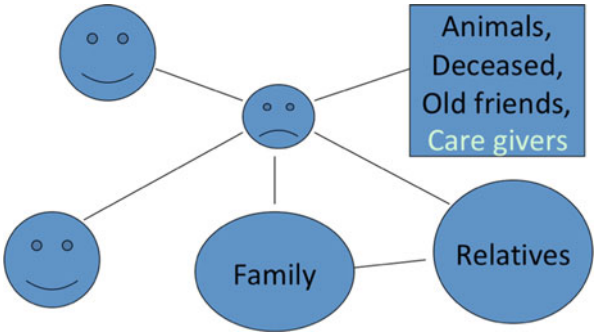

Fig. 6.3 Outpatient social network N = 10–19, 2–3 groups, partially reciprocal, 60 % connected

hundred to a few thousand people). Among adults, the relationships are reciprocal, so that members contribute to or help one another as well as the corporate group in some fashion (e.g., exchanging goods or services, providing interpersonal help or support, meeting common goals). Membership in any one group within the ISN often requires getting along with several people. In this fashion, a person may transcend conflict with any one or a few members of the group in order to retain access to valued members of the group and keep the group intact. Such networks tend to persist over time. Any one person in the proband's network knows about 80 % of the people in the total network (i.e., connectedness = 80 %).

People who seek outpatient mental health services tend to have at least ten, but less than 20 people in their ISN (Westermeyer and Neider 1988); see Fig. 6.3. The network members often fall into two or three groups plus an additional number of one-to-one relationships; see Table 3. These one-to-one relationships may include a recent friend, lover, or someone who provides service or care (e.g., a therapist, clergy, bar tender, barber, or hairdresser). The one-to-one relationships may be more recent as well as vulnerable to change or dissolution over time. At times they report ISN members as being pets, deceased friends or relatives, or close friends from years or decades earlier. Connectedness is around 60 %. These people are typically discomforted, even miserable, but they are functional in one or more capacities, such as working, parenting, or going to school. Among adults, their

relationships tend toward reciprocity although asymmetric relationships may occur in the event of enabling or rescuing relationships (see above). Their entire network may consist of other addicted people (Dumont 1967).

People who are disabled tend to have less than ten members in their ISNs. The members of this group tend to know one another through their supportive roles vis-à-vis the proband. For example, the proband's parent, social worker, and landlord may all know one another as a result of previous experiences with the proband. Connectedness is often 100 %. People in this group tend to have asymmetric or nonreciprocal relationships, since they may not have the resources or skills to reciprocate.

Severely ill people can come to distrust or alienate others to the point that they report no one in their current ISN. They may be homeless and paranoid, surviving on their ability to obtain food, shelter, clothing, and other necessities from the environment. Many, but not all, people in this group have been addicted in the past or remain addicted. Most require psychiatric services, but many can recover over a period of months and years with support.

6.4.2 The ISN in Addiction and Recovery

Actively employed addicts living with family can have social networks that resemble normal networks with one exception: as many as half of the network is comprised of other addicted people (Favazza and Thompson 1984). In order to pursue recovery, they must abandon and then replace the addicted people with whom they are affiliated. This precipitates loss, engenders grieving, and can both help and hinder the adjustment to sobriety.

Most people presenting for addiction treatment have the "discomforted" network, with 10–19 people, 2–3 groups, and one or more individual relationships (with minimal connectedness to the rest of the network). In achieving a comfortable, balanced life and recovery, they usually rebuild their network backup to 20–30 people and four to five groups over a period of years – a much longer period than that needed by people who must rebuild their ISNs after relocating for work or education.

Relatively few addicted people seeking treatment have "disabled" networks with fewer than ten people and a single nonreciprocal group focused on their care. Those who are in this group may be mentally ill (e.g., Korsakoff dementia, alcoholic dementia, chronically psychotic). A thorough neuropsychiatric evaluation should take place early in treatment; neuropsychological, neurological, and medical assessment may also be needed. So-called skid row alcoholics living on the periphery of society may also fall into this category.

Assessment that incorporates members of the patient's ISN can serve several purposes: elaboration of a complete assessment, communication to the patient regarding the consequences of his/her behavior on those who care about him/her, and enlisting ISN members in intervention and recovery (Speck and Attneave 1973). Ongoing treatment that involves ISN members committed to the patient's

recovery aids in social network reconstruction while alerting network members to the need of reasonable expectations during the various stages of recovery (Galanter 1993).

Contingency contracting therapy weds social network intervention with a variety of psychological and pharmacological therapies (Bride et al. 2010). For example, a family member may administer an antagonist medication (e.g., disulfiram, naltrexone) to the patient in return for continued residence at home, or an employer may provide the same service in return for continued employment. Attendance at therapy or self-help sessions may be linked to various "rewards" in a similar fashion.

6.4.3 Artifactual ISNs in Recovery

Most people in a community have a normal social network and do not want additional network members. Since such relations require reciprocity, regular contact, and long-term emotional commitment, there is a self-limiting component to ISN size. It cannot grow beyond finite limits. Moreover, the network tends to accrete in groups rather than solely via individuals (although individual contacts can grow to subsequent group affiliations). Such affiliations also grow over time, almost like a courtship, in a series of small-but-reciprocal events, as trust and friendship develops. Thus, acquiring new individuals and groups poses a major challenge during recovery.

During the early period of recovery, a number of created or artifactual groups are available to the recovering person. These groups can include one or a few mutual-help groups (e.g., Alcoholics Anonymous) and perhaps a treatment team or case manager (Willenbring 1995). Certain community organizations open to all can provide a nidus for later affiliations (e.g., church committees, neighborhood political committees, hobbies or pastimes). Each culture and community contains its own entrees to such groups. Even in remote rural communities of a few hundred people, recovering people can rebuild a functional social network (Westermeyer 1982).

Recovering people can also be on the lookout for people whose social networks have been depleted and are expanding. People migrating to a new community typically rebuild their social network within several months. Those starting a new job, school, or training program may be open to new affiliations. A limiting factor for the recovering addict is the need for sober members in at least some of his or her social network and the absence of addicted people in the remainder of the network.

6.5 The Community and Addiction

Some communities are more addiction friendly, some are more recovery friendly, and many possess elements of both. Perhaps the most important pro-addiction environmental factor is a high prevalence of people using substances excessively

(Hughes et al. 1974). Widespread excessive use reduces social inhibitions against use. Having a large number of substance merchants also contributes to widespread use, as it increases access and – if market forces are at work – reduces the cost. Absence of restrictions against sale to youth or intoxicated persons, or unlimited hours of sale, fosters widespread use (Smart and Murray 1983).

Widespread intoxication in a neighborhood or illicit sales can, in time, undermine a neighborhood (Fagan 1989). Several avenues promote this outcome. Widespread intoxication leads to property crime (to purchase psychoactive substances) and interpersonal crime (due to increasing discord and disinhibition). Drug sellers become the role models for youth, due to their relative wealth and apparent power. Faced with these daily realities, working families involved in raising their families move elsewhere. Property values drop and licit retail stores move elsewhere. In many such settings, security falls as police abandon the neighborhood or cannot be deployed in adequate numbers due to the falling tax base. Corruption of elected officials and other governmental workers often emerges (Westermeyer 1982).

The current prevalence of addictive disorders can reach crude prevalence rates (i.e., total population rate) as high as 10–12 %. Examples include Southeast Asian and South Asian communities that raise opium poppy (Westermeyer 1981) and American native reservations with high alcohol and drug rates (Kinzie et al. 1992). Since most addiction in these communities occurs in those aged 18 years or older and adults comprise about half of the community, the adult prevalence rates are twice as high, in the range of 20–25 %. Since men in these settings have rates two or three times that of women, current adult male rates run around 26–38 % and adult female rates run around 10–26 %. Two additional factors argue for lifetime risks of addiction that exceed these crude prevalence rates: some of the younger adults will develop addiction during their adult years in the future, but have not done so yet (Bean and Zinberg 1981), and some of the addicted adults in the population have already died at an early age from substance-related causes, so that addicted people are underrepresented (Berne 1964). Although no firm lifetime rates are available for these high-rate communities, extrapolations from current prevalence rates, risk factors favoring future addiction in some adults, and early removal of addicts from the population through premature death suggest that even higher lifetime rates, perhaps 15–30 % in women and 30–50 % in men, can exist. Burdens in such communities include child neglect and abuse, malnutrition, marital disruption, violence, infectious disease, poverty, crime, and premature death (Westermeyer 1999). Although some community leaders in such settings focus public attention and action on addiction, many others deny its existence and accuse clinicians or epidemiologists of exaggerating or lying about the extent of addiction in the community (Foulks 1989).

Addiction services within a community must be integrated to be successful. For example, failure to engage newly released prisoners in treatment produced a high drug-related mortality rate during the first 2 weeks post release (Farrell and Marsden 2008). Mortality is also high during the first month following discharge from opioid maintenance treatment (Cornish et al. 2010). Availability of chronic pain services may comprise a safety net for patients transitioning from one phase of addiction treatment to another (Barry et al. 2012).

6.5.1 State Government and Addiction

Actions by governmental bodies can greatly influence the rate and course of addiction in a society. Governmental efforts can be most effective and efficient when rates are low and decreasing. Conversely, governmental efforts are most apt to go awry when rates are high and increasing. Under such circumstances, the government striving to reduce the addiction rates is at odds with the large number of the populace who value heavy, excessive, widespread use. The latter group includes not only the heavy consumers, but also many others who profit from heavy, widespread use. Profiteers include basic producers (e.g., farmers, biochemists), manufacturers (distilleries, pharmaceutical companies, illicit gangs), transporters, wholesalers, retailers, bankers, advertisers (if the substance is legal), private security forces (if the substance is illegal), and government workers, altogether comprising a virtual army of citizens and public workers dependent on or corrupted by the industry (Suwanwela and Poshyachinda 1986).

Despite the myriad of obstacles, many governments have reduced widespread addiction over the last three centuries (Lowinger 1977). There is evidence from Mexican glyphs that Aztec laws limited alcohol use even earlier (Anawalt and Berdan 1992). Successful means of limiting or eliminating certain addictions have included the following:

- Taxes on import and/or sale of certain psychoactive substances (e.g., beverage alcohol, tobacco)
- Licensure to import, produce, or sell certain psychoactive substances in specific amounts
- Restriction of certain substances to medically supervised prescription use (e.g., opioids, sedatives, stimulants, cocaine)
- Constraints on density of retail outlets for certain licit psychoactive substances, as well as hours and days of sale
- Punitive laws against behaviors that undermine governmental authority with regard to psychoactive substances (e.g., bootlegging, illicit production), risky behaviors during use (e.g., driving, boating, flying, hunting), and actions that may engender addiction (e.g., sale to minors or intoxicated persons)
- Providing treatment for addicted victims of alcohol-drug epidemics while punishing those who illegally produce or distribute these substances or commit illegal acts while influenced by these substances (the so-called carrot and stick approach)

Governmental actions can also foster addiction and/or the consequences of addiction in numerous, often unintended ways, as follows:

- Placing tax revenues on psychoactive substances into the general revenues of the state, so that governmental officials seek to increase substance use as a means of increasing revenues (rather than targeting these funds to reduce addiction and address its consequences)
- Providing governmental funds for housing or unemployment incomes to addicted persons with no supervision or expectation for recovery while overlooking opportunities for community reinforcement of sober behaviors (Azrin 1976)

- Overlooking the propensity of simple-but-fundamental social interventions (such as prohibition, so-called "medical" use of addictive substances outside of ordinary channels, free unsupervised shelters for addicted persons) to produce large-scale effects opposite to those intended or predicted (Schwartz et al. 2011)
- Permitting various organs of governance or public sectors to avoid or undermine governmental efforts to limit or reduce addiction (e.g., health, education, law enforcement, taxation/important agencies, military units)
- Issuing psychoactive substances to military units (e.g., opioids, alcohol, cannabis, amphetamines, benzodiazepines) supposedly to increase combat efficiency
- Ignoring widespread addiction on local, regional, or national levels as a means of cultivating popular support, promoting one's own reelection, or emasculating public criticism
- Accepting governmental corruption by elected and appointed officials, as well as among frontline government employees
- Neglecting to ensure availability of mental health services, so that people treat their symptoms with alcohol and illicit drugs (Castaneda et al. 1994)
  See Sect. 4 for more on this topic.

6.5.2 The Sociocultural Milieu and Addiction

In numerous traditional societies in which psychoactive substances are used with minimal problems, a functional social group determined the occasion for use and amount used (Bennett and Ames 1985). The group was often the extended family, but could be a religious group or other social organization. Feasting and other celebrations (e.g., dance, song, stories, speeches) accompanied substance use. Across the world, alcohol was perhaps most commonly used substance, but tobacco, hallucinogens, and other substances were also used. Occasions for such celebration include annual feasts (e.g., New Year, harvest, religious holy days), life-cycle milestones (e.g., birth or naming day, adolescence, marriage, death), and various individual achievements (e.g., graduation, membership in an elite group, "potlatch" or giving away accumulated wealth). Child, adolescents, or young adults received supervised initiation (or ensocialization) into substance use, guided by a relative. Substance use outside of these boundaries comprised a culturally forbidden or taboo behavior. Under these circumstances, addiction was rare or even nonexistent. However, this well-organized entrée into use of a given substance did not protect the individual for addiction on other substances that did not involve this type of regulated orientation. In addition, adolescents can be ensocialized into the healthy use of only a limited number of substances (usually two to four in most cultures).

A second type of pathogenic orientation into substance use is more apt to result in addiction. This mode generally occurs within a non-kin peer group. Those conducting the ritual are often slightly older than the initiates. Females may instruct females, and males may instruct males; but if cross-gender familiarization occurs, typically males teach females. The setting is secular, rather than familial or

ceremonial. The main event is the use of the substance, its subjective effects, and the peer group experience. If the substance is illicit, it may occur in a surreptitious fashion (which may add to the excitement of the event and the subjective effects of the substance). Depending on the culture or the individual group, the coaching mostly occurs from early adolescence to early adulthood. It may occur when the person has left home (for school, work, or military service) or during individualization from the family to adulthood. Initially the peer group sets the occasion and perhaps also the amount of use. However, with time, individuals decide their own frequency or amount of use. With age, marriage, parenting, and work responsibilities, many people fall into a pattern of nonuse (if the substance is illicit) or mild-to-moderate use (if the substance is legal and culturally acceptable). Others choose heavy or excessive use, paving the way to addiction as a lifestyle (Westermeyer 1999).

Both patterns of instruction can occur in a given family, community, or culture. For example, alcohol use may be carefully taught within the extended family, while tobacco smoking may be learned from peers. This scenario would favor addiction to tobacco but nonproblematic use of alcohol. Supervised substance training may prevail in traditional societies with specifically traditional substances, such as alcohol, tobacco and hallucinogens (in the Americas), caffeine (in teas and coffee), and khat. Society-wide education in the use of certain other substances takes place infrequently for other substances, such as coca leaf or cocaine, betel-areca, opium and its derivatives, or industry-produced substances (sedatives, amphetamines, anesthetics, anticholinergics).

The use of substances can impede enculturation into adulthood by alleviating the anxiety or insecurity that accompanies acquisition of maturity. Maturity-related tasks consist of social performance (e.g., speaking or performing before a group), comfort with sexuality (e.g., conversing with the opposite sex, expressing affection, courting), and various interpersonal skills and problem solving (e.g., conversation, coping with confrontation, settling differences). If an individual can engage in these activities only under the influence of psychoactive substances, two problems ensue: maturation is delayed, with detrimental effects on self-confidence and self-esteem (Bean and Zinberg 1981), and the substance is needed to perform the task, setting the stage for eventual addiction, as a higher dose and more frequent use is required to alleviate social fears or performance anxiety (Berne 1964).

Psychoactive substance use may accompany certain types of work. For centuries, coca leaf, betel-areca, tobacco, and alcohol use have attended long hours of heavy or repetitive work (e.g., factories, road building). For tasks requiring heightened awareness or bursts of energy (e.g., hunting, warfare, athletics), some societies have employed stimulant use (caffeine, cola nut, khat, kratom). Traditional healers, spiritual leaders, or members of spiritual or healing associations (such as Zar-like healing cults across Asia) may use substances to facilitate trance. Depending on the culture and current practice, these substances have encompassed opiates, hallucinogens, tobacco, and other drugs. Rather than use drugs of any kind, some groups have employed fasting, sleeplessness, social isolation, silence, or repetitive music or dance as a means of achieving trance, communication with spirits, or healing.

Many workers around the world relax at the end of the work day with a variety of substances, including alcohol, caffeine, khat, tobacco, opiates, and cannabis.

Epidemics of addiction have occurred around the world over the last five centuries, beginning with epidemic alcohol use in Europe, epidemics of opium smoking across Asia and parts of Europe, and tobacco almost everywhere. Factors supporting these early epidemics comprised the following:

- Appearance of new substance forms, which were not subject to traditional customs (e.g., gin and rum in European countries where beer, ale, or wine had been traditional)
- Appearance of new modes of administration not subject to traditional mores (e.g., smoking opium replaced medicinal oral ingestion of opium)
- New substances (e.g., tobacco, cocaine) over which no traditions or rituals had governed use
- Profiteers who endeavored to increase use and thereby increase their profits
- Diverse, conflicting, or ambivalent beliefs and attitudes toward use, so that any given society could not act in a coherent fashion vis-à-vis the substance
- Delay in the appearance of epidemic consequences, so that addiction spread widely before the extent of the problem could be appreciated

As addiction spreads to epidemic proportions, it tends to do so in a hidden fashion during its early stages (Westermeyer 1982). This unique phenomenon is due to the consequences of addiction epidemics showing up in numerous sectors, including health, family life, productivity, child raising, property crime, interpersonal crime, economic burdens, and various other manifestations. Moreover, the spread occurs over years or even decades and centuries, unlike infectious disease epidemics that can devastate a population within weeks, months, or a few years. The low incidence of any one addiction-related index allows profiteers and other supporters to pass the occasional problem off as being unrepresentative, or "the small price" necessary in providing this new benefit or recreation or life enhancement to the population at large.

6.6 Addiction from International Perspectives

6.6.1 International Participation

Beginning five centuries ago, the largest addiction epidemics involved international trade. Substances were produced legally in one region (e.g., gin and rum in the Caribbean, opium in India, tobacco and cocaine in the Americas) and transported, often illegally, to countries in another region. Relatively safe and inexpensive international transport facilitated the trade. Large investments in production, transport, and security were secured from banks and profiteers – and sometimes even governments (Westermeyer 1987).

The scenario described above has continued in recent decades. However, several international organizations have united many countries against addiction. Government-supported organizations include the United Nations and its Narcotic

Control Board, the World Health Organization, and numerous other groups concerned with pharmaceutical production, crime, and drug trafficking. Several professional groups have formed international associations to oppose addiction, including physicians, pharmacists, police, and various nonprofit nongovernmental groups (NGOs).

6.6.2 Technology and Addiction

Recent centuries have produced numerous technological advancements that have contributed to addiction epidemics. One general trend has been the isolation of powerful chemicals from raw plant compounds (e.g., morphine and heroin from opium, cocaine from coca leaf). Another trend has been the spread of methods of administration, such as smoking from the Americans to the other continents, hollow needles and syringes for parenteral administration, and recent topical methods. Entire new compounds have emerged from the pharmaceutical industry, i.e., barbiturates, benzodiazepines, volatile inhalants, amphetamines, certain hallucinogens, and new opioid drugs. Rogue pharmacists and biochemists have produced "designer drugs" to produce specified effects. These trends continue.

Rapid means of transportation and easier international travel have reduced the time needed to travel from one place to another. Rapid safe transportation has also reduced the difficulty of marketing substances from one area to another. With increased profits and more secure, stable addiction markets, profiteers from many economic sectors are drawn to subsidizing addiction, either openly or behind various facades.

6.6.3 Addiction as a Transmissible Condition

Many health conditions pose international threats (e.g., HIV, influenza), while others appear more related to local conditions (e.g., heart disease, diabetes, schizophrenia). Although local factors can impede or accelerate addiction, nonetheless addiction can resemble the transmissible disorders. An evolving addiction epidemic in one country threatens its immediate neighbors, and sometimes other countries at a greater distance. For these reasons, international collaboration in studying successes as well as failures in reducing addiction stands to benefit all.

6.7 Discussion

Social-environmental factors weigh heavily in the etiology of addiction. In spite of genetic and psychopathological risk factors that are omnipresent, some communities, states, and cultures have nil-to-minimal rates of addiction (i.e., current prevalence <1 % crude prevalence). In settings with even moderate rates of addiction (i.e., 1–5 % crude prevalence rates), addiction can be the main contributor to crime,

family dysfunction, violence, and incarceration. At high rates (6–12 % crude prevalence rates), addiction may be the main precipitate of hospitalization, suicide, accidents, mental-emotional-behavior disorders, infectious disease, degenerative disease, nutritional disease, and even all-cause mortality (Westermeyer 1982).

Although social-environmental factors can be a major factor in addiction, these factors can also furnish potent prevention, early intervention, effective treatment, and successful rehabilitation for addiction. Therapeutic approaches can occur on the level of the dyad (i.e., the addict and one other person), family, intimate social network, neighborhood or village, local or state government, and various sociocultural entities. All social sectors can lend their powers to these efforts. Charitable organizations and foundations, churches and their clergy, clinics and their staff, community leaders, courts of law, departments of public safety, elected officials, hospitals, licensure bureaus within government, mass media, public health departments, schools and their teachers, universities, and other institutions can be part of the addiction problem or part of the solution to addiction.

Cultural Aspects and Responses to Addiction

7

Robin Room

Contents

Abstract

The use of psychoactive substances and our interpretations of the effects of the substances are affected by culture, defined broadly to include social worlds and subcultures as well as tribal, societal, and linguistic groupings. Prototypical patternings of use include medicinal use, customary regular use, and festival and other intermittent uses (where the psychoactivity is most attended to). A fourth pattern, addictive or dependent use, was a conceptualization arising after the Enlightenment. Cultural norms may both encourage and discourage use and heavy use and may make the use more or less problematic. Cultural factors also shape responses to substance use, including the social handling of problematic situations and persons. Thus, there are characteristic differences between cultures in the institutional and professional location of the handling of substance use problems. In the modern world, there is substantial diffusion of practices and understandings between cultures, and in multicultural societies,

drinking or drug use patterns often serve as markers of cultural distinctions. Despite all the diffusion, there are persisting cultural differences in thinking about, patterns of, and responses to psychoactive substance use.

7.1 Introduction

This chapter is concerned with cultural factors in addiction. In discussing cultural aspects, we are referring to shared beliefs, norms, and patterns of behavior, both about the use of psychoactive substances and about how the use should be interpreted and responded to. "Cultural" is used to mean pertaining to a variety of kinds and levels of collectivity. This can range from a small tribal group, for instance, the traditional inhabitants of Easter Island in the Pacific, to a large multinational aggregation, as in a discussion of how English speakers understand addiction, in contrast, say, to French speakers.

Often in discussing cultural factors, we are dealing with multicultural situations, with a diversity of cultures or subcultures. In such situations, the particular norms and behaviors of a group may serve as markers differentiating between groups, where most people drink alcohol, for instance, abstaining from alcohol may become a mark of difference for Muslims or Mormons (Room 2005).

We also use "cultural" here to refer to "social worlds" (Shibutani 1955; Unruh 1980) within a society in which understandings, norms, and behaviors are shared but in which the cultural boundaries are less marked. For instance, one can speak of a social world of heavy drinkers who know what is the expected behavior at the bar in a tavern in a particular society (Cavan 1966). Are male drinkers expected to buy drinks for each other, or does each always pay just for himself? What signals are being sent between a man and a woman when he buys a drink for her, and she accepts?[1] Among young adults in Oslo, Norway, for instance, "when men buy drinks for women, this may be interpreted as a negotiation for further intimacy" (Træen and Hovland 1998). Answers to such questions will be obvious to those within the social world, but may not be to outsiders.

7.2 Cultural Expectations About and Definitions of Psychoactive Substances and Their Effects

By definition, psychoactive substances change our mental state. But how we interpret that change, and how we behave under the influence, is strongly influenced by "set and setting" (Zinberg 1986) – including our expectancies about the effects, which in turn are influenced by cultural factors as well as previous experience. Although the psychoactive effect of tobacco may not register in the consciousness

[1]See "Buying and accepting drinks" thread on http://forums.plentyoffish.com/datingPosts8464582.aspx (accessed 16 June, 2013).

of a habituated cigarette smoker, in other circumstances, the effect of tobacco use may be so strong that the user is rendered unconscious, as early Spanish observers reported in describing tobacco use among native South Americans (Robicsek 1978). How those under the influence of a given dose of alcohol behave differs widely between cultures, as MacAndrew and Edgerton (1969) argued in their landmark work on *Drunken Comportment*. Whether or not someone taking LSD experienced a "bad trip" in the USA in the 1960s and 1970s, Bunce (1979) argued, was strongly influenced not only by subcultural expectations but also by the extent of sociopolitical controversy at that particular historical moment concerning the drug.

Three social patternings of psychoactive drug use can be distinguished as prototypical: medicinal use, customary regular use, and intermittent use. In many traditional societies, some drugs or formulations have been confined to medicinal use, that is, use under the supervision of a healer to alleviate mental or physical illness or distress. For several centuries after the technique for distilling alcoholic spirits had diffused from the Arab world to Europe, for instance, spirits-based drinks were regarded primarily as medicines (Wasson 1984). This way of framing drug use has been routinized and made subject to official control in the modern state through a prescription system, with physicians writing the prescriptions and pharmacists filling them. Drugs included in the prescription system usually are forbidden for nonmedicinal use (Babor et al. 2010), although the modern international drug control system has been fighting a losing battle to enforce this rule.

When a drug becomes a regular accompaniment of everyday life, its psychoactivity often is muted and even unnoticed, as is often the case for a habitual cigarette smoker. Similarly, in southern European wine cultures, wine is often differentiated from intoxicating "alcohol"; wine drinkers are expected to maintain their original comportment after drinking. This may be called a pattern of *banalized use*: A potentially powerful psychoactive agent is domesticated into a mundane article of daily life that is available relatively freely in the consumer market.

Intermittent use – for instance, on sacred occasions, at festivals, or only on weekends – minimizes the buildup of tolerance to a drug. It is in the context of such patterns that the greatest attention is likely to be paid to a drug's psychoactive properties. The drug may be understood by both the user and others as having taken control of the user's behavior and thus to explain otherwise unexpected behavior, whether bad or good (Room 2001). As in Robert Louis Stevenson's fable of Jekyll and Hyde, normal self-control is expected to return when the effects of the drug wear off. In light of the power this framing attributes to the substance, access to it may be limited – in traditional societies by sumptuary rules keyed to social differentiations and in industrial societies by other forms of market restriction, including outright prohibition.

In modern societies, a fourth pattern of use is commonly recognized: addicted or dependent use that is marked by regular use, often of large doses. Where such use for the particular substance is not defined in the society as banalized, addiction tends to be defined as an individual failing rather than a social pattern.

Conceptualizing repeated heavy use in terms of addiction means that the categorization becomes an explanation – an explanation of why the pattern of use continues, despite problems resulting from the use for the individual and often for others. The concept thus focuses not on the pattern of use in itself, but rather on an apparent inability to control or refrain from use despite adverse consequences.

The addiction concept became established for alcohol in general understandings of European societies in the period after the Enlightenment. Particularly as temperance movements sprang up in response to the waves of very heavy alcohol consumption that accompanied the Industrial Revolution, the addiction idea came into common use as an explanation of why backsliding was common among temperance members who had pledged to give up drinking (Levine 1978; Room 2003). In the late nineteenth century, the concept was extended by doctors to cover other psychoactive substances, and more recently popular and professional discourse has commonly applied it also to other behaviors (Marks 1990; Saïet 2011), though not without dispute (Jaffe 1990). Though the concept has diffused into many cultures, there are substantial differences in cultural understandings of what it characterizes and implies (Room 2006).

7.3 Norms Concerning Use and Related Behavior

The use of psychoactive substances in any society or cultural group is structured by norms concerning use and behavior while and after using. Laws and regulations on these matters, such as laws forbidding sales to or use by those under a certain age, or prohibiting driving after use, or regulations such as a church denomination's rubric specifying how leftover consecrated wine from a communion service it is to be handled ("reverently" consumed; Anonymous 1662), may be described as formal norms. At least as important in structuring use are informal norms concerning use, which are often highly differentiated according to the social context (Greenfield and Room 1997) and to the user's demographic and social position. Bruun's division between controls at the phases of use, of pattern, and of consequences (Bruun 1971b) – whether use at all is disallowed, or there are controls on the pattern of use, or controls aiming to insulate the use from adverse consequences – describes the main strategies of both formal and informal norms in limiting the damage from substance use.

It is important to note that norms may encourage use – and indeed heavy use – as well as discourage it and may make the use riskier or more problematic. Taking alcohol as an example, heavy drinking or drug use is not always a matter of individual choice, but in particular social contexts may be a strong expectation. For example, in cultures where buying rounds is customary, once the round has been established, a man drinking with a group of friends will face a strong expectation to stay and drink as many drinks as there are men in the group. In a Mongolian cultural group in China, competitive drinking is a norm: "a refusal to drink signifies a refusal to engage the other on equal and respectful terms. Drinking partners take turns challenging each other to drain the cup, and the cups

are inverted immediately afterward to prove the liquor is gone" (Williams 1998). Among young adult Italians, as also elsewhere in Europe, drinking games, enforced as a group ritual, serve the function of "becoming drunk quickly so as to amplify the effects of drinking: less shyness and disinhibition" (Beccaria and Guidoni 2002). Cultural expectations may thus facilitate heavy drinking and even enforce it, so that in some circumstances addiction or dependence might better be described as located at collective levels rather than in the individual's mind or body (Room 1973). This idea is carried by the French term *alcoolisation*, used concerning a society such as France when alcohol consumption was at its highest there in the 1950s (Jellinek 1954).

7.4 Cultural Factors in Responses to Substance Use

Intoxication and habitual use of psychoactive substances can be problematic in many ways for those around the user, and societies and cultures respond in many ways in efforts to limit or prevent the problems. Informal responses by those around the drinker, smoker, or drug user are very common (e.g., Hemström 2002; Hradilova Selin et al. 2009) – at levels ranging from a spouse's raised eyebrow to strenuous retribution.

Societies also respond to alcohol and drug problems at more formal levels. In the modern world, there is considerable uniformity across societies in the general roster of agencies and professions with responsibility for the social handling of problematic situations and persons. In most societies, there are hospitals and other health services and medical professionals, courts and police and judges, welfare institutions and social workers, and churches and other faith institutions and clergy. But none of these sets of agencies and professions have clear and unchanging custody of alcohol and drug problems. Typically, all of them handle some part of drug and alcohol problems, but drug and alcohol problems are not central to the jurisdiction of any one of them. The result is a diversity of competing models of how alcohol and drug problems should be handled (Bruun 1971a). As an eminent addiction doctor, Norman Kerr, put it already in the late nineteenth century: "in drunkenness of all degrees of every variety, the Church sees only the sin; the World the vice; the State the crime. On the other hand the medical profession uncovers a state of disease" (Kerr 1888).

There are characteristic cultural differences in the location of the handling of alcohol and drug problems. For alcohol problems, for instance, the welfare system has been the traditional central location in several Nordic countries; liver clinics within the medical system have played a major role in France and Italy; psychiatry has had a principal role in Switzerland and Austria (Baumohl and Room 1987; Klingemann and Hunt 1998; Klingemann et al. 1992). But it is also true that, in a given society, the handling of alcohol and drug problems has often changed over time – particularly because these are "wicked problems" (Rittel and Webber 1973) where whatever solution is in effect will seem inadequate. As Bruun (1971a) remarked about the Finnish history of the social handling of alcohol problems,

"the consistent frustrations concerning the relative lack of success in fighting alcoholism made [Finland] move compulsively from one model [of response] to another."

The responses to alcohol and drug problems, both informal and formal, are thus just as subject to cultural definitions and norms as are the substance use and related behaviors. The responses are influenced both by the cultural definitions and norms concerning the substance use and by cultural beliefs and practices concerning appropriate responses. For the formal responses, general cultural and societal understandings and practices concerning the social handling of social and health problems also come into play.

7.5 Intercultural Influences and Diffusion

No man is an island, and no cultural group in the modern world is completely on its own. A particular solution to a set of problems worked out in the cultural conditions of one society may travel far. Thus there is much about the ideas and organization of Alcoholics Anonymous that reflects cultural understandings and practices in a particular society, the United States (Mäkelä et al. 1996; Room 1993). But AA has diffused widely across the world, into cultures with considerable differences from US society. Even so, it is clear that the patterns of diffusion of AA show some regularities in terms of which societies it has flourished in, and these regularities tell us something both about core characteristics of AA and about patterns of culture (Mäkelä 1991). And to some extent, AA practices have been adapted to the local culture (Eisenbach-Stangl and Rosenqvist 1998). Furthermore, even where AA was seen as culturally alien in some way, the news of its existence stimulated adaptations seen as more culturally congenial – and often the outcome has been AA and the adaptation coexisting side by side (Room 1998).

We have already mentioned above the tendency of cultural groups in multicultural societies to define themselves in distinction from each other, with drinking or drug use practices fairly often used as markers of the distinctions. On the other hand, it is clear that there is also some assimilation: Immigrant groups take on practices from the receiving society, often forming a new cultural bricolage (Room 2005). Influences and diffusion are also common between societies and cultures. Such influences are carried by four major forces: mass media, producers and other economic actors, intergovernmental bodies and agreements, and the professions. News reports, television and film entertainment, and now also Internet channels convey information and images between cultural groups, perhaps particularly between youth cultures in different societies. In an increasingly globalized world with diminishing trade barriers, global corporations and other economic actors (and their equivalents for illicit drug markets) actively and tirelessly try out promotion methods and materials which have worked elsewhere in new cultural settings. Dissemination and influence also flow through the international drug and tobacco treaties and the agencies which implement them, as well as increasingly through other agencies such as international nongovernmental organizations in a

cross-national policy community. And doctors, police, and other professionals, through professional societies, journals, newsletters, and meetings, diffuse ideas, evidence, and practices internationally.

Despite all the dissemination, cultural differences persist. In terms of cultural differentiations in psychoactive substance use and problems, and in the societal and cultural responses, it is possible to point to trends both of change and of stasis, both of convergence and of divergence, depending on where one looks. In thinking and acting across cultures concerning alcohol and other drugs, it is wise to take into account that even matters that are taken for granted in a given society or culture, or that are assumed to be universally valid in a profession's thinking, are often understood differently in different cultural traditions.

Prevention Strategies and Basics

Contents

Abstract

Prevention has the potential to be effective in changing substance use and related behaviors such as delinquency, violence, and sexual behavior. Interventions that achieve this do not solely inform people about the dangers of drugs but also focus on the key determinants of successful socialization, now confirmed by neuropsychological research: social norms and control, executive and social skills, as well as impulse control. Thus, universal prevention addresses the population at large and targets the development of skills and values, norm perception, and interaction with peers and social life; selective prevention addresses the vulnerable groups where substance use is often concentrated and focuses on improving their opportunities in difficult living and social conditions;

and indicated prevention addresses vulnerable individuals and helps them to deal and cope with the individual personality traits that make them more vulnerable to escalating drug use. While these prevention types predominantly use persuasion, prevention can complementarily and effectively change human behavior by modifying its social, physical, and economic context. Environmental prevention uses these means to subtly alter social cues and norms and their perception. Effective examples range from intervening at society level through market regulations of alcohol and tobacco, changing the physical environment of party settings, to more rule setting and monitoring within families. The challenge for drug prevention lies therefore in helping people to adjust their behavior, capacities, and well-being in fields of multiple influences – such as social norms, interaction with peers, living conditions, and their own personality traits – in order to reduce risk behaviors related to substances.

8.1 Introduction

Drug prevention is traditionally conceived of as interventions or policies to avoid or delay the initiation into substance use by adolescents. It is a key element of national and international drug policies. Prevention is thought to act on the demand reduction side of drug interventions, helping people to avoid the use (or problem use) of psychoactive substances and their negative consequences. This understanding of prevention is complementary to treatment (which targets recovery and cure) and harm reduction (which helps people avoid the secondary negative effects of the use, or problem use, of addictive substances).

8.1.1 Neuroscience and Prevention

The most obvious contribution of neuroscience to prevention is that it has explained why and how the developing brains of adolescents are particularly vulnerable to the noxious effects of alcohol, tobacco, and illicit drugs – the greatest neuronal reshaping processes of the human life cycle take place during adolescence. Psychoactive substances used in this period therefore have longer lasting and more deleterious consequences in the neurobiological substrates of human development. Prevention work can use findings from neuroscience to tailor interventions to the peculiarities in the neuropsychological functioning of adolescents. However, research (outlined below) has found that the usual approach of information provision and simple warning strategies has little effect on how adolescents take decisions and deal with risk. Professionals and policymakers have only just started to use these new insights.

8.1.1.1 Personality Traits and the Common Liability Model

Another, less publicized, contribution of neuroscience to prevention has been to (re) introduce concepts such as personality traits and temperament as risk factors, giving a longer-term perspective to prevention, which starts in early childhood. Many

prevention professionals still see substance use as the main risk factor for substance use disorders and addiction and therefore conclude either that substance use must be prevented altogether or that it must be detected early and discouraged. While early use is a necessary step, other variables may be of crucial importance in the transition from use to substance use disorder. In fact, the same variables that predict initial acute drug effects and early use may significantly contribute to continued use, escalation, and dependence (De Wit and Phillips 2012). Traditional prevention work focuses exclusively on substance use and is based on a stage model where the use of legal substances precedes and anticipates the use of illicit drugs. More recent research has introduced an alternative view, the common liability model, which suggests that early-manifesting personality traits such as neurobehavioral (i.e., cognitive, affective, and behavioral) disinhibition predict both early initiation of substance use and rapid escalation into problem use. Other problem behaviors can also have this effect, especially if both parents have a substance use disorder (SUD). Longitudinal, prospective studies with Finnish twins found that the liability to initiate tobacco smoking predicts illicit drug use and suggested that shared genetic and environmental influences may be related to the use of tobacco and illicit drugs (Huizink et al. 2010). Early externalizing behavior also suggests significant and shared underlying genetic and environmental influences that may lead to later substance use (Korhonen et al. 2012).

Other personality traits, such as high levels of pleasure seeking and low levels of shyness and avoidance, have shown in prospective studies to increase the risk of progressing from smoking to several measures of cannabis use (Creemers et al. 2009). A longitudinal study (Malmberg et al. 2012) showed that hopelessness and sensation seeking were predictive for using alcohol and tobacco. The latter was also correlated with marijuana use.

In a recent paper, Sloboda et al. (2012) provide an exhaustive revision of the risk factor models relevant for prevention, which include many developmental factors in early childhood that interact with environmental factors in family and school in later childhood and adolescence.

Instead of targeting drug users generally, these findings point to a need for more sophisticated prevention interventions that specifically target individual vulnerability traits that are not a priori substance use related. This is the premise for indicated prevention.

8.1.1.2 Neuroscience and Social Norms

Recent findings in the field of neuropsychology (Steinberg 2008) have shed light on why information provision does not deter young people from drug use and other problem behaviors. Findings show that their behavior is determined more by social context than by individual choice.

Judgement of risk seems to be a crucial element at this age. Galvan et al. (2006) found that the activity of the nucleus accumbens within the limbic system, responsible for drive and impulsivity, begins to increase in adolescence, while the prefrontal cortex, responsible for behavioral control, is not yet fully developed at this age. This imbalance alone does not necessarily result in impaired judgement

of risk. However, an additional developmental process, the increase of oxytocin receptors in the limbic system during adolescence, explains why adolescents – compared with children and adults – respond more intensely to emotional and social stimuli and have increased awareness of others' opinions (Steinberg 2008). There is an important overlap between neural circuits responsible for social information processing and those for reward, so that reward seeking is increased in the presence of peers when the brain's socio-emotional system is stimulated.

The interplay of these processes suggests why adolescents more often take risks (especially substance use and reckless driving) in peer group environments. When adolescents are alone or not emotionally excited, the cognitive control of the prefrontal cortex is strong enough to control or regulate impulsive and risky behavior. Under these conditions, adolescents perform risk assessment of situations and behaviors similar to adults. The more developed limbic regions only manage to override the less developed behavioral control of the prefrontal cortex when young people are with peers or emotionally aroused, resulting in poor and impulsive decisions. High sensation seekers in particular seem to learn to delay gratification by engaging in risky behavior such as substance use, which might provide them with experiences that lead to greater patience in anticipation of long-term rewards (Romer et al. 2010).

Therefore, it seems to be normative, biologically driven, and to a certain degree inevitable and functional that adolescents are prone to risk-taking during adolescence. Mature judgement needs time to develop, and therefore cognitive–informative techniques seem unlikely to make adolescents wiser, less impulsive, or less shortsighted.

The considerations above have manifold implications for prevention.

(a) They help to explain why information provision has little impact on behavior, especially in this age group.
(b) They offer explanations for the harmful effects of mass media campaigns that increase normative beliefs, giving the implicit impression that most or many people do engage in a given problem behavior.
(c) They help to explain why drug legislation, which prosecutes individuals, often fails to dissuade adolescents from continuing to use drugs (Scarscelli et al. 2012). School sanctions, on the other hand, may have important long-run benefits (Waddell 2010) as they have high social visibility. Informal social control and social sanctions (from family and peers) may have more of an impact than the certainty and severity of formal sanctions (Paternoster 1987).
(d) They provide the theoretical underpinning on why adolescents – who are unaffected by possible legal sanctions – are heavily influenced by social norms, peer environments, and social control. In fact, "in places where informal social controls have been weakened, young people tend to see delinquent behaviour as a sign of strength, incarceration as a rite of passage, and law enforcement as illegitimate" (Berman 2012). Reinforcing informal social controls and changing the perception of normality are core objectives of environmental prevention.

8.1.2 Logic Frame

Section 8.1.1 described a number of factors influencing the risk of developing problematic patterns of substance use. The following section aims to show that the challenge of prevention is more than just avoiding or delaying substance use. Instead, it should help young people adjust their behavior, capacities, and well-being in fields such as living conditions, social norms, interaction with peers, social status and opportunities, and their own personality traits, drawing from the findings of evidence-based interventions in all these fields. Prevention could therefore be defined as evidence-based socialization where the primary focus is individual decision making about socially appropriate behaviors. Its aim is not solely to prevent substance use or to delay initiation but also to reduce intensification of use or prevent escalation into problem use. Socialization, in this context, means to transfer culturally acceptable attitudes, norms, beliefs, and behaviors to young people and to respond to cues for risky behaviors in an appropriate way by helping them to develop adequate impulse control.

Socialization takes place under the influence of family, schools, and society. The concept of environmental prevention has therefore been added to the three classical prevention strategies defined by the Institute of Medicine (Mrazek and Haggerty 1994) based on addressees' overall level of vulnerability, which was found more practical for the substance use prevention field than the medical paradigm of primary, secondary, and tertiary prevention. While the latter works fine for the natural course of, for example, cancer and infectious diseases, it seems less adequate to describe human behavior.

Mass media campaigns are the most instinctive form of prevention, and we will review them at the very start of our overview. These campaigns assume that informing and warning people about the dangers and consequences of a specific behavior is enough to prevent them behaving in a particular way. This is a problematic assumption, as we have seen above. Adolescent behavior seems to be little influenced by purely cognitive processes, and a number of different factors and processes intervene between the perception of factual information and adolescents' behavior.

The four main prevention strategies described below address the most relevant spheres of behavior influence: social norms and occasionally inequality are targeted by environmental strategies, interaction with peers and social life by universal prevention, social conditions and exclusion by selective prevention, and personality traits by indicated prevention. This simplified classification provides us with an overview of the different preventive approaches taken. Prevention can also be segmented by the level of environment on which it is acting. Bronfenbrenner's (1979) ecological systems theory conceptualizes as follows: macro level interventions, referring to those at societal and state level (e.g., legislation and taxation); meso level, which are at the level of communities, schools, and other setting; and microlevel, defined as proximal environments such as the family or peer groups.

Each part in Sect. 2 refers to the available evidence and describes trends and examples. As the majority of prevention activities focus in practice on substance use and problem behavior in general, they do not differentiate between alcohol, tobacco, and illicit drugs.

8.1.3 Assessing the Effectiveness of Prevention

While there has been a long-standing tradition in the field of prevention of welcoming any type of preventive measures – taking the good will for good results – evidence is now playing a crucial role in prevention work. However, the very nature of the intervention and target behavior makes research even more challenging than in the fields of treatment or harm reduction. Most prevention strategies address their target group at a very young age. This implies that there will be a long period of time between intervention and assessment of the outcome, which is a challenge to methodology (many influences will have to be taken into account), sample size (which inevitably shrinks over time), and research funding and organization. In all fields of research such long-term follow-ups are extremely rare. Prevention also tends to be generic, while outcome behaviors with respect to drug use and drug-related problems are specific. This again makes it more difficult for research to prove a logical link between intervention and envisaged outcomes. The conclusion drawn from this long list of difficulties and problems is not to discredit prevention interventions because they are difficult to evaluate but instead that existing findings should be critically evaluated to try to further improve the available evidence.

8.2 Prevention Strategies: Definitions and Effects

8.2.1 Mass Media Campaigns

A large proportion of the general public and substantial numbers of policymakers have, for some time, seen drug prevention as purely informing or warning young people about the effects or dangers of drugs. Quite logically then, mass media campaigns were often the first choice of prevention intervention.

Mass media campaigns can reach large and heterogeneous audiences and have shown to be beneficial in promoting some health behaviors like healthier nutrition, physical activity, and participation in screening for breast and cervical cancer (Wakefield et al. 2010). However, they seem to be much less successful in discouraging problem behaviors. While some positive effects on tobacco smoking have been found, there is actually no evidence that simply informing adolescents about the effect of drugs has a beneficial impact on their illicit drug use, as a recent Cochrane Review (Ferri et al. 2013) confirms. Since mass media campaigns seem to be more effective in tackling adolescent use of legal drugs, and when they target parents instead of young people (Crano 2010), perceptions of normality seem to play an essential role in their success and failure.

A worrisome case study for this is the evaluation of the National Youth Anti-Drug Media Campaign (1998–2004) in the USA (Hornik et al. 2008). It found – besides zero effects overall – that greater exposure to the campaign was associated with increasing intention to use cannabis (and even actual use) in some subgroups that previously had little interest in the drug. The analysis found evidence that these effects were due to an increase in the perceived popularity and prevalence of marijuana use through the campaign. Also, in the evaluation of Scotland's Know the Score cocaine campaign, Binnie et al. (2006) found that 11 % of those exposed to it claimed that they were more likely to use cocaine after the campaign compared to before. There is another reason for being cautious with warning campaigns that, for example, describe the negative outcomes of first using marijuana. If non-using adolescents realize that the harms of marijuana use are not as grave as they had been led to expect, their intention to use it might intensify considerably (Skenderian et al. 2008).

It is an important ethical concern that mass media campaigns may have iatrogenic effects – by increasing normative beliefs, resulting in higher intentions to use. This is even more problematic in this case, as the target population has typically not requested this (potentially harmful) kind of social intervention, and the organization funding and/or running the campaign has taken the initiative.

Against this background, the lack of adequate evaluations of media campaigns is even less acceptable – in Europe, only the Netherlands and Scotland/the UK have assessed effects of these campaigns on behavior or intentions, while the large majority of reported campaigns have not been evaluated at all. A few evaluations in Europe (Bulgaria, Denmark, France, Netherlands, Sweden, and the UK) have merely assessed how people perceive the campaign and its impact on their knowledge but were not able to assess if people changed their attitude or behaviors in the intended direction.

8.2.2 Environmental Prevention

Environmental prevention strategies aim to alter the immediate cultural, social, physical, and economic environments in which people make their choices about drug use. These strategies typically focus on social norms and climate (e.g., in schools) instead of persuasion and tend to address behavioral problems, for example, violence. This approach takes into account that individuals who might become substance users are influenced by a complex set of factors in their environment, including social norms, defining what is considered normal, expected, or accepted in their reference group; the rules or regulations and taxes of their state; the publicity messages to which they are exposed; and the availability of alcohol, tobacco, and illicit drugs. Environmental prevention strategies often entail changes at the macro level (legislation or society), such as market control using taxes and publicity bans or coercive measures including age controls and tobacco bans, which are effective but often resisted in some sectors of the population. These strategies alter the system of environmental – often unconscious – cues that influence

behavior, such as images and associations or the observed behavior of others. Since certain industries try to use these cues in their own interest, the term "industrial epidemics" has been coined for obesity, tobacco, and alcohol use (Jahiel and Babor 2007). Public regulation and market intervention are seen as the only evidence-based mechanisms to prevent the harm caused by commodity industries (Moodie et al. 2013). But efforts to create protective and positive school and family climates also belong to environmental prevention. Their modus operandi is not persuasion but positive "scaffolding" in the sense of providing opportunities, stimuli, and encouragement for change in confined contexts.

8.2.2.1 Environmental Influences in Schools

There is evidence that the school climate (e.g., the "alienation" of pupils from school) and the nature of the school environment substantially influence substance use and violence in school. Students' perceptions of whether they are treated fairly, school safety, and teacher support are also related to substance use. Interventions that increase student participation, improve relationships, and promote a positive school ethos (involvement, engagement, and positive teacher–pupil relations) therefore appear to reduce substance use. Programs based on this concept have shown to be transferable between countries (Markham et al. 2012).

Other strategies at the meso level include municipal strategies to reduce public nuisance, drug "policies" in schools, targeted policing, conditional venue and event licensing, fines and venue design guidelines, and community action strategies such as neighborhood watch schemes.

8.2.2.2 Environmental Influences on Nightlife

The known environmental determinants of alcohol abuse and violence also apply to nightlife settings: dirty conditions, poor ventilation, high levels of noise and music, low comfort, high density of patrons, predominant patronage by males, high numbers of intoxicated patrons, and high boredom (Miller et al. 2009). A European review (Hughes et al. 2011) found that important environmental contributions to alcohol-related problems include a permissive environment, discounted drinks promotions, poor cleanliness, crowding, loud music, and poor staff practice. Changing the environment also offers club owners and managers an approach that is less disruptive, which may motivate them to try it. Environmental approaches to reducing drug use and other risky behaviors may be more profitable for a business, improve its image, reduce the risk of city and police interference, and limit problems in its neighborhood (Miller et al. 2009).

Two European reviews of prevention interventions in nightlife settings (Bolier et al. 2011; Calafat et al. 2009) conclude that they can effectively reduce high-risk alcohol consumption, alcohol-related injury, violent crimes, access to alcohol by underage youth, and provision of alcohol to intoxicated people. However, some popular types of intervention (such as providing information or pill testing) were not considered evidence based. Interventions such as "responsible beverage services" or "designated driver programs," often backed by the industry, are less effective, especially if they are not enforced. The most effective strategies were

those that combined training, cooperation, and enforcement with "classical" environmental measures such as taxation, reduced blood alcohol concentration (BAC) limits for driving, and reinforced minimum legal purchasing age.

8.2.2.3 Environmental Influences Within Families

Substance use is influenced by social modelling by a person or group that is perceived as an authority or inspiration. Later in this chapter we will describe family-based programs that aim to improve the behavior of children and young people through better parenting. In this section we address some aspects of families that are not necessarily related to direct parent–child interaction but instead form part of environmental action on youth that might also include how young people select their social environment.

One aspect is the amount of pocket money, which has been found to be associated with increased prevalence of risky alcohol use (Bellis et al. 2007) and higher odds of smoking, getting drunk, using cannabis, and using ecstasy, even after controlling for socioeconomic status, gender, delinquency, parental supervision, and having a risk-taking personality (McCrystal et al. 2007). The findings are inconclusive on the influence of families' socioeconomic situation. In one French study (Legleye et al. 2012), adolescents from affluent families were more prone to experimentation with cannabis and to use it at low levels but had lower levels of frequent, heavy, or problematic use than those from other socioeconomic status categories. In a study in the USA, however, higher parental income was associated with higher rates of binge drinking and marijuana use (Humensky 2010).

How parents tell their own substance use history may also play a role. A recent study found an association between parents admitting their own past drug use in detail and teenagers having a more positive attitude to substances (Kam and Middleton 2013).

Parental ingenuousness about their offspring's substance use can have a protective function in the sense of a Pygmalion effect. In a longitudinal study (Lamb, C., & Crano, W.D. under revision#), adolescent users whose parents indicated that their children used marijuana at baseline were more than twice as likely to continue compared to children of parents who assumed that their children had not initiated marijuana use, even if this assumption might have been wrong. The assumed effect of this "ingenuous" prophecy resulted in a 39 % decline among the original sample of users while the "realist" prophecy resulted in a 4.3 % increase in use among nonusers at baseline. When parents had (maybe wrongly) assumed their children's marijuana use at baseline, these young people were 3.3 times more likely to begin using it compared to the other group. These findings indicate that parental trust – even if not based on facts – might have a positive effect on drug use behavior. A better assessment of the "real" situation, such as through testing, might destroy this Pygmalion effect and cause the situation to deteriorate. Obviously, monitoring and family rules play major roles in creating protective environments, but since such elements imply an active role by parents, we discuss those in the section dedicated to family-based prevention.

8.2.2.4 Environment, Social Norms, and Substance Use

Even if environmental prevention targets predominantly legal drugs and antisocial behavior, its approaches are important for the whole prevention field because early, widespread, and accepted use of alcohol and tobacco is associated with illicit drug use in many countries. Alcohol has a key role in the initiation of illicit drug use, especially among adolescents: European Monitoring Centre for Drugs and Drug Addiction (EMCDDA) analyses of general population surveys in nine European countries (see Further Reading) showed an increased prevalence of amphetamine and ecstasy use among frequent or heavy users of alcohol. European School Survey Project on Alcohol and Other Drugs (ESPAD) data for 22 countries showed that 86 % of the 15- to 16-year-old students who had used ecstasy during the last month had also consumed five or more alcoholic drinks on one occasion. Similar relationships were found for alcohol with cannabis and cocaine.

In prospective longitudinal studies, tobacco smoking has been shown to mediate the initiation into cannabis use (Mayet et al. 2010; Vega and Gil 2005) and predicts an earlier initiation (Agrawal et al. 2013). It seems that the social and physical contexts of consumption are influencing the level of alcohol, tobacco, and illicit drug use in the same way. Environmental prevention focuses on these contexts.

The effectiveness of environmental prevention is well established in the alcohol and tobacco fields. At the macro level, taxation and regulations have been found to be effective, reducing alcohol use and related problems (Wagenaar et al. 2010). Increases in the minimum price of alcoholic beverages in Saskatchewan, Canada, have substantially reduced alcohol consumption (Stockwell et al. 2012). At the meso level, a study in Glasgow, Scotland (Young et al. 2013), on outlet density and proximity found that 15-year-old adolescents living within 200 m of an alcohol-selling outlet were more likely to drink frequently than were adolescents living in areas with less accessible alcohol-selling outlets. This suggests that certain alcohol behaviors (e.g., binge drinking) may be linked to the characteristics of alcohol supply in the area. Similarly, a study with the same age group in Switzerland (Kuntsche and Kuendig 2005) suggests that alcohol outlet density and related perception of adolescent drinking in public are positively correlated with individual alcohol use among adolescents. In the USA, a study (Plunk et al. 2013) of more than 39,000 subjects found that a legal age of below 21 years for buying alcohol was associated with an increased risk of binge drinking later in life. Additionally, drinkers who lived in states with lower minimum drinking ages were more likely to drink heavily, while they were not more likely to consume more alcohol overall, or to drink more frequently. Binge drinking was most pronounced among men who did not attend college. Among college students, however, previous studies' findings were inconclusive about the effect of the minimum drinking age (Wagenaar and Toomey 2002).

While alcohol and tobacco policies and their effectiveness are discussed in other chapters in this book (▶ Chap. 9, "Regional and Cultural Aspects of Prevention"), the following section focuses on the common effects and trends across substances and behaviors. Starting with the observation that prevalence rates for cannabis smoking were found to fall among European adolescents after more restrictive

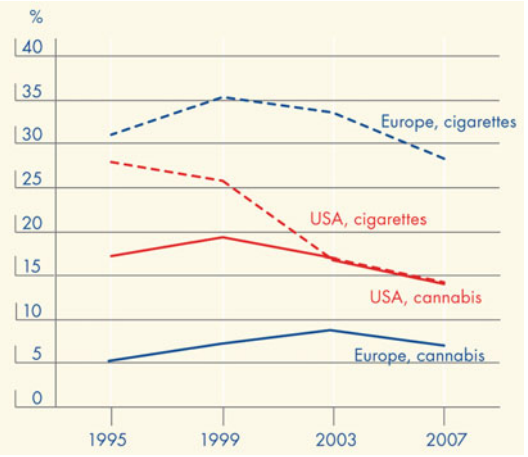

Fig. 8.1 Trends in last month prevalence of cannabis use and cigarette smoking among 15- to 16-year-old school students in 17 European countries and the USA

policies on tobacco smoking were introduced, one might assume some link between trends in the use of licit and illicit substances (Fig. 8.1).

Besides the perceived availability of substances, normative environmental aspects such as cultural values, descriptive norms, and the social acceptance of use seem to influence initiation into problem behavior and substance use (for more details on this, see ▶ Chap. 9, "Regional and Cultural Aspects of Prevention" in this book). Kuntsche and Jordan (2006) confirmed that close contact with substance-using peers is strongly related to individual substance use. Students who saw others attending school while intoxicated with cannabis, or taking cannabis on the school premises, used more cannabis themselves and had more cannabis-using peers. Similar relations were not found for alcohol. The authors suggest establishing an overarching environment of disapproval as an effective means of preventing cannabis use by adolescents.

Normative beliefs are important factors in the success or failure of interventions, and prevention work needs to address them (McAlaney et al. 2011). While several studies confirm that behavioral change is mediated by descriptive norms, the social norms approach has to be used with caution as social groups may also develop minority norms that deliberately deviate from the healthy descriptive norm that is being promoted. According to optimal distinctiveness theory, people adhere to social norms of highly valued groups that can simultaneously satisfy their needs to belong and to be different. For instance, messages that portray nonusers as a large and undifferentiated majority may not be as successful as messages that emphasize the uniqueness of nonusers (Comello 2011).

8.2.2.5 The Prevention Paradox

It is unlikely that environmental prevention will have much of an impact on the behavior of highly vulnerable individuals. However, the prevention paradox postulates that the majority of alcohol-related problems in a population are associated with low to moderate drinkers simply because they are much more numerous than heavy drinkers. A study in 23 European countries (Danielsson et al. 2012)

confirmed this prevention paradox for adolescent boys and girls for measures of annual consumption and heavy episodic drinking; similar results were found in Brazil. There is also some evidence for the validity of this phenomenon for other substances. Stockwell et al. (2004) confirmed it for regular tobacco, alcohol, and cannabis use among 15- to 16-year-olds. Still, there are limitations to this concept. A minority of people with frequent heavy episodic drinking accounted for a large proportion of all problems in one study (Danielsson et al. 2012), and Stockwell et al. (2004) found that most illicit drug use occurred in the high-risk group, 15 % of the sample.

The practical consequence of the prevention paradox is that all available approaches should be used: environmental and universal prevention strategies should aim to reduce initiation and overall levels of substance use, and targeted strategies should address particularly vulnerable subgroups and individuals, addressing harm related to early-age drug use or frequent cannabis use.

In summary, there is evidence for the beneficial effects of environmental prevention at the macro level (the state), at the meso level (recreational settings and schools), and above all at the microlevel (in families); and there are beneficial effects beyond substance use alone. More elements of environmental prevention should therefore be used to complement and support persuasive prevention strategies. It should be noted, however, that vulnerable subgroups and individuals also need targeted interventions, which will be described in the following sections.

The concepts of universal, selective, and indicated prevention are used to classify different preventive approaches in the following sections, based on differences in the vulnerability (and risk) of the target group. For universal prevention, all members of the population are assumed to share the same general risk for substance use problems, although the risk may vary greatly between individuals. Selective prevention applies social and demographic indicators that roughly indicate increased levels of vulnerability among some groups such as marginalized ethnic minorities, youth in deprived neighborhoods, young (drug law) offenders, vulnerable families, or some settings (such as clubbing environments). While these, often readily available, institutional or demographic indicators can help to identify groups where problem drug use is more likely to be concentrated, they cannot tell us anything about the vulnerability of any individual in such a group. In indicated prevention, however, vulnerable individuals are screened and needs have to be defined on the basis of "properly diagnosed" risk conditions, such as attention deficit disorder or conduct disorder.

8.2.3 Universal Prevention: Intervening with Populations

Universal prevention addresses the population at large, regardless of differing vulnerabilities of individuals or subgroups. It aims to reduce substance-related risk behavior by providing necessary competences to avoid or delay initiation into substance use, acting like a "behavioral vaccine." In Europe at least, universal

prevention predominantly takes place in schools, as they facilitate access to the largest target populations.

The overall effectiveness of school-based (universal) prevention has been repeatedly questioned, but there is abundant evidence from reviews (Bühler and Kröger 2008; Faggiano et al. 2008; Foxcroft and Tsertsvadze 2011a; Midford 2010) that programs based on the social influence approach have consistently been more effective than programs based on any other approach. The approach consists of components such as social skills training (listening, making compliments, empathy, and communication), strengthening personal skills (goal setting, coping, identifying feelings), and correcting normative beliefs (i.e., on the level of acceptance and use of substances among peers). It has to be delivered in an interactive way that engages young people. It is not yet fully understood which elements within social influence programs contribute most to behavior change. While the life skills (i.e., social, personal, and refusal skills) components are well known and have been well researched (Bühler 2008), the role of social norms (see Sect. 8.2.2) in the success of an intervention is only recently gaining the attention of researchers. Its premise is that overestimating the substance consumption among peers may lead young people to initiate or intensify consumption beyond their original intention. Such effects have been found in a range of other health and non-health behaviors. Evidence from trials mostly carried out in the USA but also in Australia and Europe suggests that the social norms approach is a new avenue for reducing substance-use-related harm (McAlaney et al. 2011). As part of the first European drug prevention trial, European Union Drug Abuse Prevention (EU-Dap) (Faggiano et al. 2010), a mediator analysis found that the level of normative beliefs (but not the level of social and personal skills) mediated the program's effect on cannabis use.

Martinus et al. (2012) tested the transferability of the "social norms" approach to a UK (Scottish) secondary school setting and found similar substantial misperceptions (i.e., overestimation) among secondary school pupils of their peers' drinking behavior when with friends.

Even if the effects of school-based prevention at the intervention level are often small, social influence programs can be an important mechanism for transmitting societal norms on substance use to young people. They can help them to further develop their skills to make and implement safer decisions about substance use or in situations where others are using. They also offer the potential of creating a more sympathetic environment for complementary systemic strategies, such as restrictions on advertising for legal psychotropic substances (Midford 2010).

8.2.4 Selective Prevention: Intervening with (Vulnerable) Groups

Selective prevention intervenes with specific groups, families, or communities that, mostly due to their limited social ties and resources, may be more likely to develop drug use or progress into dependency. Often, this higher vulnerability to problem drug use stems from social exclusion, lack of opportunities, and less-nurturing family or community environments. Therefore, European countries most frequently report

vulnerable groups as being young (drug law) offenders, youth in deprived neighborhood, homeless youth, some ethnic minorities and immigrant groups, school dropouts, students who are failing academically, and vulnerable families. These vulnerable groups are mostly identified using social, demographic, or environmental risk factors known to be associated with SUD. Targeted subgroups may be defined by family status or place of residence, such as living in deprived neighborhoods or areas with high drug use or trafficking. This means that prior to providing the intervention, the situation and vulnerability pattern of a given target group has to be studied. This clearly differs from universal prevention, where universal risk factors are addressed. Since this vulnerability assessment relies on social and demographic characteristics at the group level, individual risk cannot be assessed.

Implementing experimental evaluation designs with groups that are often hard to reach is extremely difficult and frequently impossible. For this reason, evidence for the effectiveness for selective prevention is currently limited. However, the American cross-site evaluation of interventions for high-risk youth, together with European (Jones et al. 2006; Roe and Becker 2005) and American (Hansen et al. 2007; Sussman et al. 2004) reviews of the evidence, allowed effective elements of such interventions with vulnerable populations to be identified.

Effective elements include changing access within the environment, promoting the development of personal and social skills, promoting positive relations in families, addressing social influences, providing social support and helping participants to develop goals and alternatives, developing positive schools, and enhancing motivation to avoid substance use (Hansen et al. 2007). The effective components in selective prevention – inside and outside school settings – seem to be virtually the same as in universal prevention. Interventions that do not solely address drug use, adapt to young people's experiences, and avoid rigid abstinence-oriented messages have proven to be more effective. They address social needs connected to drug use, rather than drug use behavior (Steiker 2008). After all, drug use in these populations should be considered as just one of several expressions of behavioral maladjustment. The specific challenge lies in targeting the right group with the right type of prevention intervention and delivering the effective components in appropriate ways. Vulnerable groups are often not so easily "available" as pupils in schools and typically do not approach public services.

In summary, prevention that targets vulnerable people may moderate the effect of an early developmental disadvantage, its translation into social marginalization, and progression into substance abuse. Several research studies have shown that interventions delivered during the early school years that aimed to improve educational environments and reduce social exclusion also had a moderating effect on later substance use (Toumbourou et al. 2007), without specifically targeting youth who experiment with drugs.

Although often unacknowledged, outcomes of the prevention programs described here can also be beneficial in behavioral domains beyond substance use, such as the prevention of violence, delinquency, academic failure, teenage pregnancies, and unprotected sex. Substance use prevention professionals are often unaware that smoking, drinking, safe sex, and healthy nutrition among adolescents

share common determinants. Recent empirical studies and reviews identified several common factors for all of them: beliefs about immediate gratification and social advantages, peer norms, peer and parental modelling, and refusal self-efficacy (Peters et al. 2009).

The prevention of different problem behaviors belongs to segregated political portfolios in most countries, and therefore a cohesive, coherent, and efficient approach to adolescent vulnerability is often lacking. In those few countries where such cohesive policy responses to multiple risk behaviors have emerged (e.g., the UK and North America), there is increasing evidence for the effectiveness of such integrated approaches. However, the implementation and evaluation of such interventions are causing complex challenges (Hale and Viner 2012).

Both professionals and policymakers in Europe have easily adopted the concept of selective prevention. Since universal prevention has been criticized as being abstinence focused and therefore inappropriate for young people's experiences (Skager 2007), many professionals began considering selective prevention as panacea and the "best fit" for European realities. Several researchers have, however, raised concerns regarding possible iatrogenic effects when vulnerable young people are grouped together in selective interventions. Problem behavior may get worse when members of this selective group model to each other's problem behavior ("deviance modelling"), thereby corroborating their belief that their deviant behavior is "normal" while the surrounding social environment is not ("norm narrowing"). Such iatrogenic effects are unlikely to occur in universal prevention, where some program evaluations in school and family settings (Koning et al. 2012) found that the more vulnerable subgroups within the universal target population benefited relatively more from the intervention, possibly because they adjusted their behavior to that of the "conventional" majority.

8.2.5 Family-Based Prevention: Universal and Selective

Many parents in the Western world tend to assume that a close, warm, and open relationship with their children is protective against SUD, by providing them with a space to test their own boundaries. Recent research has provided considerable support for the idea that not only parental support but also monitoring and control are strong determinants of lower prevalence levels of adolescent risk behavior.

There is now a plethora of studies on the relationship between parental styles and their offspring's drug use. They classify parental behavior on two axes, warm–distant and strict–lenient. Research indicates that the authoritative style (strict and warm) is the most protective against substance use, while the neglectful style (lenient and distant) increases the risk of drug use; research on the authoritarian and permissive styles is as yet inconclusive. Factors beyond parenting style, such as parents' drug use, emotional support and warmth, family structure, and influence of culture, need to be taken into consideration (Becoña et al. 2012).

For instance, Van der Vorst et al. (2006) suggest that clear rules about alcohol drinking in families are protective, while talking about alcohol and its risks proved

rather counterproductive. In a recent longitudinal study with over 1,400 students aged 14–20, high parental monitoring predicted significantly less use of alcohol, cocaine, prescription drugs, ecstasy, and drinking to intoxication, and this also applied for high-risk students in alternative curricula (Clark et al. 2012). A meta-analysis (Lac and Crano 2009) that assessed the perceptions of 35,367 adolescents (from 17 studies) of parental monitoring and linked it to their marijuana use found a strong protective effect ($r = 0.21$) of parental monitoring activities. The association was significantly stronger in females and even existed when parental monitoring was defined purely in terms of parental knowledge of the child's whereabouts, activities, and relations.

Monitoring and warmth together appear to predict adolescents' social and interpersonal perceptions of drug use and their actual drug use 1 year later (Hemovich et al. 2011), which reminds us again of the importance of adolescents' social and intrapersonal beliefs for their use of illicit substances. Results of studies on monitoring from before 2009 are difficult to include here, as they often measured parental knowledge instead of actual active parental monitoring (Racz and McMahon 2011).

A recent study in the Netherlands (De Looze et al. 2012) found that specific parental rules about smoking, drinking, and adolescent risk behavior were associated with a lower prevalence of the targeted behaviors (i.e., smoking and drinking). Independent of adolescent smoking and drinking behaviors, these parental rules on smoking also predicted lower prevalence of cannabis use and a lower rate of early sexual intercourse. This suggests that clear parental rule setting is more strongly related to lower levels of risk behaviors in adolescents than are more general parenting practices.

The findings give additional etiological underpinning to an intervention study that tested the Swedish Örebro program in the Netherlands. The program combines parent and student interventions and establishes simple drinking rules, coordinated between home and school, which had shown to be effective in most implementations in Sweden (Koutakis et al. 2008).

The program in the Dutch context (Koning et al. 2012) was only effective in preventing weekly drinking when family and school interventions were combined, and among those adolescents reported that they had lower self-control and more lenient parents at baseline. The mediators of these effects were clearer rules and attitudes in parents. It is interesting that a program that only requires, on the part of the school, a 15-min intervention at the regular parents' meeting at the beginning of the school year has relevant effects on self-control in adolescents and restrictive parenting.

Strict family rules about drinking were also tested against a (harm minimization) model according to which alcohol use is a part of normal adolescent development while parents should supervise their children's use to encourage responsible drinking. The study (McMorris et al. 2011) compared adolescent alcohol use and related harms among adolescents ($N = 1{,}945$; 989 females) in Washington State, USA, and Victoria, Australia, two states that have respectively adopted zero tolerance and harm minimization policies. Despite those differences, family context was related

to alcohol use and harmful use in a very similar way, but adult-supervised alcohol use resulted in higher levels of harmful alcohol consequences. This challenges the assumption that supervised alcohol use or early-age alcohol use would reduce the development of adolescent alcohol problems. Both Mediterranean drinking cultures and Danish drinking parties where parents organize and supervise alcohol consumption among their teenage offspring are based on this rationale. A large European study (Kuntsche and Kuendig 2006) confirmed that the perception of excessive drinking in a family is more closely related to both frequent and excessive drinking than to family structure, but family bonding was even more closely related than drinking perception. The findings underline – for European contexts – the importance of factors related to family life and support that minimize the risk of frequent and excessive drinking despite given risk factors (Kuntsche and Kuendig 2006).

In terms of prevention practice, the question again arises of how parental control, warmth, rules, and monitoring can be increased or strengthened by interventions and how these interventions should be delivered and to which families. The analysis by Hemovich et al. (2011), for example, found that single-parent families and those with lower incomes provided less monitoring, which was related to more drug use, but not less warmth. This leads back to the importance of distinguishing between universal family-based approaches that target all parents and those selective ones designed for the more vulnerable families that have fewer financial, personal, and time resources.

Most of the effective family-based programs contain elements of monitoring, rule-setting, and contingency management. Some of them – such as the Strengthening Families Program (SFP) – were originally designed for the most vulnerable families. In systematic reviews (Foxcroft and Tsertsvadze 2011b; Petrie et al. 2007), the SFP was considered effective in preventing substance use – including over the long term – and other problem behaviors. It seems to be the only program to demonstrate in randomized control trials improvements in the outcomes for the children, in addition to improved parenting skills and reductions in child maltreatment. Particularly, selective family-level interventions might not demonstrate benefits where they are applied more universally to include families with very low rates of problems at child or family level. However, addressing all families using a universal prevention approach might allow more vulnerable families to adopt educational, normative, and behavior models from the more conventional families in the same group, so that often the more vulnerable families profit most from such programs. Depending on how they are delivered, some universal programs might predominantly attract the well-off, low-risk families; however, effective (often selective) programs tackle this imbalance by offering transportation, child-care, and food at the venues – elements that might be essential for families in need.

A systematic review (Broening et al. 2012) of programs for substance-affected families found interventions to be effective when their duration was longer than 10 weeks and when they involved children's, parenting, and family skills training components. Proximal outcomes (e.g., knowledge, coping skills, family relations)

showed better results than more distal outcomes (e.g., self-worth and substance use initiation). Apart from a few studies, the long-term effects on young people's substance use, delinquency, mental health, physical health, and school performance have rarely been assessed in the evaluations.

The need to break intergenerational cycles of poor parenting practices was addressed by Hill et al. (2010), who examined the extent to which interactions between behavioral disinhibition, behavioral inhibition, and family management during adolescence (from age 10) predict alcohol abuse and alcohol dependence at age 27. Young people who were high in behavioral disinhibition were at increased risk of later alcohol abuse and dependence, but only in consistently poorly managed family environments, while in consistently well-managed families, high levels of behavioral disinhibition did not increase the risk of later alcohol abuse or dependence.

Overall, across universal and selective interventions, there is good evidence from Cochrane Reviews that family-based prevention interventions are effective in reducing young people's alcohol, tobacco, and drug use (Foxcroft and Tsertsvadze 2011a; Gates et al. 2007).

8.2.6 Indicated Prevention: Intervening with (Vulnerable) Individuals

Indicated prevention aims to identify individuals with behavioral or psychological problems that may be predictive of developing problem substance use later in life and to target them individually with special interventions. Indicators of increased risk can be dissocial behavior and early aggression as well as alienation from parents, school, and peer groups. The aim of indicated prevention is not necessarily to prevent substance use but to prevent or at least delay development of a dependence, to diminish the frequency and to prevent more risky patterns of substance use (e.g., moderate drinking instead of binge drinking). This European definition of indicated prevention differs slightly from the original definition by the Institute of Medicine (IOM) (Mrazek and Haggerty 1994), "to identify individuals who are exhibiting early signs of substance abuse (but not DSM-IV criteria for addiction) and other problem behavior and to target them with special interventions." "Early intervention" stands for a subgroup of measures of indicated prevention focusing only and specifically on identifying substance-using individuals to prevent them from progressing into problem drug use.

The IOM definition for indicated prevention has spread the notion that signs of problematic substance use would be the principal aspect we need to look at if we want to prevent SUD in vulnerable individuals. However, a considerable body of evidence (Glantz et al. 2009) suggests that a set of behavioral and mental problems and disorders with onset in early childhood significantly increase the propensity of affected children to develop SUD earlier or faster, once they have initiated substance use. These aspects of vulnerability at the individual level do not seem to be covered clearly enough by the IOM definition, and therefore, professionals tend to

ascribe even very personality-focused interventions like Preventure (see below) to selective prevention (Conrod et al. 2013).

The European definition considers problematic substance use to be one among the behavioral or mental health problems that lead to SUD, which can be diagnosed at the individual level. It thereby maintains the distinction between vulnerability at the group level (selective prevention) and vulnerability at the individual level (indicated prevention) as it was originally intended by Gordon (1983): "Selective measures are advisable for population subgroups distinguished by age, sex, occupation, or other evident characteristics, but who, on individual examination, are perfectly well. Indicated measures are those that should be applied only in the presence of a demonstrable condition that identifies the individual as being at higher than average risk for the future development of a disease." This distinction is highly relevant for practice and policy because vulnerabilities at the social (demographic) level, those at the individual (mental health) level, and those at the environmental level affect the pathways to substance use disorder in quite distinct ways (Sloboda et al. 2012), and the focus of the respective prevention strategies should match the kind of vulnerability of the target populations.

In the European Union, the term "early intervention" has been coined for those specific forms of indicated prevention that consider exclusively the level of drug use as a predictor for developing SUD and aim to intervene early in a drug use career. Even though this interpretation has somehow become established in European policy documents, the original and predominant use of this term in the scientific literature refers to intervening early in lifetime (i.e., first childhood) to prevent a range of behavioral problems in disadvantaged children (Guralnick 2008). Most of the interventions in this group can be described as brief interventions (BI), sometimes including elements of motivational interviewing (MI).

There are no systematic reviews or meta-analyses assessing the effectiveness of interventions that target individuals with behavioral or psychological problems independent of any substance use. Nevertheless, the few available single intervention studies in Europe tend to be better designed and to provide stronger outcomes than those in selective prevention.

For example, the indicated school-based program Preventure targets adolescents (aged 13–14) with specific personality risk factors for early onset substance use disorder and other risky behaviors, in only two sessions. Even when implemented by nonspecialists, participants showed a lower likelihood of later onset of drinking or a less-steep increase in consumption and binge drinking. Effects beyond substance use included reduced scores in depression, panic attacks, truancy, and shoplifting (Castellanos and Conrod 2006). For young alcohol drinkers at baseline, the findings suggest that only four to six young people need to be exposed to the intervention to prevent one from later taking up heavy drinking. This "number needed to treat" (NNT) is one of the most favorable found to date in prevention interventions. Coping Power, a program targeting young people aged 8–13 with disruptive behaviors in the Netherlands showed at follow-up better results for smoking and cannabis use compared to treatment as usual (Zonnevylle-Bender et al. 2007).

These findings again illustrate that contemporary prevention interventions go well beyond simply presenting abstinence-oriented messages. Carney and Myers (2012) assessed the effectiveness of "early interventions" for adolescent substance use and behavioral outcomes in a systematic review (nine studies) and found benefits in reducing substance use and improvements in associated behavioral outcomes with small but significant behavioral and drug use outcomes, especially for individual interventions with more than one session.

Brief interventions (BI) consist of one-to-one counselling sessions, sometimes including follow-up sessions, which are delivered by trained health and social workers to people who might be at risk because of their substance use. It involves a prior assessment of substance use problems. In reviews, BI were found to be effective when delivered in the primary healthcare system and colleges, as well as online or via computers. However, these positive findings currently only relate to alcohol.

Brief interventions usually contain elements of motivational interviewing (MI). MI is a nondirective interaction technique where active listening and feedback are used to support clients in making decisions, hence using their own motivational momentum to change behaviors and set goals regarding their substance use. Motivational interviewing alone can be effective in reducing drug use – even in a single session – as shown in reviews by McCambridge and Strang (2004), but the outcome seems to depend on the quality of its delivery (McCambridge et al. 2011). Also, a Cochrane Review (Smedslund et al. 2011) found significant effects of motivational interviewing in short- to midterm follow-ups and in comparison to nonintervention.

A study of nightlife settings from Florida (Kurtz et al. 2013) suggests that even simple assessment and feedback interviews can reduce substance use in club-goers, a phenomenon that has previously been found in emergency room interventions for alcohol drinkers and might be a promising technique to be applied in conjunction with pill testing services at nightlife events.

8.3 Conclusion

Prevention has developed and made some progress in recent years, but there is still quite a lot of room for improvement. Overall, universal prevention seems to be dominated by interventions that might attract public attention but are not likely to be effective in preventing drug use. Policy interest in selective prevention has increased in the same period, but this has not translated into more interventions for vulnerable youth or more evaluation research. Finally, there has been some recent interest in indicated prevention in Europe. Here, well-designed evaluation studies have taken place, but the intervention coverage as such is still limited to only a few countries. Too many prevention interventions continue to appeal to cognitive processes only, namely, information provision, regardless of the negative evidence that has been reported about such interventions.

With the arrival of the phenomenon of "legal highs" and continuously innovating synthetic psychoactive substances offered on a globalized market, this weakest

of all prevention paradigms has been revived, and once again decision makers seem to be convinced that prevention funds are best spent in detecting, assessing, and warning youth about the dangers of these new substances. Policymakers and professionals have only reluctantly begun to acknowledge that social norms and their perception (environmental prevention) as well as impulse control (indicated prevention) are powerful determinants of adolescent behavior. The potential for using emotional and unconscious processes in prevention is virtually unacknowledged, while implicit cognition is regularly used in advertisement and marketing in order to boost consumption. Reviews found the largest effect sizes in studies that assessed implicit semantic associations employed word association measures and focused on marijuana use, suggesting that implicit cognition is a reliable predictor of substance use (Rooke et al. 2008). Only a few prevention approaches, particularly in the alcohol field, use techniques that aim to reverse the influence of the abovementioned unconscious cues by attempts to change learned associations, attention biases, and implicit attitudes.

In terms of gender differences, a number of program evaluations found, overall, less or no effects for girls (Kumpfer et al. 2008; Poduska et al. 2008; Vigna-Taglianti et al. 2009). One possible explanation might be a lower vulnerability at baseline, which could also reflect the fact that neurobehavioral disinhibition is found more frequently in boys. Alternative hypotheses are that these interventions are less appealing to girls or that the timing of delivery with regard to their cognitive, social, and emotional development is less appropriate, since girls mature earlier (Vigna-Taglianti et al. 2009). Kelly et al. (2011) found that girls' alcohol use was – compared to boys – more influenced by high-risk peer networks, while parental disapproval was less protective for them, compared to boys. So girls who, overall, use psychoactive substances less and have fewer problems might also gain less from existing prevention programs.

Reflecting the criticism that prevention is only abstinence oriented and is inappropriate to contemporary youth's need to acquire risk competence, the term "risk reduction" has been coined as a viable alternative for vulnerable or drug-using youth, as an analogy to what harm reduction would be in relation to treatment. However, the evidence, intervention examples, and theoretical frameworks discussed in this chapter show that "risk reduction" is intrinsically included in all prevention measures. Most prevention intervention in fact do not simply strive for abstinence but try to delay initiation, achieve generally better behavioral control and adequate socialization, or avoid rapid escalation from experimental use into SUD or even addiction, hence reducing risk and harms. Risk reduction can hardly be seen as separated from prevention, while such "harm reduction" approaches within prevention might only be effective and acceptable when targeted at older adolescents (over the age of 14) but not for younger adolescents (Poulin and Nicholson 2005).

As described above, there are still a number of limitations in the evidence behind prevention interventions. Nevertheless, given the limited number of options available for tackling addiction problems, one cannot only rely on treatment and harm reduction. Recent discussions about "recovery," in particular, bring us back to approaches that target a life free from the negative impacts of addictive substances and behaviors.

While treatment is based on the informed consent of the treated person, prevention interventions are usually the result of a unilateral decision taken by experts or policymakers, based on their assumption that an intervention will have positive effects on the targeted person and/or the social environment. While parents and teachers might take such a decision "on behalf" of their children and pupils, for adult target groups the responsibility clearly lies with experts and policymakers. As has been shown for mass media campaigns, the question of responsibility and consent is not an academic one, as iatrogenic effects of preventive interventions are possible. It is crucial, therefore, that decision makers take a well-informed position on behalf of their citizens in such instances.

As has been seen, especially in selective and indicated prevention, there is a considerable overlap between treatment and prevention. In many cases prevention offers an improved understanding of an individual's situation, a self-examination, or test, which might lead to treatment. A good example of this is treatment programs for cannabis users offered via the Internet, which frequently start as self-tests and may end up with a one-to-one treatment arrangement. Motivational interviewing can be used as a tool helping to bridge the gap between prevention and treatment.

While prevention has been traditionally linked to school curricula, TV, and information campaigns, the range of media and approaches now available has widened considerably. Web series, avatars, contacts, and information provided via SMS or Twitter are no longer considered new approaches and have now become part of the toolbox for prevention specialists. At the same time – also based on neuropsychological findings – prevention has become more unified, and a number of problematic behaviors, including destructive and violent behavior, substance use, and pathological use of computer games and the Internet, are today targeted with the same interventions. The need for a strong evidence base, critical reflection of practice, and adequate training of the staff involved remains central to all these approaches.

As we have seen in various sections of this chapter, social norms have a strong influence on behavior, suggesting that the effect of informal social control and social sanctions (from family and peers) may be more important than the certainty and severity of formal sanctions. These examples illustrate that comprehensive prevention policies ought not only to address individual vulnerabilities and illicit drug use. Informal social norms have a major but largely underestimated influence on initiation and level of substance use and related behaviors.

Regional and Cultural Aspects of Prevention

Roland Simon and Gregor Burkhart

Contents

Abstract

Drug use and prevention has to be understood within its cultural environment and conditions.

There is increasing evidence that cultural values, descriptive norms, and the social acceptability of use influence people's initiation into substance use and problem behavior directly as well as indirectly through parenting practices. It has been argued that especially inconsistency between parenting style and culture can cause harm to adolescents' mental health.

Cultural and contextual differences between regions can also affect the implementation, acceptance, and effectiveness of prevention interventions.

The focus of prevention approaches has differed between Europe, North America, and other parts of the world in recent years. North America has in the past decade focused more on manualized substance use prevention programs. While this has not been the traditional approach in Europe, such programs have been successfully transferred and adapted to European environments, either in content (words, names, examples, and images) or in structure (organization, training, staff, time, and length of sessions). This approach should be pursued further, especially at a time when it is unlikely that substantial new investments in prevention research will be made.

9.1 Introduction

Burkhart and Simon (# in this publication #) have shown that collective behavior and perceived norms have a significant influence on substance use behavior. This has implication for interventions, their effectiveness, and cultural acceptance. Most universal and selective prevention strategies only target individual behavior and decision-making, putting the onus of responsibility for behavioral control entirely on the individual and disregarding the influence of network and collective behavior (Szmigin et al. 2011).

9.1.1 Culture and Substance Use

From an etiological perspective, there is increasing evidence that the perceived availability of substances, normative environmental aspects such as cultural values, descriptive norms, and the social acceptability of use influence people's initiation into substance use and problem behavior. Several longitudinal studies have confirmed that descriptive norms and the misperception of normality ("Everybody does it") are important predictors of tobacco smoking (Cunningham 2007), frequency of alcohol consumption, and readiness to take significant risks to use cannabis, alcohol, and tobacco (Olds et al. 2005). Kuntsche and Jordan (2006) confirmed that regular contact with substance-using peers strongly correlates with individual substance use. Students who saw other young people attending school while intoxicated with cannabis or taking cannabis on the school premises used more cannabis themselves and had more cannabis-using peers. Cannabis use in the school environment seems to create an atmosphere that favors cannabis use independent of whether students have cannabis-using peers. The authors suggest that schools should create an overarching environment of disapproval of cannabis use as an effective means of prevention.

Societal values and norms not only influence student and adolescent behavior, but they also guide parenting practices. For this reason, "contextual" rather than "universal" monitoring activities would probably be more appropriate in family-based programs. While families' concern for their offspring is universal, the level of individuation and autonomy varies between individuals and between cultures. Arab

societies, for example, tend to be more collective and authoritarian than Western societies, with higher levels of emotional and financial connectedness and sometimes collective monitoring alongside parental monitoring. This higher level of adolescent–family connectedness has been associated with better mental health among adolescents in eight Arab societies (Dwairy 2006), indicating that authoritarian parenting within an authoritarian culture does not harm adolescents' mental health as this would be the case within Western liberal societies. The authors hypothesize that it is the inconsistency between parenting style and culture that causes harm to adolescents' mental health. This suggests that education has to be understood within its cultural environment and conditions.

9.1.2 Implementation of Interventions and Cultural Conditions

From an intervention perspective, cultural and contextual differences between regions – sometimes going back over centuries – can affect the successful implementation, acceptance, and effectiveness of prevention interventions. Interventions therefore have to take account of the collective aspects of some of the behaviors they wish to address. For example, differences in culture, context, and history must be taken into account when adapting North American programs for use in Europe. Essential components of community prevention approaches that are present in self-governance cultures such as the USA might not exist to the required extent in countries with different political traditions. This might include factors such as defining community norms and rules, volunteering and citizen involvement, self-organization, and social control. Such differences in political traditions explain why "community-based prevention" is difficult to implement in many countries. In most of Europe, the concept has a different meaning from the USA and is used to describe the activities of municipal services or institutions in nonschool settings.

These differences are also reflected in how prevention policy is managed. While in Europe stricter tobacco control has sometimes even been denounced as "fascism" and alcohol control as the surrogate of Nordic Puritanism, other regions of the world do not seem to have such an aversion to social and market control; for example, alcohol has been banned in Brazilian football stadiums since 2003. A country's social norms can create more opportunities for environmental prevention strategies, and this seems unrelated to the level of "repression" in a country; for example, several Latin American countries, including Brazil, have decriminalized drug use.

9.2 International Perspectives and Trends

The following chapter presents an overview of recent developments and trends in preventive measures. While the focus is on Europe, North America and other parts of the world are also considered.

9.2.1 Mass Media Campaigns

Mass media campaigns continue to be popular both in the Americas and in Europe, although they are evaluated more often in the USA. However, over a third of European countries have reduced or abandoned mass media campaigns on illicit drugs because of concerns about possible iatrogenic effects of such interventions and a lack of funds to implement them. Some countries, such as Bulgaria, the Czech Republic, Italy, Spain, France, and Romania, still use local and national mass media campaigns. It is possible that mass media campaigns still have a wider role to play in comprehensive social marketing strategies, such as those trying to change social norms.

9.2.2 Environmental Prevention

Environmental prevention is a new concept in Europe, even though in German-speaking countries the corresponding term (*Verhältnisprävention*) has been in use for many years.

Since the introduction of the Irish smoking ban in 2004 (following the EU signing of the WHO Framework Convention on Tobacco Control in 2003), environmental prevention strategies to restrict tobacco advertising and places where smoking is allowed have rapidly gained momentum, and today, a majority of Member States have total smoking bans in public places (for details, see www.emcdda.europa.eu/prevention-profiles). Following these changes – and possibly also as a result of them – the prevalence of smoking has fallen (Spinney 2007), particularly among adolescent boys (Hublet et al. 2009).

Advances in the environmental prevention of alcohol use have been less visible. The EU Alcohol and Health Forum was set up, and in 2006, the EU alcohol strategy was launched requiring several environmental measures to be taken. The 2009 implementation report of the strategy still lists a greater number of persuasive approaches (such as campaigns) than environmental strategies (such as regulation, taxation, or legislation). However, there is a continuous trend towards establishing a minimum age of 18 for selling and serving alcohol. Within EU Member States, environmental prevention approaches in schools have expanded, and today, almost all of them report total smoking bans in all schools, and a majority of countries report full or extensive provision of drug policies in schools, i.e., rules on the use and sale of substances on school premises and procedures to deal with violations. At the community level, the provision of environmental strategies such as community prevention plans and cooperative prevention work between community agencies has increased steadily since 2004.

It has been argued that a range of social problems, including substance use, teenage pregnancy, and violence, are more prevalent in countries with high levels of social and health inequality (Wilkinson and Picket 2010). Many Scandinavian countries invest heavily in broader environmental policies that are geared towards increasing social inclusion at family, school, community, and society levels and

that work to reduce and maintain lower levels of drug use. Prevention programs and interventions targeting specific problems or drugs are less often used in these countries.

Guidelines for the creation of better environments in recreational settings, such as the "safer dancing" guidelines in the UK, were developed since the end of the 1990s as simple but important environmental prevention tools to reduce the occurrence of problems related to drugs and alcohol. They include access to free drinking water, rules on glassware, noise, and staff training. Additional elements are policies on and monitoring of interior space in respect of risky sexual or aggressive behavior, training staff for medical emergencies related to intoxicated patrons, and policies for serving alcohol and handling drug-related problems. The strategies that are applied in Sweden and the USA (Miller et al. 2009) add more repressive elements, such as monitoring interior space for drug use and drug-related problems, training staff to detect drug-impaired patrons, and excluding "problem" patrons (drug dealers, drug users, those carrying weapons). While between 2004 and 2009 the number of EU countries that reported the existence of such guidelines increased from 3 to 12, only half of them appeared to monitor and enforced their implementation. In practice, even free drinking water – a core requirement for safe clubbing to counter the effects of dehydration and high temperatures while dancing – was available in the majority of relevant nightclubs in only 11 EU countries (2009 data).

9.2.3 Universal Prevention

Of the four main drug prevention strategies in Europe, universal prevention predominates and is probably the most commonly implemented, particularly in schools and families. The objective of delivering prevention interventions of the best possible quality in the context of increased financial pressures due to the economic downturn in Europe has led some countries to focus on improving the quality of their prevention programs and professionals. The Czech Republic, for example, has centralized the government's prevention funds and has introduced Europe's first accreditation system, under which funding is available only to certified programs. The certification of professionals is designed to improve the quality of delivery and to ensure that public funds are spent efficiently.

In comparison with the Americas, very few countries in Europe have implemented "manualized" programs (with the program details published in a manual which facilitates implementation according to set standards and rules), even if most of the available evidence on school-based prevention originates from them. The manuals provide material and guidance for teachers and pupils on the content of each of the sessions, promote discussions, and enable implementation and behavioral changes to be evaluated. The most important program is Unplugged, the only multisite randomized controlled trial (RCT) on prevention in Europe to date. This comprehensive social influence program consists of twelve 1-h interactive sessions delivered by class teachers and has proven its effectiveness in

a cluster randomized trial involving 7,079 pupils aged 12–14 in seven European countries (www.eudap.net). Drunkenness and cannabis use showed reductions after six 6 and 18 months; there was a reduced prevalence of all behavioral outcomes related to problematic drug and alcohol use among boys, but not among girls (Faggiano et al. 2010). Participation in the program was associated with decreases in drunkenness, intention to get drunk, and alcohol-related problem behaviors among adolescents from a low socioeconomic level. After this first European multisite prevention trial, Unplugged was implemented in more eastern European and Asian countries, in some cases replicating the initial promising outcomes.

One unusual school-based prevention approach deserves special mention. The Good Behavior Game (GBG) is not a typical lessons-based classroom prevention program but rather a way of managing whole primary school classes during regular lessons and socializing children to be self-controlled, emphasizing the role of significant others (teachers and peers) in children's social adjustment in school. Divided into teams, children systematically learn over a period of one school year to respect basic class rules through a well-designed process providing team rewards for respecting rules. RCTs reported a beneficial impact up to the middle school years and even young adulthood. These effects included reductions in alcohol and drug dependency disorders; antisocial personality disorder; delinquency and imprisonment; regular smoking; suicidal ideation and attempts; use of services for behavioral, drug, emotional, and school learning problems; and risky sexual activity such as unprotected sex. Substances and substance use are not explicit themes in GBG; instead, it focuses on socialization, and the children themselves define the behaviors that will be rewarded. GBG has been or is being implemented in at least four EU Member States. In a similar modus operandi, the Smokefree Class competition is an evaluated and effective program implemented in some European countries that works predominantly by setting alternative peer norms about smoking and stimulates their reinforcement by the peers themselves, but without mentioning the dangers or risks of smoking.

While these are excellent examples of more developed concepts and their implementation in Europe, the everyday practice of universal prevention in European schools still seems to focus primarily on nonevidence-based components – information days about drugs, visits by police officers, lectures from experts or former drug addicts, and interventions providing information (with no skills training) on the risks of drugs. There has, though, been a slight increase in manualized multi-session programs like Unplugged. These include training in communication skills and in the ability to handle conflict, stress, and frustration. They also try to correct normative misperceptions about drug use. This area, called "normative education," is still quite underdeveloped despite positive evidence (Martinus et al. 2012; Sussman et al. 2004). Many other manualized programs, though, still have information provision as the key component, with frontal (as opposed to interactive) delivery.

9.2.4 Selective Prevention

Compared to other parts of the world, Europe seems to have invested much political effort in addressing the problems of vulnerable groups, and since 2004, an increasing number of EU Member States have indicated vulnerable groups as primary targets for prevention interventions. However, in real terms, the reported level of intervention provision has only increased for two subgroups: young offenders and pupils with academic and social problems. The latter might be due to some Member States shifting attention in general to young people with academic problems and school dropouts, who share many risk factors with problem drug users. Young offenders as a group are easy to identify, but interventions provided are often not appropriate for them. While almost all EU Member States offer alternatives to imprisonment or penal sanctions for underage drug law offenders, treatment is not particularly tailored for them. They may be treated alongside more problematic drug users and/or dealt with as though they are themselves problematic drug users, increasing the risk of further marginalization and deviant behavior. In many cases, more suitable interventions would have clear and structured protocols, be of adequate duration, and be provided in neutral settings. The manualized program for young offenders (FreD) takes this approach. Developed at the national level, it has been expanded to and adapted by one-third of EU Member States.

Some countries have reacted specifically to the increased vulnerability to drug use found among pupils in vocational schools, for example, with tailored programs to generally improve literacy and numeracy levels among disadvantaged students. At the community level, municipalities in northern Europe and in Italy aim to combine drug and alcohol policies, action plans, and youth work through binding cooperation agreements between local authorities and nongovernmental organizations. Combining norm-setting environments and individual counselling approaches in this way might avoid segregating vulnerable young people into specific interventions for high-risk youth, which has the potential to cause further harm, as described above. Municipalities have closer contact with citizens and can better coordinate the different services involved. The strengthening of local responsibility for prevention has fostered community plans and interagency work, particularly in northern European countries.

Early intervention approaches, in the original meaning of the term, provide social, emotional, and learning support to children in the early years of life (this is distinct from the recent use of the term "early intervention" to mean "early in the career of substance use"; see below). It can delay or prevent future problems (including substance misuse) more effectively and economically than intervening only when problems appear. Parenting programs at a local level would be an essential part of early intervention, but proactive parental work and training is still an exception.

The content of interventions presented as "selective prevention" is often unclear, and problems in defining the scope of the concept make monitoring difficult.

The effectiveness of prevention is substantially affected by whether evidence-based (Sussman et al. 2004) elements – motivation, skills, and decision-making – are included or if there is just a distribution of, for example, information leaflets about drug taking, as some countries' data suggests.

Finally, the problem of delivery seems to be very relevant. In roughly two-thirds of EU Member States selective prevention is carried out by the many existing services and offices for youth, families, migrants, etc., usually via meetings with their clients at a service's office ("come structure"). Outreach work ("go structure") may be able to reach a wider group of people in need, but while outreach work as such is definitively well developed in Europe, it does not seem to be the main channel for approaching and engaging with vulnerable young people in selective prevention interventions.

9.2.5 Family-Based Prevention

Family-based prevention is widely utilized in universal prevention, but despite a lack of evidence about this approach, it seems to be mainly focused on providing information. Intensive coaching and training of families, an approach that has shown consistent efficacy across studies (Petrie et al. 2007), is provided in less than a third of EU countries. Very few countries report on more sophisticated interventions such as parents' peer-to-peer groups, personal and social competence trainings, or manualized parenting programs, although the number of countries using these types of intervention is increasing. There has been a general increase in the use of selective approaches targeting only vulnerable families, most notably families with substance use and who are socially disadvantaged. This might be related to the increasing popularity in Europe of the Strengthening Families Programme (SFP), a prevention program for parents and children in high-risk families that includes elements of parenting skills training, children's life skills training, and family life skills training. Outcomes include increased family strengths and resilience and reduced risk factors for problem behaviors in high-risk children, including behavioral, emotional, academic, and social problems, as well as reductions in substance use, conduct disorders, aggression, violence, and juvenile delinquency.

A practical problem is that many parents cannot be reached using the classic instruments of work with parents, such as parents' evenings or invitations for a talk during office hours. Interventions in Denmark, Germany, Italy, and Austria (e.g., Family Ties, www.familienbande.cc) aim to increase the parenting skills of parents and other adults involved in bringing up children and help them to develop responsibility and decision-making skills. The approach has made it possible to reach families with migration backgrounds as well as socially disadvantaged families. Special networks of counselling centers have been set up (e.g., in Germany and France) to provide concrete advice to families about how to deal with children who are using drugs.

9.2.6 Indicated Prevention

Children with behavioral disorders, such as coexisting attention deficit (hyperactivity) disorder and conduct disorder, are at a particularly high risk of developing substance use problems later in life (Szobot et al. 2007). Intervening with these children requires close cross-sector cooperation at the community level between medical, social, and youth services, from childhood on. This is rarely achieved, except in some isolated examples that combine counselling for parents and carers with concurrent medical, psychotherapeutic, psychosocial, and educational support.

In 2004, the concept of indicated prevention was practically unknown in Europe, with only Germany and Italy reporting measures for children with behavioral disorders. In 2010, some 14 Member States reported various forms of indicated prevention, the majority of which were "early intervention" and counselling for drug users; interventions for early onset behavioral problems were much less frequent. In 2012, few countries reported the use of structured or manualized interventions for such problems.

The school setting has become crucial for identifying vulnerable children and adolescents. In 2004, five EU Member States reported full or extensive availability of early identification of pupils with behavioral or drug-related problems, and this had increased to 11 in 2010. However, it remains unclear (i) whether this assessment is limited to drug-related problems or to a broader array of behavior problems and (ii) what actually happens once a pupil has been identified as being at a particular risk. While interventions for young people with behavioral problems as such are rare in Europe, specific indicated prevention that focuses on young people with problematic substance use is much more frequent. A quarter of Germany's registered prevention interventions are this type of "early intervention," and in France, prevention seems generally to be conceived in this way.

Unlike adult drinkers who request primary health or emergency services, young alcohol or drug users feel healthy and mostly have no self-perception of problems. Screening and assessing them for possible problems is therefore a particular challenge. In Europe, drug tests are very rarely used for assessing drug-related problems in pupils (under suspicion), and often tests are not allowed; in the USA, by contrast, even random drug tests seem to be common (Ringwalt et al. 2008). Even in those few countries (the UK, Finland, Croatia) where confirmatory drug testing in schools is legally allowed, it is seldom used.

Once a pupil has been identified as a problem or risky drug user, referral to treatment and counselling centers seems to be common, while interventions for drug-using pupils within the school itself are found in only a few countries. SKOLL (www.skoll.de), a 10-week program of training in self-control for young people with risky substance use, was implemented nationwide in Germany at schools and in other settings. Its evaluation showed that the participants had reduced drug use and risky behaviors over the course of several months, and at the same time, they developed more self-confidence, alternatives to risky behavior, and social contacts. Those young people who were more vulnerable benefited most. SKOLL has been

continued, is used to supplement existing interventions, and is especially attractive for sparsely populated areas as provision through the school environment allows regular access to all children at that age. France has set up special cannabis counselling centers in many cities.

Brief Interventions programs have been implemented in a small number of European countries, targeting mostly alcohol users in primary healthcare or emergency room settings (www.esbirtes.eu). Brief Interventions with elements of Motivational Interviewing are occasionally used to target young people and their cannabis use in street-work setting. While these interventions have not been reported in schools in the EU, in US schools, in comparison, Brief Interventions have been used fairly frequently (Winters et al. 2012).

Brief Intervention with elements of Motivational Interviewing is delivered both face-to-face and via interactive counselling websites in an increasing number of countries. Telephone helplines and SMS-based programs – often linked with these websites – aim to provide similar services. Since "early intervention" relies on detection and proper assessment of potentially harmful substance use, its implementation beyond schools, primary care (alcohol), and emergency services is a challenge. The advantage of the Internet-based approaches – especially when they address illicit drugs – is that they guarantee their users' anonymity and might attract substance users who would not approach any regular assessment or counselling service.

Indicated prevention could reduce the negative impact of neurobehavioral problems, such as early aggression on later substance use, and other problem behavior from childhood on. This possibility still seems to be largely ignored in Europe, where some prevention professionals reject the approach as being a "medicalization" of educational problems because it is based on neurobiological and neuropsychological findings (e.g., Sloboda et al. 2012).

9.3 Transfer of Prevention Technologies

Prevention research in North America is generally more developed than in Europe. This is related to structural differences in social policies and prevention practice as well as to research funding. In the European Union services such as healthcare and education are generally of quite a high quality and are widely available, which is not the case in most other regions of the world. As a consequence, in these regions, prevention programs are developed or used to promptly address a range of emerging social problems; this approach might hence be a consequence of a lower availability of universal social, youth, and health services.

The evidence for the effectiveness of substance use disorder prevention comes almost exclusively from evaluations of sophisticated manualized programs (Bühler and Kröger 2008; Faggiano et al. 2008; Foxcroft and Tsertsvadze 2011a, b, c; Gates et al. 2007), but these programs require considerable investment and incur high developmental costs. Given the structural differences described above, this is a more common approach to prevention in North America. Investment in research

and tools helps to improve prevention interventions and to assure their effectiveness in replication trials, as well as making them easy to apply. Their implementation is more likely to be set out in a manual (i.e., manualized) to assure accuracy of implementation and to allow trained staff who may not be prevention experts to implement them. Such programs are also more likely to have been pretested (to confirm the validity of their theory base), to have been checked for unintentional (iatrogenic) effects, and to prove positive outcomes. Such interventions could be considered "high-tech prevention," as their development and partly also their implementation require specific know-how, research, repeated refinement procedures, quality control, proof of effectiveness, replication studies, and some certainty that they do not harm. In medicine, most people would naturally expect such a level of "technology assessment," especially of medications, before they can be distributed to the population.

In Europe such high-tech programs are rare, especially outside classrooms. Prevention strategies mainly consist of varying combinations of policies for vulnerable populations; isolated or combined activities for school-aged youth to raise their awareness, self-competence, social skills, risk perception, and/or autonomy; events and advice for parents; and youth work and counselling interventions for those with existing risky substance use patterns. Such approaches have to make use of the existing services and infrastructure, and they allow for innovation and adaption to local needs and perceptions. However, they are sometimes based on little more than common sense and often lack evidence of both effectiveness and possible iatrogenic effects. While Europe has a range of innovative and pragmatic selective prevention interventions for vulnerable groups, many of them are not rigorously evaluated. Few indicated prevention programs are running, even though some well-evaluated and effective programs exist.

In broad terms, it seems that the relative lack of prevention infrastructure in the USA has led to more prevention research and program development. Europe, on the other hand, relies on a more elaborate infrastructure but spends much less energy on ensuring that the many different existing services deliver prevention work of a specific quality. However, there are examples in Europe that do control the quality of programs. In the Czech Republic, quality control is carried out through an accreditation system and through regulating training of the professionals involved. Recently developed European drug prevention quality standards might help to steer prevention policies in the EU as a whole in new directions.

9.3.1 Examples of Successful Transfer

Well-developed programs from North America have been culturally adapted to suit other parts of the world. Using a preexisting program means that the resources, manuals, and methodologies are ready for immediate use, facilitating implementation.

However, in Europe, there has been an aversion to the standardization inherent in manualized interventions and a belief that cultural and organizational differences between North America and Europe would make the adaptation problematic. Some problems seem to be real: (i) evidence-based programs from North America are often more demanding and complex than European interventions, which tend to be shorter, simpler, and more flexible, and (ii) North America has a long history of community mobilization and commitment to address problems from the bottom up. Europeans tend to have a state-oriented focus and generally believe that social problems should be addressed by service provision. Citizens in some regions outside the EU appear to see the state as having a reduced role and therefore have fewer expectations of state provision. This may be why countries in Latin America and in Asia do not appear to have many problems in adopting and adapting evidence-based programs from other parts of the world.

Despite the difficulties and hesitations described above, in the past decade, a number of manualized substance use prevention programs from North America have been successfully transferred and adapted to European environments, either in content (words, names, examples, and images) or in structure (organization, training, staff, time, and length of sessions). The most relevant examples are as follows:

- Preventure (Conrod et al. 2013), an indicated program in school settings for sensation-seeking young alcohol drinkers, developed in Canada, is currently being implemented in the Czech Republic, the Netherlands, and the UK.
- The Good Behavior Game (GBG) (Kellam et al. 2011), a universal classroom-based program that sets and reinforces simple behavioral norms, has been implemented in Belgium and is currently being implemented in the Netherlands, Slovenia, and the UK.
- The Strengthening Families Program (SFP), originally a selective family-based program first developed in 1983 in Utah in the USA (Kumpfer et al. 2012), was revised in 1992 into a shorter (and more universal) version (Molgaard et al. 2000), the Iowa SFP. Versions of the SFP are currently being implemented in Germany, Ireland, Greece, Spain, the Netherlands, Austria, Poland, Portugal, Slovenia, Sweden, and the UK.
- Communities That Care (CTC), a community empowerment and planning approach that includes a set of universal and selective interventions to be implemented in and with communities, was developed (Hawkins et al. 2008) in Seattle, Washington, and is currently being implemented in Germany, the Netherlands, Sweden, and Croatia.

It has become clear from the publications and experiences of the implementers and evaluators of those programs in at least 12 EU Member States that adaptation and implementation were both feasible and effective (where outcomes are available). While a considerable amount of time and effort was spent preparing, pretesting, and consulting with the target populations in order to adjust the programs to culture and context, in most cases, it was preferable to adapt an available effective program than to develop a new one from scratch.

9.3.2 The Role of Social Capital

Professionals who intend to transfer prevention technologies between different contexts might need to examine social capital levels in each context. While social capital is a product of both social history (context) and traditional values (culture) and is outside the immediate influence sphere of prevention programs or policies, it defines the setting in which an intervention is going to be implemented. In areas with higher social capital, networks of trust make it easier for programs to be implemented and enable resources to be better used. In societies with lower social capital, where community involvement is low, family-based prevention programs, for example, might encounter more difficulties.

As Fukuyama (2001, p. 18) argues, "the greatest direct ability to generate social capital is education. Educational institutions do not simply transmit human capital; they also pass on social capital in the form of social rules and norms." By the same line of reasoning, prevention programs are an important mechanism for transmitting societal norms (Midford 2010). If prevention programs manage to increase the cooperation of community agencies and families, social cohesion might grow as a consequence of program implementation. Such cultural and structural differences have also influenced the advancement of environmental prevention in different regions. We have argued that environmental prevention has gained momentum in most European countries in the last few years in relation to tobacco, but remains unpopular in relation to other aspects, such as alcohol and nightlife settings. Also in the USA, tobacco legislation is not homogeneously and rigorously implemented (see http://www.stateoftobaccocontrol.org/state-grades/state-rankings/smokefree-air-laws.html), and the USA has not signed WHO's Framework Convention on Tobacco Control. However, strong tobacco control policies and social norms against smoking were already well established in Canada and many Latin American countries before Europe began implementing tobacco legislation in 2004. This is one factor contributing to the lower smoking prevalence found in many Latin American countries compared to Europe (Eriksen et al. 2012).

9.4 Conclusion

Cultural and contextual differences between regions – sometimes stemming from old historical roots – can affect the implementation, acceptance, and effectiveness of prevention interventions. Interventions therefore have to take account of the collective aspects of some of the behaviors they address. Culture influences drug use behavior directly, but also indirectly, for example, through differences in education and parenting.

Prevention in Europe has developed and made some progress in recent years, but the situation is still far from perfect. Overall, universal prevention seems to be dominated by interventions that might get the public's attention, but are most likely

not effective in preventing drug use. Interest in selective prevention has increased during this period, but this has not translated into more interventions for vulnerable youth or more evaluation research. Finally, there has been some interest in indicated prevention in Europe, and effective evaluation studies have been carried out, but these types of intervention are still limited to only a few countries. Too much prevention in Europe and seemingly elsewhere – apart from North America – continues to appeal to cognitive processes only, namely, information provision. And too often interventions only target individual behavior, ignoring the fact that it is culturally embedded.

Findings from country-level ecological analyses on the health of young people (Viner et al. 2012) show that the strongest determinants of adolescent health worldwide are structural factors such as national wealth, income inequality, and access to education. As a consequence, safe and supportive families and schools, together with positive and supportive peers, are crucial in addressing risk and building protective factors. These are not limited to the neurobiological factors outlined at the beginning – childhood trajectories towards health and well-being are also modified by economic and social factors within countries, leading to inequalities. But there is evidence that effective prevention programs can reduce the effects of social inequality on behavioral outcomes. In fact, some universal prevention programs have shown differentially better effects on more vulnerable children (Kellam et al. 2008); some selective family-based programs seem to be more effective the more vulnerable the targeted families are (Kumpfer et al. 2008); and indicated programs can bring the most behaviorally difficult children to better social functioning. Most importantly, almost all interventions have positive spin-off effects beyond substance use disorder on aggressive behavior and on mental health. Despite this, these tools are still underused.

As we have seen at various parts of this chapter, social norms have a strong influence on behavior, suggesting that the effect of informal social control and social sanctions (from family and peers) may be more important than the certainty and severity of formal sanctions (Paternoster 1987). These examples illustrate that comprehensive prevention policies ought not only to address individual vulnerabilities and illicit drug use. Informal social norms have a major but largely underestimated influence on initiation and level of substance use and related behaviors.

There is a limited number of prevention programs with well-proven evidence of effectiveness that are relatively easy to implement through manuals and other supporting materials. Better use could be made of these interventions, which have often been developed in North America. A number of successful examples have shown that this approach is worthwhile and promising. While cultural conditions cannot be ignored, it is possible to successfully adapt programs developed in one cultural environment to another culture. This approach should be pursued further, especially at a time when it is unlikely that substantial new investments in prevention research will be made.

Screening and Early Interventions: An Introduction

10

John B. Saunders and Noeline C. Latt

Abstract

This introduction describes the chapters published in Sect. II on "Diagnosis, Detection and Early Intervention for Substance Use Disorders". The first chapter provides an overview of the hierarchy of diagnoses employed in the substance use disorders field and presents the diagnostic criteria for the central disorders of repetitive substance use. Following this there are two chapters on screening tools and brief intervention approaches for alcohol use disorders and drug (including nicotine) use disorders respectively. A detailed literature review on early and brief interventions of substance use disorders follows. The final two chapters are concerned with biological markers of alcohol and laboratory techniques for identification of drug use respectively.

This section is concerned with the diagnoses that apply to substance use disorders and how these disorders can be identified at an earlier or milder stage and appropriate advice and treatment provided. The aim of early detection and brief intervention is to both reduce harm that would otherwise occur were substance use to continue unchecked and to prevent the progression to substance dependence (addiction) which would otherwise be a likely consequence of continued use.

Current definitions and diagnostic criteria for substance use disorders form the opening chapter of this section. Written by John Saunders and Noeline Latt, the chapter begins with a reflection on the importance of a common language by which human disorders and problems can be communicated amongst addiction specialists and other health professionals and in a way that can be understood and appreciated by patients with these disorders. A historical review of the various concepts of substance use and its disorders follows. It will be seen that many different concepts have been promoted over recent human history and by different professional groups. Some of the concepts and definitions disagree as to the nature and also etiology of substance use problems, and these competing concepts are reviewed to provide a background to currently employed diagnoses.

A key development was the description, based on detailed clinical investigations, of the substance dependence syndrome by Edwards and Gross (1976). This concept initially applied to the alcohol dependence syndrome and has been subsequently accepted as the core syndrome for nearly all types of psychoactive substance that have abuse and addictive potential. The substance dependence syndrome is an atheoretical and non-etiological concept, purely descriptive but emphasizing the essential syndromal nature of substance dependence in which clusters of symptoms, experiences, and physiological features tend to occur in combination with each other in the affected person at around the same time and repeatedly so.

The substance dependence syndrome has been powerfully influential. It was the basis for the definitions and diagnostic criteria for substance dependence in two successive versions of the Diagnostic and Statistical Manual of Mental and Behavioral Disorders of the American Psychiatric Association, namely, DSM-IIIR (published in 1987) and DSM-IV (published in 1994). It also forms the basis for the understanding of substance use disorders amongst the literature developed by the World Health Organization, including the 10th revision of the International Classification of Diseases, ICD 10. Rather surprisingly, the concept of dependence has been aggregated with that of substance abuse in the latest DSM revision, DSM-5. The central diagnosis in DSM-5 of substance use disorder is a looser rather disaggregated concept, and although empirically based on questionnaire data, its value to guide clinical practice remains to be established.

Comprehensive clinical assessment of substance use disorders, with a particular emphasis on alcohol, is a subject of the following chapter by Teresa Bobes-Bascáran (► Chap. 14, “Clinical Assessment of Alcohol Use Disorders”). Clinical assessment of substance use disorders, like that in most medical practice, is based primarily on the clinical interview, supplemented by findings on observation and examination and importantly in many cases of substance dependence on collateral and corroborative information. Clinical assessment is also complemented by results from laboratory tests, but these are the subjects of two separate chapters in this section.

This second chapter outlines the areas necessary for exploration in the clinical interview, including the (i) assessment of the use (intake) of the particular

substance, (ii) substance-related behaviors particularly those that might reflect dependence on the substance, and (iii) the range of harms arising from substance use, be they medical, traumatic, neurocognitive, psychiatric, social, or legal. Several tables summarizing key domains for enquiry are included in this chapter.

Screening and brief intervention for alcohol use disorders has been the subject of much emphasis since the mid-1980s. This followed reviews conducted by the World Health Organization, The Institute of Medicine, and many national and professional authorities which emphasized that it was inadequate merely to provide treatment for people with established dependence and late stage and often irreversible complications. Far better to identify an alcohol use disorder at an earlier or milder stage of its development, which it would be termed hazardous alcohol use, harmful alcohol use, or alcohol abuse, when the person affected would not have the physiological changes of a dependence syndrome and would be better able to modify their use and at a change when their life generally was more likely to be intact. The empirical evidence for screening and brief intervention for alcohol use disorders is compelling. Scores of randomized controlled trials and met analyses have shown evidence for effectiveness of this approach, although the overall effect size is modest. The real advantage of screening and brief intervention is that it can be offered at the point of first contact with the health care system, it can be repeated as appropriate, and – a more recent development – it can be presented electronically in a way which is confidential and engages the person with the substance disorder.

This chapter, written by John Saunders and Noeline Latt, reviews the available screening instruments for alcohol use disorders with an emphasis on the modern generation of instruments such as the Alcohol Use Disorders Identification Test (AUDIT). There follows a summary of the available data on the effectiveness of brief therapeutic interventions for alcohol use disorders, which typically but not necessarily follow a screening process. Evidence is provided for a significant reduction in alcohol intake, frequency of drinking to impairment, alcohol-related injuries, and other problems and even in one analysis long-term mortality. The authors emphasize that the key issue for the screening and brief intervention approach in clinical practice is to provide incentives in the health care system for practitioners and also health care services to deliver these interventions in a systematic way. In an effort to provide greater reach to persons with substance use disorders, screening and intervention has been adapted to various types of electronic format, including computer-presented and website-based interventions which offer a high level of interaction and tailor-made advice.

Screening and early detection has also been adapted for other substance use disorders. With the expanding evidence on the adverse health effects of tobacco smoking, notably carcinoma of the bronchus, chronic obstructive airways disease, and accelerated vascular disease, public health approaches were established, initially in some English-speaking countries and Nordic countries to reduce cigarette smoking at a population level. In addition to public policies to discourage the uptake of smoking and the application of sales taxes to reduce the level of use,

programs of screening for cigarette smoking and nicotine dependence, combined with brief "quit smoking" interventions, were developed. The chapter by Sawitri Assanangkornchai and Guy Edwards reviews the commonly used screening instruments, including the various forms of the Fagerstrom questionnaire and also briefly the evidence for the effectiveness of brief smoking cessation techniques (▶ Chap. 13, "Screening for Nicotine and Drug Use Disorders").

The authors follow with a review of approaches for screening and early detection of drug use, including cannabis (marijuana), amphetamines, cocaine, and other psychostimulants and heroin and related opioids. They describe a purpose designed screening questionnaire developed as part of a World Health Organization collaborative study, the Alcohol and Other Substances Screening and Identification Test (the ASSIST). They review the utility of this instrument, both within formal screening programs and as a tool for early detection in clinical practice. Screening with the ASSIST leads conveniently to a brief intervention, and the format of the ASSIST initially identifies which substance is of most concern to the respondent. The therapeutic intervention then focuses on the nominated substance with the aim of cessation or minimization of use of that substance. The principle of adjunctive behavior also facilitates reduction of other unhealthy forms of substance use by that person.

The range of brief interventions currently available for drug use disorders is reviewed by Jennifer Harland and Linda Gowing. They examine the evidence for effectiveness of brief interventions as applied to the main forms of psychoactive substance use, namely, cannabis, psychostimulants, and opioids. Several controlled trials have shown that brief structured intervention can reduce the use of cannabis. The interventions tend to be lengthier and more intensive than the brief interventions described earlier for alcohol and cigarettes. With regard to cannabis, between one and four sessions each lasting for up to 1 h have been shown to lead to a significant reduction in cannabis smoking in a dose-dependent manner. These interventions represent the most effective ones to help people cease cannabis use, and the main question is how they might best be offered in health care systems. They are clearly too lengthy to be offered by general medical practitioners. Potentially, primary health care could be a suitable venue and with the involvement of a therapist to undertake the necessary screening and intervention. Other forms of drug use are less common in the general population, and the issue here is how brief interventions might be adapted for these forms of drug use and presented to populations at risk. We certainly have evidence for effectiveness of brief structured interventions aimed at cessation or reduction in psychostimulant use. Studies have shown that between one and six therapy sessions lead to an overall reduction in methamphetamine use by approximately 40 %. Similar findings are seen with cocaine-related therapies. As with cannabis these interventions tend to be lengthier, taking up to 1 h per session and are therefore out of the scope of general medical practice. Again, primary care settings could for a venue for these interventions to be provided by specific therapists.

The final two chapters in this section concern laboratory testing for alcohol and other drugs. Friedrich Wurst reviews laboratory tests of alcohol consumption, with

an emphasis on a new range of markers which represent intermediary metabolic products of alcohol. These include ethyl esters such as ethyl sulfate and ethyl glucuronide. Contrast is made between the existing conventional biological markers of alcohol and these new ones. The conventional markers reflect the pathophysiological effects of alcohol, particularly in excessive amounts on various organs and body systems. For example, alcohol-related bone marrow toxicity results in abnormalities of various indices in the full blood count, notably an increase in mean erythrocyte cell volume (MCV). Enlarged red cells are produced by bone marrow and persist for the typical length of a red blood cell, which is 4 months. The MCV can therefore provide a useful indicator of alcohol consumption in recent months, and, with the turnover of red cells, abstinence or substantial reduction in alcohol intake results in a gradual reduction in MCV. There is a range of liver function tests which can also reflect hepatic enzyme induction or hepatotoxic effects of alcohol. These include the transaminases, aspartate aminotransferase (AST) and alanine aminotransferase (ALT), and gamma glutamyl transferase (GGT). Other liver function tests are affected by alcohol, but these, especially GGT, are the more sensitive markers. However, it will be apparent that other causes of liver disease, unrelated to alcohol, can cause abnormalities, as indeed can certain diseases of muscle and bone where these enzymes are also present. Other biological markers of alcohol that have been employed include uric acid, HDL cholesterol, and urinary metabolites such as 5-hydroxy tryptophol. As Dr Wurst indicates, the particular advantage of the ethyl esters and related compounds is their greater specificity for excessive alcohol consumption. These markers are still in the research phase, but their potential may well be realized for clinical and population-level screening.

The final chapter in this section covers laboratory testing for drugs and is written by Philip Paull. In contrast to the laboratory markers for alcohol, detection of drug use involves identification in urine, blood, saliva, or other body fluids of the parent drug or a metabolite. Equivalent biological markers of drug use (to those available for alcohol) do not exist. Paull reviews the currently available assay systems for drug detection. Broadly, they encompass screening tests, several of which can be undertaken in hospital wards, clinics, and consulting rooms. More definitive assays are undertaken in specialist drug testing laboratories, and in addition to various screening tests based on electrophoresis and radio immunoassay, definitive identification of the specific substances is also available using gas chromatography combined with mass spectroscopy (GCMS). This technique is based on a unique signal that different chemical compounds produce in terms of the mass ratio at a particular point in the spectrum. There is increasing emphasis on drug screening which can be undertaken in clinic settings. This is particularly valuable when decisions on treatment or the application of contingencies has to be made when the drug user is attending for therapy. The ability to provide feedback within a short period of time based on the presence or absence of a particular drug is a considerable advantage compared with the time that is commonly taken for a urine (or other) sample to be delivered to a laboratory, for the assay to be undertaken, and the result returned to the requesting practitioner.

In summary, the chapters in Sect. II provide a state-of-the-art account of methods of screening and brief focused interventions, with the first chapter on "Diagnosis and classification" (▶ Chap. 11, "Diagnostic Definitions, Criteria and Classification of Substance Use Disorders") providing a clear categorization of the various types of drug-related disorder that are the target of these interventions.

Abstract

Diagnostic terms exist to identify forms of substance use which are causing clinical impairment or risk and to distinguish them from normality. Acute intoxication refers to a state caused by the acute pharmacological effects of the substance. Repetitive substance use which confers the risk of harmful consequences is termed "hazardous" or "risky" use. Substance abuse is a DSM-IV term which denotes a maladaptive and repetitive pattern of substance use which causes essentially social and personal problems. "Harmful use" is an ICD-10 term which denotes repetitive substance use which is actually causing physical or psychiatric harm. At the top of the hierarchy of disorders in both DSM-IV and ICD-10 is the substance dependence syndrome. This is defined as a psychobiological syndrome that comprises impaired control over substance use, tolerance, and withdrawal symptoms and is characterized by continued use of the substance despite harmful consequences. Underlying the dependence syndrome is a set of enduring neurobiological changes in brain reward, stress, salience, and control systems. These result in an internal "driving force" to use and continue to use a particular substance (or group of substances) in a self-perpetuating way. The recently published DSM-5 has changed the diagnostic landscape as it has deleted the diagnoses of substance dependence and substance abuse and replaced them with a broader condition of "substance use disorder." DSM-5 also classifies as "substance-induced disorders" the conditions of intoxication and withdrawal. In addition to these diagnoses are the numerous mental, neurocognitive, and physical complications. They include substance-induced mental disorders such as depressive disorders, anxiety disorders, psychotic disorders, bipolar and related disorders, obsessive–compulsive and related disorders, sleep disorders, sexual dysfunctions, delirium, and neurocognitive disorders. ICD-10 has comprehensive coverage of all physical disorders induced by psychoactive substance use. However, DSM-5 essentially neglects the significant medical/physical complications of alcohol and other substance use and has abandoned the multiaxial system, which included (as Axis III) associated physical conditions.

Diagnosis is based on a set of specific diagnostic criteria which reflect the particular pattern of substance use and the psychophysiological attributes and mental and other consequences of the condition. The key diagnoses in DSM-IV, DSM-5, and ICD-10 are reviewed in this chapter. Clinical diagnosis of these disorders is based on clinical knowledge and training. In addition there are several diagnostic interview schedules, together with screening and assessment instruments, which contribute to the diagnosis.

11.1 Introduction

Psychoactive substance use exists as a continuum and substance use disorders as a hierarchy. Some forms of substance use, for example, alcohol, are not harmful, or at least very low risk, in small amounts. Other psychoactive substances such as prescribed benzodiazepines are medically necessary and appropriate in many

situations. Illicit drugs, such as cannabis (marijuana), may have functional value to some people, and there may be a threshold of use for some beneath which little harm occurs. However, all these substances have an inherent capacity to cause intoxicating effects, dependence (addiction), and a range of physical, neurocognitive, psychological, and social harms.

Diagnoses are made to facilitate communication between different health-care providers and to provide a basis for some form of intervention. The intellectual process underlying diagnosis also serves to distinguish the patient's condition from normality. Some diagnoses indicate forms of substance use that confer the risk of harmful consequences in the future, others indicate current clinical illness or impairment, and yet others indicate syndromal disorders. A coherent system of diagnosis and classification provides a vital structure for the practice of addiction medicine.

The present time is a period of considerable change in diagnostic concepts and terminology. One of the principal diagnostic systems, the Diagnostic and Statistical Manual of Mental and Behavioural Disorders, has recently published its fifth edition (DSM-5) (American Psychiatric Association 2013). Substance use disorders have been radically restructured within it, and this will be described below. At the present time, the International Classification of Diseases, which is the international basis for disease, morbidity, and mortality coding, is undergoing revision, with the 11th revision (ICD-11) being scheduled for publication in 2015. Changes to the diagnostic criteria of addictive disorders are contemplated, but the essential diagnostic concepts may be similar to the current version ICD-10 (World Health Organization 1992). Many addiction specialists in North America and elsewhere adopt the diagnostic concepts and criteria developed by the American Society of Addiction Medicine and the International Society of Addiction Medicine. The conceptual understanding of substance disorders is rather different in these formulations and the diagnostic criteria have only passing resemblance to those employed in the DSM and ICD systems. A further contrast is provided by the emphasis in the fields of epidemiology and public health on quantification of substance use and not to define specific behavioral or psychophysiological disorders.

It will be apparent from the foregoing comments that a synthesis of diagnostic concepts in the current classification systems is not possible. In this chapter we shall present a history of common concepts of substance use disorders and then review the key diagnoses in the current international diagnostic systems. Before this we shall briefly review the range of addictive (dependence-inducing) and potentially harmful psychoactive substances and also the patterns of substance use that need to be captured by a diagnostic classification system.

11.2 Diagnoses

11.2.1 The Range of Addictive Substances

There are many thousands of naturally occurring and synthetic substances that have the capacity to induce addiction, and new ones are continually being synthesized.

Substances with addictive potential tend to have acute psychological effects which consumers find pleasant, at least initially and in the majority of cases. They tend to cause euphoria and, in many cases, a sense of relaxation. Certain substances are valued because they relieve pain or sickness and therefore are described as having a medicinal effect as opposed to a primary hedonic one. The pharmacokinetic properties of the substance influence its addictive potential, with the rapidity of absorption (and therefore action), ease of penetrating the blood/brain barrier, and duration of action influencing the likelihood of recurrent self-administration and therefore addiction. Addictive potential is also influenced by the mode of administration, with the smoking and intravenous injecting routes inducing more rapid addiction than oral ingestion. Addictive substances tend to have a biphasic action, whereby the hedonic effect is typically followed by negative symptoms consequent on declining blood and tissue levels of the substance. The neurobiological changes which occur in this phase could be regarded as "restorative," with the aim of returning neuronal systems to their normal functioning state.

The propensity of psychoactive substances to induce addiction therefore ranges considerably depending on the mode of administration, the substance's pharmacodynamic and pharmacokinetic properties, and also the social setting in which the substance is taken. Caffeine as occurs in coffee, tea, and certain soft drinks and once considered a minor stimulant at the lowest end of the addiction spectrum is listed in modern systems such as DSM-5 (American Psychiatric Association 2013). Certain other substances have psychoactive properties and are harmful, but are not or only rarely addictive. These include most of the hallucinogens, where the acute psychoactive effects (often of a psychedelic or psychotomimetic nature) commonly result in clinical presentations but where addiction/dependence is very uncommon. Other substances such as sugar and certain commercial soft drinks exist in a borderline area where addiction is described, but is not typical and is often rare. Substances in this last domain will not be further considered in the present chapter.

Many prescribed and proprietary ("over the counter") medications have addictive potential. Because of the commercial value of these medications, there is controversy as to whether they should be termed addictive substances as opposed to their inducing physiological dependence. In the medical community there is a divergence of opinion between those who would exclude medication use when it is being prescribed through a prescription or advised by a medical practitioner and those authorities who regard the occurrence of a desire for repeated administration of such medications and the occurrence of withdrawal symptoms to indicate that addictive processes are present in the individual.

11.2.2 Excessive Use and Repeated Use

Diagnoses are applied to the use of psychoactive substances to denote:

- An episode of excessive use, producing clinically significant effects – termed acute intoxication but which may in severe cases be termed poisoning.

- Repeated substance use which places the person at risk of harmful consequences – this is typically termed "hazardous" use, "risky" use, or "unhealthy" use.
- Repeated use which is causing physical, mental, or neurocognitive damage – termed "harmful use" in ICD-10.
- Repetitive substance use which has resulted in personal or social problems – termed "substance abuse" in DSM-IV.
- Repetitive substance use which has the features of a syndrome where there is an internal drive to continue and self-perpetuating use – termed "substance dependence" in DSM-IV and ICD-10.
- Repetitive substance use which is causing some form of addictive or harmful consequence – this is the new DSM-5 formulation of "substance use disorder."
- Substance-related problems or disabilities, which encompass the multiple physical disorders, mental health disorders, neurocognitive impairments, and social, personal, occupational, and legal problems.

In the diagnostic systems covered in this chapter, not all of these diagnostic entities are incorporated.

11.2.3 Mechanisms Underlying Repetitive Substance Use

There are numerous psychological and social influences which determine whether a substance with psychoactive properties is actually used, periodically or repeatedly, and may potentially lead to harmful consequences and addiction. An important determinant is the availability of a particular substance in a society, and this is in turn may be determined by whether it is of plant origin and requires particular climatic conditions or level of rainfall to grow. Other substances are chemically synthesized and require a corresponding level of knowledge and technical equipment to produce.

Psychological mechanisms are involved in substance use becoming repetitive use, and classical conditioning theory, operant conditioning theory, and social learning theory all contribute to our understanding of how this eventuates. The reader is referred to suitable reviews for further reference.

Neurobiological mechanisms come into play in particular when a pattern of repetitive substance use has developed and result in that repetitive use tending to become more stereotyped and self-perpetuating, being driven by internal cues rather than external circumstances. The essential result of the neurobiological mechanisms of addiction is the generation of an internal driving force, which is enduring and which promotes further substance use even in the absence of external cues and continues to do so even when circumstances are inappropriate for substance use and the person may actually be experiencing harm as a result of that use. The driving force of what is termed substance dependence or addiction results in substance use occupying a more and more central role in the person's life, with other interests, enjoyments, activities, and responsibilities being relegated to the periphery. Much has been learned about the neurobiological

processes, and it appears there are interlinked neurocircuits which are "re-set" in a person with addiction. These subserve reward, alertness (excitation), and salience on behavioral control.

In summary, in the early period of psychoactive substance use, that use is influenced strongly by external circumstances and also by the person's mood state. As repeated use continues and dependence develops, the repetitive use reflects more the internal neurobiological mechanisms that have developed. It is these mechanisms that result in repetitive substance use becoming more and more syndromal and to produce the clinical disorders we recognize as addiction.

11.2.4 Concepts of Substance Use Disorders

11.2.4.1 Personality Disorder

In the first edition of DSM, published in 1952, substance misuse was included in the personality disorders (American Psychiatric Association 1952). Drug addiction was not specifically defined, but there was a statement that it was usually symptomatic of a personality disorder. The second edition, published in 1968 (American Psychiatric Association 1968), had substance use disorders classified within the personality disorders. There were no specific definitions or criteria and little description of the conditions. The diagnosis of drug dependence required "evidence of habitual use or a clear sense of a need for the drug" (American Psychiatric Association 1968).

11.2.4.2 The Disease Concept

Many groups view substance use disorders as reflecting a disease process, which is biologically determined and results in the individual having an individualistic reaction to a psychoactive substance and a relatively predictable natural history. This conceptualization influenced and was subsequently embraced by the self-help movements, such as Alcoholic Anonymous. Jellinek developed the concept of the disease of alcoholism in the 1940s and 1950s (Jellinek 1960), although in his later work he increasingly recognized the role of environmental influences. During the 1960s and 1970s, the concept that substance misuse might represent a disease process was dismissed by most scientists and professionals. Likewise, the role of genetic predisposition was thought to be inconsequential, with the familial aggregation of substance misuse explained by cultural influences, role modelling, or malfunction within families.

11.2.4.3 Epidemiological and Sociological Formulations

A third tradition may be described as the epidemiological and sociological one. Put simply, substance misuse and problems arise fundamentally because of the overall level of use of that particular substance in society. In the 1950s Ledermann (1960) proposed a relationship between the level of alcohol consumption in a community and the prevalence of alcoholism. The level of use is, in turn, influenced by the availability of alcohol, its manufacture and distribution, its price (importantly), and

cultural traditions and sanctions. Inherent in these conceptualizations is that individual pathology is considered of secondary importance. The social constructionist school views substance use problems as disaggregated, with no special relationship among them. This school of thought was concerned about the stigma attributable to diagnostic labels and the potential of treatment as a form of social control (Room 1989).

11.2.4.4 Learned Behavior

The 1970s saw the rise of social-cognitive theory (Bandura 1977) as an influential paradigm to explain the development and resolution of alcohol and drug problems. This school of thought teaches that the (many) influences that determined behavior in general apply to the uptake of substance use and the development of disordered use. Positive consequences encourage repeated use, negative ones the opposite. Patterns of substance use behavior could become established in this way, but, equally, repetitive substance use could be "unlearned." This led to the development of a range of cognitive behavior therapies, some of which aimed at moderated or "controlled" substance use (Sobell and Sobell 1993).

11.2.4.5 Clinical Syndrome

The need for an understanding of substance misuse which spanned these various discipline-bound conceptualizations and terms was largely met by the formulation of the concept of a "substance dependence syndrome" originally proposed with regard to alcohol dependence by Edwards and Gross in 1976 (Edwards and Gross 1976). The basis of the dependence syndrome was a clinical description of key clinical features in a way that was essentially theoretical and was not based on any particular etiological understanding of the disorder, be it biological, behavioral, or sociological. Rather, certain experiences, behaviors, and symptoms related to repetitive alcohol use were identified as tending to cluster in time and to occur repeatedly. The advantage of a descriptive account of dependence is that it can accommodate etiological models, but not be beholden to them.

The concept of the dependence syndrome applies to many other psychoactive substances that have the potential for reinforcement of use, including benzodiazepines, illicit and prescribed opioids, cannabis, inhalants, psychostimulants such as cocaine and the amphetamines, nicotine, caffeine, and anabolic steroids (Feingold and Rounsaville 1995; Owen and Tyrer 1983; Saha et al. 2006; Teesson et al. 2002). It may also apply to repetitive behaviors that do not involve self-administration of a psychoactive substance. These include pathological gambling and compulsive shopping and exercise (Lejoyeux et al. 2000; Potenza 2006). "Disordered gambling" has now been added to DSM-5 (American Psychiatric Association 2013).

The dependence syndrome has been at the heart of the classification systems of psychoactive substance use disorders since the 1980s (Krabman and Saunders 1996; Saunders 2006). It is the principal substance use disorder in DSM-IV and ICD-10 (World Health Organization 1992) and in the more recent revisions of DSM, namely, DSM-IIIR and DSM-IV (American Psychiatric Association 1968, 1994, 2000). However, in the latest revision DSM-5 published in May 2013,

the dependence syndrome is subsumed under substance use disorder or alcohol use disorder (American Psychiatric Association 2013).

11.2.4.6 Neurobiological Disorder

Neurobiological mechanisms come into play particularly when a pattern of repeated use has become established. They induce a driving force to use the substance in preference to other human activities or interests and do so in continuing and seemingly compulsive way. They cause reinforcement and indeed self-perpetuation of psychoactive substance use. Increases in tolerance favor consumption of larger and larger doses of the substance. The three key neurobiological changes in dependence are:

(i) Activation and then inhibition of brain reward systems, particularly involving dopaminergic transmission and opioidergic transmission. These have the effect of re-setting the reward systems such that larger amounts of the substance are needed to produce the desired effect and natural rewards are not as reinforcing (Volkow et al. 2004).

(ii) Recruitment of brain stress systems, including those subserved by glutamate neurotransmission and corticotrophin releasing factor (CRF) (Room 1989) and suppression or uncoupling of antistress systems (Roy and Pandey 2002).

(iii) Impairment of inhibitory control pathways from the prefrontal cortex to the mesolimbic systems, resulting in impaired decision-making capacity (Yücel and Lubman 2007).

(iv) Re-setting of the salience circuitry arising from the cingulate gyrus of the frontal lobe and changing the importance of substance use relative to other interest, activities, and responsibilities.

A publication on the neuroscience of addiction by the World Health Organization summarizes the key developments in biomedical research over this period (World Health Organization 2004).

Investigations into possible genetic influences have accompanied this research on neural circuitry. Biometric genetic studies have shown that children born of parents with substance dependence are more likely to have substance dependence themselves (Saunders 1982) and that this is largely explained by genetic transmission rather than environmental factors (Ball 2008; Saunders 1982). Genomic analysis in human and laboratory animals has identified several areas of the genome where mutations are associated with increased risk of substance use disorders (Ball 2008).

11.2.5 Substance Use Diagnoses in DSM-IV, DSM-5, and ICD-10

Although many different systems of diagnosis and classification have been proposed for substance use disorders over the years, two have international recognition. They are the Diagnostic and Statistical Manual of Mental Disorders (DSM) of the American Psychiatric Association, Fourth and Fifth Editions (DSM-IV and DSM-5 respectively) (American Psychiatric Association 1994, 2000, 2013),

which covers only mental and behavioral disorders, and the International Classification of Diseases (ICD) of the World Health Organization (World Health Organization 1992), now in its Tenth Revision (ICD-10), which is a classification of all diseases, injuries, and causes of death.

11.2.6 Substance Dependence

Substance dependence is defined similarly in DSM-IV and ICD-10 (Table 11.1). The dependence syndrome is defined in DSM-IV and ICD-10 as a cluster of behavioral, cognitive, and physiological phenomena that develop after repeated drinking or substance use and which tend to be self-perpetuating. Typically it occurs in people who use large amounts of psychoactive substances repeatedly consuming alcohol in excess of 120 g/day (men) or 80 g/day (women). The diagnosis of substance dependence is not, however, primarily made on the level of consumption but on criteria based largely on the original Edwards and Gross formulation (Edwards and Gross 1976). The criteria in the two systems (in summary format with comments) are listed in Table 11.1.

Substance dependence in DSM-IV is defined very similarly to ICD-10. As with all diagnostic systems, to be of optimal use in the clinic or for the needs of epidemiology and public health planning, the criteria must be both valid and straightforward, and this was foremost in the minds of those who fashioned them. The dependence syndrome applies to most psychoactive substances that have the potential for reinforcement of use (such as benzodiazepines, opioids, cannabis, psychostimulants, and nicotine). However, elements of the syndrome are not necessarily applicable to all substances, for example, hallucinogens. Dependence may also apply to repetitive behaviors that do not involve substance use such as gambling, compulsive shopping, and compulsive exercise (Lejoyeux et al. 2000; Potenza 2006).

Substance dependence does not feature in DSM-5. In its place is the broader and more disaggregated condition of "substance use disorder." This will be discussed further below. The criteria for substance-induced disorder are listed in Table 11.1 for the purpose of comparison with dependence.

11.2.7 Substance Withdrawal

The substance withdrawal syndrome refers to a state which may occur in persons with the dependence syndrome (ICD-10; DSM-IV) and (in a smaller proportion) with substance use disorder (DSM-5). The substance withdrawal syndrome refers to a state seen in persons with the dependence syndrome when use is curtailed. It is an important manifestation of the neurobiological changes that underpin dependence. In general the features of the withdrawal syndrome are opposite to those of the acute pharmacological effects of the substance. In contrast to dependence, the withdrawal syndrome varies appreciably according to the substance. Psychostimulant withdrawal is very different to withdrawal from sedative/hypnotics.

Table 11.1 Diagnostic criteria for dependence/alcohol use disorder/substance use disorder in ICD-10, DSM-IV, and DSM-5

	ICD-10 dependence	DSM-IV dependence	DSM-5 alcohol use disorder/substance use disorder
Stem		A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by 3 or more of the following occurring at anytime in the same 12-month period	A problematic pattern of alcohol (other substance) use leading to clinically significant impairment or distress, as manifested by at least two of the following occurring within a 12-month period
1. New in DSM-5	A strong desire or sense of compulsion to take the psychoactive substance *(craving or compulsion)*	No equivalent criterion – mentioned in text	Craving or a strong desire or urge to use alcohol (or other substance)
2.	No equivalent criterion but text states that the subjective awareness of compulsion is most commonly seen during attempts to stop or control substance use	There is persistent desire or unsuccessful attempts to cut down or control substance use	There is persistent desire or unsuccessful efforts to cut down or control alcohol (or other substance) use
3.	Difficulties in controlling substance-taking behavior in terms of its onset, termination, or levels of use *(loss of control)*	The substance is often taken in larger amounts or over a longer period of time than was intended	Alcohol (or other substance) is often taken in larger amounts or over a longer period than was intended
4.	Progressive neglect of alternative pleasures because of psychoactive substance use or increased amount of time necessary to obtain or take the substance or to recover from its effects	Important social, occupational, or recreational activities are given up or reduced because of drinking or psychoactive substance use	Recurrent alcohol (or other substance) use resulting in a failure to fulfil major role obligations at work, school, or home
5.	Subsumed in above criterion	A great deal of time is spent in activities necessary to obtain the substance, use the substance, or recover from its effects	A great deal of time is spent in activities necessary to obtain alcohol(or other substance), use alcohol (or other substance), or recover from its effects

(*continued*)

Table 11.1 (continued)

	ICD-10 dependence	DSM-IV dependence	DSM-5 alcohol use disorder/substance use disorder
6.	Tolerance: such that increased doses of the psychoactive substances are required in order to achieve effects originally produced by lower doses	Tolerance: as defined by either (a) a need for markedly increased amounts of the substance to achieve the desired effects or (b) markedly diminished effect with continued use of the same amount of the substance	Tolerance is defined by either of the following: (a) a need for markedly increased amounts of alcohol (or other substance) to achieve intoxication or desired effect or (b) a markedly diminished effect with continued use of the same amount of alcohol (or other substance)
7.	A physiological withdrawal state when substance use has ceased or been reduced, as evidenced by the characteristic withdrawal syndrome for the substance or use of the same (or a closely related substance) with the intention of relieving or avoiding withdrawal symptoms	Withdrawal as manifested by either (a) the characteristic withdrawal syndrome for the substance or (b) the same (or a closely related) substance is taken to relieve or avoid withdrawal symptoms	Withdrawal is manifested by either of the following: (a) the characteristic withdrawal syndrome for alcohol (or other substance) (b) Alcohol (or a closely related substance such as a benzodiazepine) (or other substance) is taken to relieve, or avoid withdrawal symptoms
8.	Persisting with substance use despite clear evidence of overtly harmful consequences	The substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance	Continued alcohol (or other substance) use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of alcohol (or other substance)
9. Former DSM-IV abuse		Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance (e.g., arguments with spouse about consequences of intoxication, physical fights)	Alcohol (or other substance) use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by alcohol (or other substance)

(*continued*)

Table 11.1 (continued)

ICD-10 dependence	DSM-IV dependence	DSM-5 alcohol use disorder/substance use disorder
10. Former DSM-IV abuse	Recurrent substance use in situations in which it is typically hazardous (drink driving)	Recurrent use in situations in which it is physically hazardous
11. Former DSM-IV abuse	Recurrent substance use which results in failure to fulfil major obligations at work, school, or home	Important social, occupational, or recreational activities are given up or reduced because of alcohol (or other substance) use
Omitted	Recurrent substance-related legal problems (e.g., driving an automobile or operating a machine when impaired by substance use)	

In DSM-5 the diagnosis of alcohol (or substance) use disorder is further classified according to severity:
Presence of 2–3 symptoms, mild; presence of 4–5 symptoms, moderate; presence of 6 or more symptoms, severe

Substance withdrawal is often listed as a "substance-induced disorder"; however, given its intimate relationship with dependence, it is discussed at this point.

The withdrawal syndrome is defined in the international diagnostic systems as a group of symptoms of variable clustering and severity that occur on absolute or relative withdrawal of a substance after repeated, and usually prolonged and/or high dose, use of that substance. The specific criteria in ICD-10, DSM-IV, and DSM-5 are listed below in Table 11.2. The onset and course of the withdrawal state are time limited and are related to the type of substance and the dose being used immediately before abstinence. Three types of withdrawal are recognized in the ICD-10 and DSM-IV criteria: simple uncomplicated withdrawal, withdrawal with convulsions, and withdrawal with delirium (American Psychiatric Association 1994, 2000; World Health Organization 1992). Cannabis withdrawal was not recognized in DSM-IV, although it is now included in DSM-5 (American Psychiatric Association 2013).

11.2.8 Nondependent Repetitive Substance Use

Repetitive substance use which does not fulfill the criteria for the dependence syndrome is still of clinical significance. It is handled differently in the two systems. In ICD-10 the term harmful use applies to repetitive use of a psychoactive substance which has caused physical or mental harm to that person. In DSM-IV the

Table 11.2 Diagnostic criteria for substance withdrawal in ICD-10 and DSM-IV and for alcohol withdrawal in DSM-V

	ICD-10 substance withdrawal syndrome	DSM-IV (TR) substance withdrawal syndrome	DSM-5 alcohol withdrawal syndrome
1.	Clear evidence of recent cessation or reduction of substance use after repeated and usually prolonged and/or high dose use of that substance. One of the main indicators of the dependence syndrome	(A) The development of a substance-specific syndrome due to cessation of, or reduction in, substance use that has been heavy and prolonged	(A) Cessation of (or reduction in) alcohol use that has been heavy and prolonged
2.	Symptoms and signs compatible with the known features of a withdrawal state from the particular substance or substances. Physical symptoms vary according to the substance being used. Psychological disturbances (e.g., anxiety, depression, sleep disorders) are also common features of withdrawal. Typically the patient reports that withdrawal symptoms are relieved by further substance use	(B) The substance-specific syndrome causes clinically significant distress or impairment in social, occupation, or other important areas of functioning	(B) Two (or more) of the following developing within several hours to a few days after cessation of (or reduction in) alcohol use described in criterion A:
			1. Autonomic hyperactivity (e.g., sweating, PR $>$ 100 bpm)
			2. Increased hand tremor
			3. Insomnia
			4. Nausea or vomiting
			5. Transient visual, tactile, or auditory hallucinations or illusions
			6. Psychomotor agitation
			7. Anxiety
			8. Generalized tonic–clonic seizures
3.	The features are not accounted for by a medical disorder unrelated to the substance use and not better accounted for by another mental or behavioral disorder	(C) The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder	(C) The signs and symptoms in criterion B cause clinically significant distress or impairment in social, occupational, or in other important areas of functioning

term substance abuse refers to repetitive use of a psychoactive substance which essentially is causing social harm or problems. There is no equivalent term in ICD-10; indeed ICD-10 eschews the motion of a disorder that is defined by social criteria. Other nondependence conditions have been proposed and tentatively defined; they are covered later.

11.2.8.1 Substance Abuse

Substance abuse is defined in DSM-IV as repeated substance use that leads to one or more social or occupational problems. It is understood as a less severe condition than dependence. The two diagnoses cannot coexist in the same time period,

as substance abuse is preempted by a diagnosis of dependence. Substance abuse can be envisaged as one axis of a biaxial conceptualization of substance use disorders, which separates the core syndrome of dependence from the consequences. However, there is blurring of this conceptualization because of its hierarchical relationship with dependence, i.e., as a less severe disorder. The extent to which the biaxial relationship applies and indeed whether abuse is properly separated from dependence remains controversial, with some studies finding a one factor solution that covers the spectrum of abuse and dependence criteria being optimal (Edwards et al. 1981; Nelson et al. 1999; Teesson et al. 2002). DSM-5 does not have a separate diagnosis for substance abuse which is subsumed under substance use disorders.

11.2.8.2 ICD-10 Harmful Use

Harmful substance use is a repetitive pattern of substance use, at levels which result in actual physical or mental harm, but does not fulfill the criteria for the dependence syndrome. The harmful effects may be acute or chronic. Examples of acute complications include fractures and other forms of trauma, acute gastritis, and acute psychotic symptoms following substance use. Chronic medical complications encompass liver disease (e.g., alcoholic liver disease or hepatitis C-induced liver disease following injecting drug use), cardiovascular diseases, respiratory diseases, various neurological sequelae, and many others. Examples of mental complications are depressive episodes secondary to heavy alcohol intake and substance-induced psychosis. In clear distinction to DSM-IV, social complications per se are insufficient to justify a diagnosis of harmful use under the WHO nomenclature (Saunders 2006; World Health Organization 1992).

11.2.9 Broadening the Definition: Substance Use Disorder in DSM-5

As mentioned above, DSM-5 has radically restructured the conceptualization and classification of substance-related disorders (American Psychiatric Association 2013) (Table 11.1). Substance dependence and abuse have been replaced by the broader concept of substance use disorder.

11.2.9.1 Alcohol (Substance) Use Disorder

Alcohol (substance) use disorder is defined in DSM-5 as a cluster of cognitive, behavioral, and physiological symptoms (which can include withdrawal, tolerance, and craving), indicating that the individual continues using the substance despite significant substance-related problems. Substance use disorders are classified separately under 10 separate classes of drugs, viz., alcohol, caffeine, cannabis, hallucinogens, inhalants, opioids, sedatives/hypnotics/anxiolytics, stimulants, tobacco, and other (unknown) substances.

Alcohol use disorder is defined as a problematic pattern of alcohol use leading to clinically significant impairment or distress, as manifested by at least two of 11 criteria (Table 11.1) occurring within a 12-month period.

11.2.10 Other Definitions of Addiction or Dependence

The two systems that have most impact internationally are the ICD and the DSM, under the auspices of the World Health Organization and the American Psychiatric Association (APA) respectively. Several professional organizations have developed definitions for use by their own members/fellows (the APA is a national professional organization, but the DSM has such international reach that it is more appropriately classified as an international system). Foremost of these other organizations is the American Society of Addiction Medicine (ASAM). It employs the term addiction rather dependence or "use disorders." The ASAM definition of addiction (American Society of Addiction Medicine 2011) is as follows:

> Addiction is a primary, chronic disease of brain reward, motivation, memory and related circuitry. Dysfunction in these circuits leads to characteristic biological, psychological, social and spiritual manifestations. This is reflected in an individual pathologically pursuing reward and/or relief by substance use and other behaviours.
>
> Addiction is characterized by inability to consistently abstain, impairment in behavioural control, craving, diminished recognition of significant problems with one's behaviours and interpersonal relationships, and a dysfunctional emotional response. Like other chronic diseases, addiction often involves cycles of relapse and remission. Without treatment or engagement in recovery activities, addiction is progressive and can result in disability or premature death.

This is a fundamentally different concept to those of dependence in the ICD and DSM systems and even more distant to the DSM-5 understanding of substance use disorders. The main points of distinction are:

1. The disorder is described as "primary" and suggests a fundamental (presumably) biological difference between those who are addicted and those who are not, rather than the notion of an acquired syndrome which is the nature of the dependence syndrome.
2. The disorder is described as "progressive" in an unqualified way, which is different to the concept that dependence can undergo "natural" remission (i.e., without treatment).
3. There is no sense of a spectrum of disorder.

There are five central features of addiction in this conceptualization, which are:

(a) Inability to consistently *a*bstain
(b) Impairment in *b*ehavioral control
(c) *C*raving, or increased "hunger" for drugs or rewarding experiences
(d) *D*iminished recognition of significant problems with one's behaviors and interpersonal relationships
(e) A dysfunctional *e*motional response

These features (note they are abbreviated ABCDE) might be considered diagnostic criteria for addiction, although it is not clear how many are required for the diagnosis and in what combination. The psychometric performance of the criteria is unknown. Despite these shortcomings, the ASAM definition well summarizes the experience of patients at the severe end of the spectrum of substance use disorders. It has an intuitive appeal to many clinicians, particularly those working in inpatient

treatment programs and residential recovery programs. The definition has been adopted, on a temporary basis, by the International Society of Addiction Medicine and the Canadian Society of Addiction Medicine.

11.2.11 Other Forms of Repetitive Substance Use

The disorders of substance dependence, substance abuse, harmful use, and (DSM-5) substance use disorder do not encompass the whole spectrum of damaging (or potentially damaging) substance use and pose limitations for prevention, for early intervention clinical work, and for epidemiological purposes. Several other conditions (or "states") were described in the report of a WHO Expert Committee, which was published in 1980 (Edwards et al. 1981). These were:

Unsanctioned use. This was defined as the use of a substance that is not approved by a society or by a group within that society. This term implies that this disapproval is accepted as a fact in its own right, without the need to determine or justify the basis of the disapproval.

Dysfunctional use. This is substance use that leads to impaired psychological or social functioning, for example, loss of employment or marital problems.

Hazardous use. This is repetitive substance use which places the person at risk of harmful consequences. In the WHO formulation, this was defined as physical and mental harm, but in other definitions harm has been taken to incorporate social and legal consequences too. Hazardous substance use is sometimes referred to as "at risk," "risky" or "medium," or "high risk" substance use.

Of these, only "hazardous use" has survived as a term in common use, and even so it does not feature in ICD-10. It, or similar terms, has been operationalized for alcohol consumption in several countries. For example, in the USA, men who drink five or more standard drinks (65 g alcohol) in a day or more than 15 standard drinks (195 g) per week and women who drink more than four standard drinks (50 g) in a day or eight standard drinks (105 g) per week are considered to be drinking excessively (National Institute on Alcohol Abuse and Alcoholism 2005; Saha et al. 2006). Repeatedly consuming 5+ (men) or 4+ (women) US standard drinks (65 and 50 g alcohol respectively) confers a risk of alcohol use disorders and acute and chronic illnesses and injuries (Dawson et al. 2005; Russell et al. 2004). In Australia hazardous or risky consumption has been defined for some years as repeated daily consumption of more than four Australian standard drinks (40 g alcohol) for a man and more than two standard drinks (20 g alcohol) for a woman (Dawson 2000), although in the most recent publication, the criteria for men have been reduced to the same level as for women. In some Asian countries hazardous or risky drinking indicates consumption at levels that lead to intoxication twice a month or more.

The application of hazardous or "risky" use to other substances has been slower. For nicotine (tobacco), it can be argued that there is no nonhazardous level of use. Likewise, because of uncertainties as to whether there is truly a safe or low-risk level of use for other substances, the concept has not been applied widely to illicit

drugs such as cannabis, the amphetamines, cocaine, or heroin, although research on quantifying and establishing the risk of low-level cannabis use is emerging. For epidemiological and public health purposes, having a term that defines various levels or patterns of substance use as conferring risk is advantageous. Indeed, recent data from the National Epidemiologic Survey of Alcohol and Related Conditions (NESARC) indicate that hazardous alcohol consumption (defined as the US 5+/4+ standard drink criterion) exists within the continuum of abuse and dependence criteria (Saha et al. 2007). As the frequency of this level of consumption increases, this experience moves along the severity continuum to overlap with abuse and dependence criteria (Saha et al. 2007).

At the same time, to examine relationships between use patterns and consequences without considering whether a diagnosable substance use disorder is present, as is usual in epidemiological studies, is limiting. The reduction in all-causes mortality among people with moderate levels of alcohol consumption is not seen in those who have had a previous diagnosis of alcohol dependence (Dawson 2000). In support of including hazardous use in a diagnostic system is the evidence that it can be defined and it responds to therapy, the evidence base for the effectiveness of interventions for hazardous alcohol consumption being particularly strong (Bertholet et al. 2005; Kaner et al. 2009). Thus, in a comprehensive diagnostic system, there are grounds for having a dependence category, a nondependence disorder that is of clinical consequence and a "subthreshold" disorder that indicates risk to individuals and populations.

11.2.11.1 Diagnostic Orphans

A term that developed after DSM-IV was published was "diagnostic orphans." These are substance users who report some symptoms of dependence, but do not meet diagnostic criteria for either DSM-IV dependence or substance abuse. In young people it is a common category, as common (with respect to alcohol) as dependence or abuse (Eng et al. 2003). Alcohol diagnostic orphans have a natural history that is closest to that of alcohol abuse, though have fewer alcohol-related problems over time. Cannabis diagnostic orphans are also similar in use patterns to those with cannabis abuse (Degenhardt 2002). The term "diagnostic orphan" is now redundant given that DSM-5 has reduced the cutoff point for criteria for substance use disorder to two.

11.2.12 Substance-Induced Disorders

Substance-related problems (or disabilities) were conceptualized by the WHO Committee as the *consequences* of repetitive substance use (Edwards et al. 1981; Saunders 2006). They include both acute (short-term) effects and chronic (long-term) ones (Latt et al. 2009). Acute intoxication is usually placed within the substance-induced disorders, although it is a manifestation of the acute pharmacological effects of the substance. Its central features are listed in Table 11.3 (which provides the DSM-5 criteria).

Table 11.3 Diagnostic criteria for alcohol intoxication – DSM-V

(A) Recent ingestion of alcohol
(B) Clinically significant problematic behavior or psychological changes that developed during or shortly after alcohol ingestion
(C) One, or more, of the following signs or symptoms developing during or shortly after alcohol use:
(a) Slurred speech
(b) Incoordination
(c) Unsteady gait
(d) Nystagmus
(e) Impairment of attention or memory
(f) Stupor or coma
(D) The signs and symptoms are not attributable to another medical condition and are not better explained by another mental disorder, including intoxication with another substance

In the remaining part of this chapter, we shall describe the common substance-induced mental disorders, with a brief comment only on substance-induced physical disorders.

11.2.12.1 Substance-Induced Mental and Neurocognitive Disorders

In DSM-IV and ICD-10 there are several substance-related mental disorders. These include substance-induced depression, substance-induced anxiety disorder, substance-induced bipolar disorder, and substance-induced psychotic disorder. In DSM-5 the same disorders are present, but they are located in the chapters describing the respective generic mental disorder. For example, substance-induced anxiety disorder is grouped within the Anxiety Disorders Section. A generic description of substance-induced mental disorders as per DSM-5 is provided as Table 11.4.

In addition, there are neurocognitive consequences of substance use disorders. Here we shall briefly describe one of the former, psychotic disorder, and two of the latter, delirium and amnesic syndrome.

11.2.12.2 Psychotic Disorder

Psychosis and/or psychotic symptoms occur in many people with substance use disorders. In some this reflects an underlying independent disorder such as schizophrenia. In others the psychosis is a consequence of drug use. In others the precise mechanism remains unclear. ICD-10 defines substance-induced psychotic disorder as a phenomenon that occurs during or immediately after psychoactive substance use (usually within 48 h) and is characterized by vivid hallucinations (typically auditory but often in more than one sensory modality), misidentifications, delusions and/or ideas of reference (often of a paranoid or persecutory nature), psychomotor disturbances (excitement or stupor), and an abnormal affect, which may range from intense fear to ecstasy (World Health Organization 1992). The sensorium is usually clear, but some degree of clouding of consciousness, though not severe confusion, may be present. The disorder typically resolves at least partially within one month

Table 11.4 Substance/medication-induced mental disorders – DSM-V

(A) The disorder represents a clinically significant symptomatic presentation of a relevant mental disorder
(B) There is evidence from medical history, physical examination, or laboratory findings of both of the following:
(a) The disorder developed during or within 1 month of substance intoxication or withdrawal or taking a medication
(b) The involved substance/medication is capable of producing a mental disorder
(C) The disorder is not better explained by an independent mental disorder, i.e., one that is not substance or medication induced. Such evidence of an independent mental disorder could include the following:
(a) The disorder preceded the onset of severe intoxication withdrawal or exposure to the medication
(b) The full mental disorder persisted for a substantial period of time (e.g., at least 1 month) after cessation of acute withdrawal or severe intoxication or taking the medication. This criterion does not apply to substance-induced neurocognitive disorders or hallucinogen persisting perception disorder, which persists beyond the cessation of acute intoxication or withdrawal
(D) The disorder does not occur exclusively during the course of a delirium
(E) The disorder causes clinically significant distress or impairment in social, occupational, or other important areas of functioning

and fully within six months. The diagnosis is excluded if the psychotic state is a manifestation of substance withdrawal syndrome. According to DSM-IV, a substance-induced psychotic disorder is defined by (i) prominent hallucinations or delusions developing during, or within a month of, substance intoxication or withdrawal, (ii) the phenomenon is etiologically related to the disturbance, and (iii) that the disturbance is not accounted for by a psychotic disorder that is not substance-induced (American Psychiatric Association 2000).

In DSM-5 (Table 11.5) substance/medication-induced psychotic disorders, is mentioned in the Chapter on Schizophrenia Spectrum and Other Psychotic Disorders with the psychotic disorder associated with alcohol, cannabis, phencyclidine, other hallucinogens, inhalants, sedative/hypnotic/anxiolytic, amphetamine (or other stimulant), cocaine, and other unknown substance. The psychotic symptoms are thought to be a physiological consequence of a drug of abuse (medication or toxin) and cease after removal of the agent. The onset of psychotic disorder during intoxication of a substance is differentiated from that with onset during withdrawal of the substance.

For psychostimulants such as amphetamines and cocaine, there is a dose–response relationship, with psychosis occurring especially in those who have been using high doses and/or over a lengthy period. According to ICD-10, a diagnosis of psychotic disorder should not be made merely on the basis of perceptual distortions or hallucinatory experiences when substances having primary hallucinogenic effects (e.g., lysergic acid (LSD), mescaline, and cannabis in high doses) have been taken. In such cases, and also for confusional states, a possible diagnosis of acute intoxication should be considered. DSM-IV has no such exclusion.

Table 11.5 Diagnostic criteria for substance/medication-induced psychotic disorder – DSM-V

(A) Presence of one or both of the following symptoms:
(a) Delusions
(b) Hallucinations
(B) There is evidence from the history, physical examination, or laboratory findings of both (a) and (b):
(a) The symptoms developed during or soon after substance intoxication or withdrawal or after exposure to a medication
(b) The involved substance/medication is capable of producing the symptoms in criterion A
(C) The disturbance is not better explained by a psychotic disorder that is not substance/medication induced. Such evidence of an independent psychotic disorder could include the following: The symptoms preceded the onset of the substance/medication use; the symptoms persisted for a substantial period of time (1 month) after the cessation of acute withdrawal or severe intoxication; or there is evidence of an independent non-substance/medication-induced psychotic disorder (e.g., history of recurrent non-substance/medication-related episodes)
(D) The disturbance does not occur exclusively during the course of a delirium
(E) The disturbance causes clinically significant distress or impairment of social, occupational, or other areas of functioning The diagnosis should be made instead of a diagnosis of substance intoxication or withdrawal only when symptoms in Criterion A predominate in the clinical picture and when they are sufficiently severe to warrant clinical attention

11.2.12.3 Delirium

Delirium is an uncommon feature of substance misuse, although sometimes the diagnosis is made in persons with acute intoxication. Substance intoxication with delirium is an accepted diagnosis in DSM (American Psychiatric Association 1994, 2000, 2013), but not in ICD-10 (World Health Organization 1992). Most commonly it is seen in those with a severe withdrawal syndrome from alcohol or sedative/hypnotic drugs. The classical disorder is delirium tremens (DTs) (Saunders and Janca 2000), which is a short-lived but occasionally life-threatening toxic-confusional state with accompanying somatic disturbances. It is usually a consequence of absolute or relative cessation of alcohol in severely dependent drinkers with a long history of use. Its onset may be preceded by features of simple withdrawal and/or by withdrawal convulsions. A similar withdrawal delirium is seen after cessation of benzodiazepines and other sedative/hypnotics although with less tremor. In DSM-5 substance intoxication delirium is differentiated from substance withdrawal delirium in the Chapter on Neurocognitive Disorders (American Psychiatric Association 2013).

11.2.12.4 Amnesic Syndrome

Amnesic (or amnestic) syndrome is an example of a substance-related disorder where, typically, neuronal loss has occurred (Table 11.6). The most common form is characterized by impairment of recent memory with relative preservation of remote memory and with normal immediate recall (American Psychiatric Association 1994, 2000; World Health Organization 1992). Disturbances of time sense and ordering of

Table 11.6 Diagnostic criteria for the amnesic syndrome/amnestic disorder

ICD-10 amnesic syndrome (World Health Organization 1992)	DSM-IV criteria for amnestic disorder (American Psychiatric Association 2000)
1. Memory impairment as shown in impairment of recent memory and learning of new material, disturbance of time sense (e.g., rearrangement of chronological sequence, telescoping of repeated events into one, etc.)	(A) The development of memory impairment as manifested by impairment in ability to learn new information or the inability to recall previously learned information
2. Absence of defect in immediate recall, impairment of consciousness, and generalized cognitive impairment	(B) The memory disturbance causes significant impairment in social or occupational functioning and represents a significant decline from a previous level of functioning
3. History of objective evidence of chronic (and particularly high dose) use of alcohol or drugs	(C) The memory disturbance does not occur exclusively during the course of a delirium or dementia and persists beyond the usual duration of substance intoxication or withdrawal
Includes Korsakov's psychosis or syndrome, alcohol or other psychoactive substance induced	(D) There is evidence from history, physical examination, or laboratory finding that the memory disturbance is etiologically related to the persisting effects of substance use

events are usually evident, as are difficulties in learning new material. Confabulation may be marked, but is not invariably present and should not be regarded as a prerequisite for diagnosis. Importantly, other cognitive functions are usually relatively well preserved; the amnesic defects are therefore out of proportion to other disturbances. Personality changes, often with apparent apathy and loss of initiative, and tendency towards self-neglect may be present, but is not regarded as necessary for diagnosis. The amnesic syndrome is not specified as such in DSM-5, but is listed under substance/medication-induced major or mild neurocognitive disorder.

11.2.12.5 Substance-Related Physical Disorders

Alcohol consumption can affect virtually every organ system in the body, while cannabis and tobacco commonly induce respiratory complications. Repetitive psychostimulant use can lead to a range of psychiatric syndromes, including mood disorder and psychotic disorder. Complications arising from repetitive substance use stem not only from the pharmacological properties of a particular substance but from unknown potency, purity, and sterility from contaminants and adulterants with which the substance is prepared, unsafe injecting practices, and the associated lifestyle of the user. The spread of bacterial infections and viral infections, such as hepatitis C and HIV, and to a lesser extent hepatitis B, is important in this regard (American Society of Addiction Medicine 2011; Latt et al. 2009). The disinhibiting effect of alcohol and substance use also places users at risk of sexually transmitted diseases.

In DSM-III, DSM-IIIR, and DSM-IV, relevant physical disorders were noted in Axis III of the multiaxial system. DSM-5 has abandoned this multiaxial system and

comorbid physical disorders receive little attention. ICD-10 by contrast lists an array of these disorders, in keeping with its objective of encompassing all human disorders irrespective of etiology.

Contents

Abstract

Self-recognition of an alcohol use disorder is often late in the natural history of this condition. Because of this and the limited impact of treatment for patients with late-stage complications of their alcohol problem, there has been considerable effort made to identify alcohol consumption where it has reached a hazardous or risky stage or is starting to cause problems, before dependence becomes

entrenched and complications irreversible. The approach of screening and brief intervention represents a secondary intervention approach, which aims to help people reduce their alcohol consumption to low risk levels, and thereby avoid progression to dependence and the development of physical and mental sequelae and social problems. This chapter describes the development of screening instruments such as the Alcohol Use Disorders Identification Test (AUDIT) and several derivatives and alternatives. The performance and applicability of the screening instrument is reviewed. Following this there is an account of brief intervention approaches which aim to provide succinct information on alcohol use and risks to the individual, often combined with brief motivational and behavioral strategies. There is considerable evidence from scores of randomized controlled trials and meta-analyses for the effectiveness of brief interventions in reducing hazardous alcohol consumption and alcohol-related problems. In the long term follow-up studies there is also evidence for reduced rates of hospitalization and mortality rates. The latest developments in screening and brief intervention are their presentation in various electronic formats. Online screening with feedback and brief intervention has shown to be efficacious and has the potential to be accessible to a greater section of the general population than face-to-face interventions in health care settings.

12.1 Introduction

12.1.1 Broadening the Spectrum of Intervention for Alcohol Use Disorders

Self-recognition of an alcohol use disorder is often late in the natural history of the condition. Frequently, patients seen in healthcare services have well-established alcohol dependence and often physical, neurocognitive, and psychiatric complications when they present for treatment. At this stage, the road back to reasonable health and well-being is a long and sometimes uncertain one, requiring considerable personal resources, involvement in treatment, support, and lifestyle changes.

An important movement in the recent years has been to broaden the spectrum of responses so that people with hazardous (or unhealthy) alcohol consumption and those with less severe alcohol use disorders, as well as those with alcohol dependence, have an opportunity to be alerted to the risks of their drinking and to change their consumption patterns in a healthy direction. Screening and brief intervention has its origins in the work of a WHO Expert Committee in the late 1970s. In its report, the Expert Committee recommended "the development of methods for identifying and modifying potentially harmful patterns of alcohol consumption before dependence developed and disease was entrenched".

Arising from this report was a WHO program of work by on development of techniques for early detection and intervention for hazardous and harmful alcohol consumption. Parallel work in the area was undertaken by pioneers such as

Kristenson et al. (1983) and Heather et al. (1987). Since those early days, there has been a substantial effort to develop screening instruments, such as the Alcohol Use Disorders Identification Test (AUDIT) and the development of brief structured therapies designed to be used at the time hazardous and harmful alcohol use is identified.

This approach has been endorsed by many authorities. In 1990, an influential report from the US Institute of Medicine recommended that healthcare responses should extend beyond the provision of treatment for people with established alcohol dependence (or "alcoholism") to encompass early detection and treatments in primary care and in other non-specialist settings. It noted the evidence accumulating for the effectiveness of opportunistic screening and brief intervention for hazardous and harmful alcohol consumption. In the United Kingdom, the National Institute for Health and Clinical excellence in 2010 supported the widespread implementation of brief intervention approaches.

Screening and brief intervention is analogous to screening for asymptomatic hypertension and hyperlipidemia and indeed screening for a range of medical, mental, and social disorders. It is predicated on the basis that early detection and treatment of a disorder in its developmental stage has advantages over treatment of the established disorder in terms of reduced morbidity, better and more guaranteed response to treatment, and the avoidance of the costs of treating the advanced disorder and prevention of premature mortality.

This chapter will (1) review the current criteria for hazardous/unhealthy alcohol consumption, (2) examine the available screening instruments (focusing on instruments specifically derived to screen for a range of hazardous consumption and alcohol use disorders), (3) review the evidence for the effectiveness of brief interventions, (4) examine the implementations of such interventions in healthcare systems, and (5) conclude with an outline of the key therapeutic components of brief interventions. Mention will also be made of electronic screening and brief intervention which has been developed to further broaden the access of people with hazardous or unhealthy patterns of alcohol consumption to information and advice, who otherwise might not be engaged in the healthcare system.

12.2 Screening and Brief Interventions

12.2.1 The Spectrum of Hazardous Consumption and Alcohol Use Disorders

Alcohol use and misuse exist as a continuum, and an important realization is that harm can occur at many points along this continuum. Accidents can occur due to a single episode of excessive consumption, and they are more likely to occur with repeated bouts of drinking; social problems can arise due to intoxicated behaviors, and acute medical disorders may also arise from periodic binges. Many chronic disease states are linked to regular consumption of alcohol that may not reflect alcohol dependence. Although the risks of all these are multiplied on people who

have alcohol dependence, and it is right that much attention be paid to this group, it is important to capture a broad range of consumption patterns and alcohol disorders.

The risk of harm is related to the level of alcohol consumption and the frequency and duration of consumption. For many harmful consequences, there appears to be a threshold of consumption below which harm is not seen or occurs only infrequently. In many countries, national authorities have defined hazardous (or risky or unhealthy) alcohol use. Some examples are as follows:

(a) *United States*: for women, more than seven drinks per week or more than three drinks per occasion and, for men, more than 14 drinks per week or more than four drinks per occasion (one drink being approximately 13 g of alcohol) (US Preventive Services Task Force 2013).
(b) *United Kingdom*: for men, over 40 g alcohol (five units) per day or 21 units per week and, for women, over 24 g alcohol (three units) per day or 14 units per week (one unit approximately equivalent to 8 g alcohol) (SIGN Guidelines 2003).
(c) *Australia*: more than two standard drinks on any day (for both men and women) or more than four standard drinks on a single occasion (one standard drink being approximately 10 g of alcohol). For those under the age of 16 years or if a woman is pregnant or planning to become pregnant or breastfeeding, the safest option is not to drink alcohol (NH & MRC 2009).

The term alcohol use disorders is typically used to denote a repetitive pattern of alcohol consumption. It may be facilitated by external factors such as cultural norms and practices, peer pressure, work culture, and work pressure or internal factors such as the person's feelings and mental state or desire to experience the euphoria and state of intoxication that alcohol can cause. Non-dependent alcohol use disorders include ICD 10 harmful alcohol use, DSM-IV alcohol abuse, and part of the spectrum of the recently defined DSM-V alcohol use disorder. DSM-IV alcohol abuse is defined as a maladaptive pattern of alcohol use over a twelve-month period, leading to clinically significant failure to fulfill major obligations at work, school, or home; legal problems; or interpersonal problems, or when it is physically hazardous. "Unhealthy alcohol use" is a term referring to that spectrum of alcohol use that can result in health consequences and broadly covers hazardous/harmful drinking, alcohol abuse, or alcohol dependence (Saitz 2005; Saitz et al. 2013).

Alcohol dependence is a psychobiological syndrome and is best understood as a disorder where there is a persistent internal drive to consume alcohol such that alcohol increasing takes "center stage" in the person's life and other enjoyments, activities and responsibilities are pushed to the periphery. It reflects enduring changes in key neurocircuits that subserve reward, alertness, response control, and salience in the ventral tegmental area of the midbrain, the nucleus accumbens, and related structures of the lower forebrain and with projections to and from the prefrontal gyrus and the circulate gyrus of the cortex. It is more "disease-like" than any other form of repetitive alcohol use and tends to be self-perpetuating and to run true when active at different periods in the person's life.

For this spectrum of hazardous alcohol use and alcohol use disorder, there is a need for reliable methods of screening and intervention. The term "screening and

brief intervention" is typically directed at hazardous use and nondependent alcohol use disorders. However, screening and early detection can be applied to alcohol dependence, and brief interventions can be adapted and can be used in therapy at the start of treatment for persons with alcohol dependence.

12.2.2 Development of the AUDIT and Other Screening Instruments

The modern era of screening for hazardous alcohol consumption and alcohol use disorders began with the development of the Alcohol Use Disorders Identification Test (AUDIT) (Saunders and Aasland 1987; Saunders et al. 1993; Babor et al. 1992). Prior to the development of the AUDIT, alcohol screening instruments focused on the detection of alcoholism. They were not designed to detect the range of alcohol use disorders or hazardous/unhealthy alcohol consumption, the reason being that these concepts had not gained general acceptance at the time the older instruments were introduced. These older instruments include the Michigan Alcoholism Screening Test (MAST), developed in 1971 and which exists in several versions including brief ones and the four-item CAGE (Ewing 1984).

The AUDIT has its origins in the WHO collaborative work that was initiated by the Expert Committee and was derived from findings in a World Health Organization collaborative study. The AUDIT was developed from the empirical selection of items contained in a WHO assessment instrument, comprising more than 150 questions. Participating centers from six countries around the world (which represented different cultures, healthcare systems, stages of economic development and political systems) were involved. The ten items which formed the AUDIT were those which had the following characteristics:

1. They had the highest or comparably high item-to-total correlations with the domains they represented.
2. Individually and collectively they had the greatest discriminatory value between patients who had hazardous consumption and/or alcohol use disorders and those who did not.
3. The questions not only conformed to the then bi-dimensional concept of alcohol dependence and its consequences but extended it to a tridimensional concept of (i) intake measures, (ii) measures of the urge or drive to consume alcohol (and putative dependence), and (iii) direct or proxy measures of alcohol-related consequences.
4. The sensitivity and specificity and positive and negative predictive values for the AUDIT in clinical and also epidemiology populations indicated a high degree of accuracy of classification and therefore practical utility.
5. Likewise the sensitivity and specificity of questions in the three individual domains were psychometrically acceptable.
6. The questionnaire as a whole and questions within the three domains had acceptable psychometric performance as judged by measures such as Cronbach's Alpha Coefficient.

7. Each individual question had high face validity and the meaning of the question was clear and it explicitly mentioned the link with alcohol consumption.
8. Each question was suitable in providing a means of exploring further the patient's experiences with alcohol and the questionnaire as a whole was suitable as a framework for intervention.
9. The individual questions could be translated readily and accurately (both grammatically and idiomatically) into major world languages.

Subsequent studies showed that the AUDIT Questions:

1. Performed as a stand-alone questionnaire as it did when the questions were embedded in a general health screening instrument
2. Had high acceptance among populations being screened
3. Could be adapted easily to electronic format including interactive media where feedback on the AUDIT score and on responses to individual questions could be provided

The AUDIT questionnaire offers a simple and systematic way of assessing alcohol intake (Questions 1–3), alcohol dependence (Questions 4–6), and alcohol-related harm (Questions 7–10). The questionnaire may be self-administered while the patient is awaiting the consultation or may be used by the clinician during the assessment. Responses in the AUDIT are quantified from 0 (far left column) to 4 (far right column) for Questions 1–8 and 0, 2, and 4 for Questions 9–10. The AUDIT score may range from 0 (for an abstainer of alcohol) to 40. A presumptive diagnosis of hazardous or harmful consumption is made if the AUDIT score is 8 or above. More severe harm and dependence are likely when the score is 13 or more and to be extremely likely if the score is 20 or more. The scores on the AUDIT can also point to the intervention required, if any. Scores of 0 and 1–7 may result in some feedback but otherwise no specific intervention. A score of 8 or more merits a brief intervention, with scores of 13 or more (and certainly 20 or more) alerting the clinician to the need for detoxification and referral for specialist treatment. Assessment by completion of the AUDIT questionnaire itself is reported to reduce hazardous drinking (Kypri et al. 2007)

Several derivatives of the AUDIT have been published over the years. The most popular of these is the AUDIT-C, which comprises simply the first three questions of consumption measures. The shorter three-item AUDIT-C has been shown to be a more convenient and effective instrument for diagnosing alcohol use disorders in a primary care setting, viz.:

1. How often do you have a drink containing alcohol?
2. How many standard drinks containing alcohol do you have on a typical drinking day?
3. How often do you have four drinks (for women) and six drinks (for men) or more on one occasion?

Scores of 3 or more in women and 4 or more in men have a sensitivity of 73 % and 86 % and a specificity of 91 % and 89 %, respectively. (Bradley et al. 2007) A score of 7–10 or more indicates alcohol dependence (Rubinsky et al. 2010).

At a minimum, one question on the quantity of alcohol consumed can be asked. "How many times in the past year have you had five (for men) or four (for women) or more drinks in a day?" (a positive test was considered to be a response >0) was

found to be useful in primary care (Smith et al. 2009). In the FAST, the consumption question is "How often do you have eight (or for women six) or more standard drinks on one occasion?" A response of monthly or more is considered a positive answer. Three further questions make up the FAST (Hodgson et al. 2002) with a score of three or more indicating hazardous alcohol drinking.

Some alcohol screening instruments have been developed to identify hazardous consumption and alcohol use disorders within specific populations such as women, pregnant women, adolescents, and the elderly. These include the TWEAK to screen for alcohol use during pregnancy (Russell et al. 1991).

Another relevant screening test is the WHO Alcohol, Smoking and Substance Involvement Screening Test (ASSIST). ASSIST is a combined screen for drug and alcohol misuse and is available for self-completion while the patient is in the waiting room or hospital clinic. It is designed to inquire about alcohol use in context of health inquiries to detect problem or risky alcohol and other substance use in primary health care. It is linked to a brief intervention based on the acronym FRAMES and incorporates motivational interviewing (WHO ASSIST Working Group 2002; Newcombe et al. 2005).

In 2001, a smoking, nutrition, alcohol, and physical activity (SNAP) framework developed by the Australian government Department of Health and Aging (SNAP 2001) was found to fit well with general practice consultations (Harris et al. 2005).

12.2.3 Brief Interventions: Background and Evidence

Once a person has been identified, through screening or clinical inquiry, as having an alcohol use disorder, a brief, focused form of therapy is beneficial. The usual term to describe this is "brief alcohol intervention." As described above, brief intervention aims to engage with people who have hazardous or harmful alcohol consumption, using the DSM terms alcohol abuse (DSM-IV) or alcohol use disorder (DSM-V). The focused advice and therapy is provided before the person has developed alcohol dependence or severe physical, mental, or personal problems.

Brief intervention is therefore a proactive strategy comprising provision of brief advice on the consequences of hazardous/harmful drinking or alcohol abuse, feedback of harm and relating this to the patient's excess drinking, setting goals for safe levels of drinking, outlining benefits obtained from cutting down drinking, and setting strategies to overcome "at-risk" times. The intervention may take only 4–5 mins.

There is a wealth of evidence attesting to the effectiveness of brief alcohol interventions in reducing alcohol intake and alcohol-related problems in persons with alcohol use disorders. Approximately 50 randomized controlled trials of various forms of brief intervention compared with no intervention or an alternative form of intervention have been published. Furthermore, several meta-analyses have been published since the early 2000s. A Cochrane Collaboration review of 23 trials of a number of interventions, most commonly brief interventions, for preventing

injuries in problem drinkers reported 27–65 % reductions in alcohol or drinking-related injuries. However, in this analysis, there was insufficient evidence of reduced alcohol consumption (Dinh-Zarr et al. 2009). In other meta-analyses, Kaner and colleagues showed reduced alcohol consumption in men (although not in women). Longer counseling and extended treatments were found to have little additional effect over brief intervention (Kaner et al. 2007, 2009; Moyer et al. 2002).

The Cochrane Database of Systematic Reviews found that interventions for problem drinking, mainly brief counseling in the clinical setting, reduced injury-related deaths (relative risk (RR), 0.65; 95 % confidence interval (CI), 0.21–2.00), which may however have been due to chance. Brief counseling also showed beneficial effects on non-fatal injury outcomes such as falls, motor vehicle crashes, and suicide attempts. The authors felt that further studies are warranted (Dinh-Zarr et al. 2009).

The overall reduction in alcohol consumption between those receiving brief intervention and control groups receiving no advice or standard care is modest and amounts to approximately 10 g of alcohol per day. There are a greater effect on hazardous drinking and an even greater effect on alcohol-related injuries, with a relative risk of 0.68 (95 % CI 0.57–0.81) for hazardous alcohol consumption at 1 year (Kaner et al. 2007a, b) and 0.59 (95 % CI 0.42–0.84) for alcohol-related injury (Havard et al. 2008).

Furthermore, systematic reviews have shown that brief intervention reduces mortality over a 10-year follow-up, with a relative risk of 0.47 (95 % CI 0.25–0.89) (Wutzke et al. 2002; Cuijpers et al. 2004). The number needed to treat (NNT) is 58.8 to achieve mortality reduction. In relation to differential response according to experience of harm, brief interventions seem to be more effective in those people who are likely to experience problems related to alcohol than other alcohol consumers.

More recently, in a UK multicenter SIPS (Screening and Intervention Programme for Sensible drinking) trial, 3,562 primary care patients were screened for hazardous/harmful drinking using either the FAST or a single alcohol screening questionnaire. Patients randomized to three interventions were compared, each of which built on the previous one, namely, (i) a patient information leaflet control group, (ii) 5 mins of structured brief advice, and (iii) 20 mins of brief lifestyle counseling linked to motivational interviewing. The WHO screening instrument AUDIT (score of <8) was used as a primary outcome measure at 6 months. There was no difference in benefit between the three arms although patients in the 20-min intervention reported slightly greater satisfaction with treatment. The authors concluded that screening followed by simple feedback and written information may be the most appropriate strategy to reduce hazardous and harmful drinking in a primary care setting (Kaner et al. 2013).

The efficiency of screening and brief intervention will vary according to the prevalence of hazardous alcohol consumption in general practice when 10–15 % of patients in many Western countries would likely be hazardous drinkers; approximately eight people will need to be screened for each hazardous drinker to be

identified. Combining that with the NNT of 5–6 for alcohol consumption leads to the result that on average 45 patients in primary care will need to be screened for each person with hazardous alcohol consumption to become a low-risk drinker. This indicates the degree of effort required to provide brief intervention in practice although information on alcohol consumption is relevant to much of the health care when other issues such as the potential for interactions with medications and advice needed for pregnant women and people with a range of chronic medical disorders are taken into consideration.

12.2.4 Implementation of Screening and Brief Intervention in Clinical Practice

There is a wealth of evidence that demonstrates that brief interventions reduce hazardous and harmful alcohol consumption, as judged by overall alcohol consumption, reduced frequency of binge drinking, alcohol-related problems, and various secondary measures such as healthcare utilization. Some of the findings vary from study to study and among the meta-analyses. However, the overall message is clear that for these interventions, benefits are clear and the strength of the evidence would suggest that their general availability in the healthcare system should be assured. The reality is somewhat different.

Brief interventions are some of the most consistently effective and potent interventions directed at individuals and considerable effort is being made to incorporate them into the healthcare system. This is proven to be more difficult than originally anticipated. Very often, screening and brief intervention can be established as a brief project, but it tends not to be continued in any systematic way when external support and interest cease.

It is fair to say that screening and brief intervention has not been taken up in the healthcare system as avidly as had been expected. Certainly systematic screening in primary care and the delivery when appropriate of a brief therapy remain unusual, even in healthcare systems that have a strong primary prevention and population health orientation. Various barriers to implementation have been reported by health professionals and include (i) reluctance to inquire about alcohol consumption, (ii) poor role adequacy, (iii) inadequate resources to address alcohol use and problems, and (iv) poor role support (Nilsen 2010). There remains significant issues regarding training and confidence in providing brief interventions, issues of remuneration and competition for the time of medical practitioners and other health professionals given their overall responsibilities. Ethical considerations have also been raised as to the appropriateness of introducing a health issue which is not on the patient's agenda when they booked the consultation. More broadly, there is debate about which healthcare professionals have the capacity to provide these interventions.

Detection and diagnosis of alcohol use disorders remains low, and it is estimated that of the 15–30 % of patients in primary care or hospital settings who have an alcohol use disorder, in only one-third of the cases is that disorder diagnosed.

Screening and early detection therefore has a greater role than leading to a brief intervention. Early detection can often result in the correct diagnosis being expedited, with the patient being spared unnecessary investigations. Equally important, knowledge of the alcohol use disorder may prevent months or indeed years of inappropriate or ineffective treatment for patients who have disorders that may be related to alcohol consumption, such as hypertension, esophagitis and gastritis, anxiety, depression, and recurrent headache. It can also often provide an answer for patients who have multiple nonspecific and seemingly unconnected symptoms.

Efforts to facilitate the implementation of screening and brief intervention in primary care began with the original WHO collaborative study. When evidence became available for the effectiveness of brief alcohol interventions in this collaborative study, thoughts were directed to how these interventions could be implemented in the primary care system. Phase III of the collaborative study included analyses of barriers to intervention and approaches that would facilitate the implementation of these interventions. This work, described above, led to controlled studies of implementation techniques (Saunders and Wutzke 1996; Gomel et al. 1998; and Funk et al. 2005). These studies examined the effectiveness of different promotional approaches to elicit interest in general practitioners in receiving materials to undertake screening and brief intervention. These studies conducted in six countries showed that direct mail techniques elicited a request for brief intervention materials among approximately half of general practitioners while telephone marketing and personal marketing (similar to pharmaceutical company academic detailing) had uptake rates of around 80 %. Thus, promotional techniques familiar to the commercial world could be adapted to the dissemination of brief alcohol interventions.

The next component of this work was to examine the effect of various training and support techniques in the actual provision of these interventions. Several such techniques were compared, with the end point being the proportion of patients with hazardous alcohol consumption who actually underwent screening and received an appropriate brief intervention. Results showed that among general practices where on-site training had been provided but where there was no subsequent training or support, approximately one-third of patients with hazardous consumption had received a brief intervention over the three-month period the study was being undertaken. On-site training followed by various levels of telephone-based support and personal contact resulted in up to 70 % of patients with hazardous consumption receiving an appropriate alcohol intervention.

Findings such as these would suggest that the widespread provision of training and subsequent support would be a successful means of incorporating screening and brief intervention into primary care. However, when an assessment was undertaken a year later, much of the screening and brief intervention had ceased. Medical practitioners typically reported they found the work interesting and they appreciated being involved in the study. However, in the absence of structural and contractual supports for brief interventions, their provision naturally tailored off and only approximately 10 % of practitioners were still providing them in any systematic way 1 year later.

Subsequent work has emphasized the importance of appropriate system of remuneration and also contractual obligation in the systematic provision of these interventions. An example is provided by the healthcare system of Scotland, United Kingdom, where general practitioners who work within the four regional health areas of Scotland have incentives and are obliged to undertake screening and brief alcohol interventions as part of the regions' contractual obligations with the Scottish Government. Overall, the level of acceptability of brief interventions with patients attending primary health care remains high. It is clear that the availability of screening and brief alcohol intervention in the healthcare system will be strongly influenced by government policy, as is translated into the contractual obligations of the healthcare system and healthcare providers.

Examples of policy recommendations and directives include the expectation that screening and brief intervention will be provided in all healthcare settings in Scotland (Scottish Intercollegiate Guidelines Network 2003), the recommendations of the US Preventive Services Task Force (US Preventive Service Task Force 2004), the guidelines published by the UK National Institute for Health and Clinical Excellence (NICE 2010), and the British Medical Association (BMJ Practice Guidelines 2011) and the National Preventative Health Taskforce, Australia (2009).

Opportunities for screening, early detection, and brief intervention for alcohol use disorders exist in many settings. These include general medical/family medical practice, other primary care settings (nurses, psychologists, social workers), emergency departments and acute care clinics, student health services, work place health programs, and also certain public areas such as shopping centers.

In addition to these primary care or community contact settings, brief interventions can be offered in hospital wards (general and psychiatric) and in a range of specialist services such as diabetes, hypertension, and liver clinics. There is mixed evidence for the effectiveness of brief intervention in hospital wards. These settings are of course quite diverse, and the extent to which a person can be engaged in any alcohol intervention will vary according to the primary task of a particular setting. Still, given that few people specifically request treatment and assistance in an alcohol use disorder, any attempt to identify these and to place them on the healthcare agenda is to be welcomed. In relation to setting, brief intervention has been demonstrated to be effective in primary care settings, emergency departments, hospital outpatient clinics and trauma centers.

Throughout this period, there has also been a tendency for patients who have actual alcohol use disorders to present for care at an earlier stage than was the case a generation ago. Furthermore, developments in general practice mean that questions on alcohol as well as cigarette smoking are more commonly part of the routine inquiry when patients attend primary care for the first time or are part of a periodic annual or biannual assessment. Even though the systematic approach of brief intervention may be less common than had been anticipated by those working in the area, nonetheless, in various areas of the world, it is more common for inquiry about alcohol use to be made.

12.2.5 Brief Intervention in Practice: The Techniques

1. FLAGS:

   Feedback: Problems experienced or likely to occur and link this with unhealthy drinking.

   Listen: Listen to the patient's response and assess his/her readiness to change (use motivational interviewing techniques as required) (Prochaska et al; 1992).

   Advice: Give clear advice to change and/or reduce unhealthy levels of drinking; list the benefits of change.

   Goals: Negotiate goals to reduce drinking to recommended limits.

   Strategies: Discuss practical methods and strategies, for example, how to determine at-risk times, and develop coping strategies.

2. FRAMES (brief intervention with motivational interviewing):

   Feedback: About personal risk and impairment.

   Responsibility: Emphasis on personal responsibility for change.

   Advice: To cut down, abstain if indicated because of severe dependence or harm.

   Menu: Menu of alternative options for changing drinking pattern and, jointly with the patient, setting a target; intermediate goals of reduction can be a start.

   Empathic interviewing: Listening reflectively without cajoling or confronting; exploring with patients the reasons for change as they see their situation.

   Self-efficacy: An interviewing style which enhances peoples' belief in their ability to change (Bien et al. 1993).

12.2.6 Development of Electronic Screening and Brief Intervention

In the recent years, we have witnessed an electronic revolution in communications. The advent of the Internet and the World Wide Web, the ready access electronically and wirelessly to the Internet, the vast array of information that can be stored electronically and be accessible, and the advent of lightweight laptop computers, tablets, smartphones, and the like mean that communication of information is easier than ever before. In addition, the potential interactivity that is possible electronically means that there can be a two-way flow of information between the person and an electronic store of information. In many areas of health care, this technology has been put to use for the provision of screening and assessment and the provision of relevant information and advice. Screening and brief intervention for alcohol use has been part of this.

Electronic screening and brief intervention has its origins in the late 1990s when the potential of the technology became apparent and also when there was interest in the widespread dissemination of health advice about alcohol. Soon, pioneering efforts in the provision of alcohol screening and brief intervention were made, and the first systematic studies appeared in the early 2000s (Kypri et al. 2003, 2004).

Electronic brief interventions have now been developed using a variety of platforms and have now achieved considerable popularity and population reach. Over the past 10 years, the use of the Internet as a means to access information – and advice – has become near universal in many countries, and even in many developing countries, 50 % of the population has access to the Internet. Technologies that have been adapted for electronic screening and brief interventions now include the older ones such as desktop computers, personal computers and laptops, touch screen instruments for use in community settings, and the new generation of smartphones, tablets, and other handheld instruments. Increasingly, people throughout the world are using these technologies as part of everyday life. The opportunities to adapt and utilize these technologies for screening and brief alcohol intervention are huge.

Screening and brief intervention has high levels of acceptability particularly among populations (such as young people) who are electronically literate. Studies among university and college students show acceptability levels exceeding 80 %, and receiving information electronically is more preferred among young people than receiving such information from a health professional.

Randomized controlled trials have shown electronic screening and brief intervention to result in significant changes in alcohol consumption and associated problems. A series of controlled studies in student populations, in both individual campuses and national studies, have shown significant effect sizes on measures of overall alcohol consumption, binge drinking, alcohol-related problems, measures of academic performance, and healthcare utilization. The effect size does appear to be slightly less for electronic interventions than that seen for clinician-provided interventions. However, given the high acceptability of electronic interventions and the potential reach to the at-risk population, electronic interventions have far greater capacity to be disseminated universally than could be achieved realistically through the dissemination of clinician-provided interventions.

More broadly, screening and brief intervention, including its electronic forms, offers the prospect of reducing alcohol-related harm at a population level as an alternative to primary prevention approaches based on control of per capita alcohol consumption. These latter approaches, although empirically sound, are difficult for governments to enact into effective policy as they impact on the availability and access to alcohol of the entire population and not just those whose drinking is hazardous and causing problems. In the modern world, governments have been reticent to impose tax imposts and restrictive legislation on alcohol consumption generally for fear of electoral unpopularity and economic considerations, particularly in those countries where the production of alcohol drinks is a significant part of the national economy. Screening and brief intervention therefore offers a population-wide and more politically acceptable approach to reducing harm from alcohol in the population at large. Both clinician-provided and electronic interventions have important roles to offer in the fulfillment of this goal.

Screening for Nicotine and Drug Use Disorders

13

Sawitri Assanangkornchai and J. Guy Edwards

Contents

Abstract

Screening aims at detecting substance use, ideally at an early stage, with a view of providing subsequent treatment if required. It is most productively employed in populations in whom there is a high prevalence of use, such as general and

emergency medical patients, those attending clinics for pain or sexually transmitted disorders, and people who have come into conflict with the law. It is of less value in well-staffed facilities that already routinely enquire about substance use during comprehensive clinical assessments.

Numerous screening instruments have been designed – those that screen for different substances in an aggregated or disaggregated way, those for one specific substance, and those for substance-related problems – but relatively few have satisfactory psychometric properties. Examples of instruments that screen for nicotine or drug use disorders or for multiple substances are the Alcohol, Smoking, and Substance Involvement Screening Test, CAGE-AID (mnemonic for items Cut down, Annoyed, Guilty, Eye-opener-Adapted to Include Drugs), Drug Abuse Screening Test, and the Fagerström Test for Nicotine Dependence. The choice of an instrument should depend on its psychometric properties, the population being screened, availability of staff to use it properly, and the practicality of introducing it into the facility.

Ethical aspects of the use of the instruments are important. Outside purely research settings, screening will have limited value unless follow-on treatment is available, and substance misusers are encouraged to accept it and adhere to it. The best test of the true value of screening will be in the prevention of Longer-term medical and psychosocial consequences of substance misuse.

13.1 Introduction

Screening for substance use and use disorders helps identify people who have suffered the consequences of using one or more substances or are at risk of future harm if they continue to use the substance(s). It aims to detect problems at an early stage and can be followed by treatment if indicated. Screening instruments for drug misuse have been evaluated in the community and health-care facilities and in relation to the law.

13.2 Facets of Drug Screening

13.2.1 Screening in Different Settings

13.2.1.1 Health-care Facilities

Screening may be undertaken in primary care; general and emergency medical, psychiatric, and other specialized facilities (e.g., HIV/AIDS, obstetric units); and community hostels. Some instruments are self-administered, and others administered by staff of various disciplines. Studies have shown the benefits of screening for drug use in various health-care settings as a first step in the public health approach in the Screening, Brief Interventions, and Referral for Treatment (SBIRT) process for illicit drug use (Babor et al. 2007).

13.2.2 Primary Care

Patients do not go to their doctors to be screened or rated, but to talk about their problems, to be listened to, and to receive treatment. In an ideal world, it should not be necessary to screen for substance use, because there would be adequately trained staff to carry out a comprehensive assessment that would "automatically" take all aspects of substance use into consideration. However, in the imperfect world in which we live – a world in which the demand for services greatly outstrips supply and conveyor-belt medicine is forced on us – screening offers a useful helping hand. It can also help educate personnel unfamiliar with substance misuse on the most important questions to ask and serve as an aide memoir for those who are already familiar with them.

Primary care deals with a wide range of people and an equally wide range of lifestyles and disorders, including substance misuse disorders. Its workers are usually seen as trustworthy, and it provides an excellent opportunity for early identification. We therefore endorse WHO recommendations on screening in general practice, with consideration given to the use of the Alcohol, Smoking, and Substance Involvement Screening Test (ASSIST; World Health Organization 2012) when time and/or staffing permits. Otherwise, shorter, simpler instruments should be used.

13.2.3 Secondary Care

13.2.3.1 General Medicine

Published evidence suggests that there is a high prevalence of substance use among general medical patients and that it is often associated with higher morbidity. Hospitals are therefore important places in which to screen patients, hoping that any substance misusers identified will accept treatment. In hospitals, there is more time for screening than in some other medical services and also more time to educate the patient about the relationship between substances misused and his/her medical condition (Mdege and Lang 2011).

13.2.3.2 Emergency Medicine

Drug misusers often attend accident and emergency departments with substance-related medical or surgical problems, notably toxic or withdrawal states, and trauma due to accidents, deliberate self-harm, or injury caused by others. Thus, emergency departments too are appropriate facilities to screen, especially for the benefit of people who have less access to alternative health care. However, because of the nature of the emergency department, where its workload is mostly stretched to capacity, screening may only be carried out with great difficulty or not at all without extra resources.

Notwithstanding these considerations, a systematic review showed that drug abuse screening in emergency departments is feasible. The study identified 11 instruments that have been used in youngsters under 21 attending these

departments and concluded that for cannabis this single question was sufficient: "In the past year, how often have you used cannabis?" with the response categories, "Once or less" or "Two or more times." The same question, reworded to screen for other drugs, might therefore be sufficient for them also (Newton et al. 2011).

13.2.3.3 Services for the Young and the Elderly

It is important to be vigilant for drug misuse in adolescents and young people and, at the other end of the age range, in elderly patients. Screening of children can be undertaken, subject to prevailing ethical and legal considerations, in schools, child welfare facilities, and the juvenile justice system (Center for Substance Abuse Treatment 1998). Screening should be with a valid, sensitive instrument, appropriate to the age group. When this suggests there is cause for concern, it should lead to a more comprehensive assessment. At all stages of the process, care should be taken not to label or stigmatize a young person as a drug misuser unjustifiably. Some drug types commonly used by adolescents or the elderly are of particular concern, for example, cannabis in the young and hypno-sedatives in the elderly.

13.2.3.4 Pain Clinics

Pain can be associated with drug misuse and dependence in several ways: there may be an underlying condition contributing to both the severity of the pain and the drug misuse (e.g., a depressive disorder); patients may become dependent on their prescribed analgesics (therapeutic dependence); and substance misusers with pain of organic origin, or with exaggerated or simulated pain, may try to manipulate their doctors into prescribing more addictive substances than are clinically needed – for themselves and/or to give or sell to other substance misusers. Whatever the relationship, screening patients attending pain clinics for inappropriate use is important. Because of the complexity of many of the disorders encountered there, however, no single instrument that is an adequate substitute for a thorough, comprehensive clinical assessment (Solanki et al. 2011).

13.2.3.5 Psychiatric Units

The prevalence of tobacco and other substance misuse is higher in patients with some mental health disorders than in others. Substance misuse and psychiatric comorbidity in general occurs so often it is essential that a history of substance use is taken routinely in all psychiatric patients. Indeed, failure to take a history can be a serious omission and in some cases may be considered negligent. Tiet and colleagues in their review concluded that there are no currently available instruments that have particular advantages in psychiatric patients, while the lengthier, more complicated ones can be confusing for those with severe illnesses – particularly when administered in addition to taking a long history (Tiet et al. 2008).

13.2.3.6 Other Specialities

Other units where screening is important are those in which there is a high prevalence of substance misuse, notably sexual health clinics and HIV/AIDS

services. Screening people attending antenatal clinics is also important, both because of the risk of adverse effects on the pregnant woman and on the fetus. Some screening questionnaires have been especially designed for this purpose, for example, the 4P's Plus, Hospital Screening Study (HSS), Substance Use Risk Profile-Pregnancy Scale (SURPPS), and Wayne Indirect Drug Use Screener (WIDUS) (ADAI Library 2013).

13.2.4 Medicolegal Practice

13.2.4.1 Criminal Justice System

There is a particularly high prevalence of substance misuse in people in conflict with the law, especially those whose alleged crimes have been carried out to acquire money for drugs. Screening in this setting poses particular ethical and legal issues. It is best undertaken by personnel working in prison medical services or in court diversion schemes. An aim of screening, in addition to providing treatment for those in immediate need, is to help interpret the cycle of addiction and drug-related crime, with benefits to society as well as to the drug misuser.

Screening should begin with simple questions regarding substance use. Opportunities for screening may include while the accused is in a police station, or in prison, and during pretrial investigations, meetings between prosecuting and defense counsel, and social assessments conducted by probation officers (Inciardi 1994).

13.2.5 Some General Considerations

13.2.5.1 Ethics

Even when using a simple screening instrument, it is important that we remain aware of the concerns and sensitivities of our patients/clients, concerns such as embarrassment or fear of the legal and other social consequences of drug use. It is essential that honesty and transparency are central to our dealings with patients.

Patient's anxieties can be allayed by emphasizing that the decision to reveal information in response to questions asked by the instrument is theirs and theirs alone. In health-care settings, the patient should be assured that anything revealed will be treated in strict confidence and not disclosed to others without their permission. In the justice system, the extent to which information will be disclosed to others will need to be made explicit. Doing this is particularly important in medicolegal work, whether in civil or criminal cases, and especially so when dealing with delinquent youngsters to help gain their trust, confidence, and cooperation.

13.2.5.2 Psychometric Properties

All instruments employed should be properly constructed and evaluated, and then administered appropriately. Even when these principles have been conscientiously adhered to, there remains the possibility that the information provided by the respondent may be inaccurate.

13.2.5.3 Main Aims of Screening

While it is of interest academically to elicit data on all substance use, clinicians will generally be less interested in people who occasionally experiment with substances (especially if this is common in the peer group) or take them only in certain situations, like parties, clubs, or raves. Although clinicians may need to advise people of the dangers of sporadic or short-lived periods of drug taking, their main focus will be on more regular and/or prolonged substance use. This is especially the case when the person is dependent on one or more substances, has already experienced medical or psychosocial problems due to the substance, or is exposed to the risk of these problems in the future.

There are debates on what are the differences between use, misuse, and abuse and when psychological and/or physical dependence begins. These are of theoretical and practical interest, but matter less at the screening stage than later in assessment. The main aim at this stage is to identify people who have or are at risk of substance-related problems and may therefore benefit from advice and/or intervention regardless of what provisional labels are applied to them.

Having done the screening the clinician, aided by the data elicited by the screening instrument, may then complete the assessment, make a diagnosis, and provide the appropriate intervention.

13.2.6 Screening Instruments for Tobacco and Drug Use Disorders

Screening instruments for substance use disorders are categorized into four groups: instruments that enquire about different types of drugs in a disaggregated way, enquire about drug use in an aggregated way, are specific to one drug, and enquire about multiple problems, including comorbidity (Table 13.1).

13.2.7 Instruments Enquiring About Different Drug Types in a Disaggregated Form

Examples in this group include the WHO Alcohol, Smoking, and Substance Involvement Screening Test (ASSIST) and its modified forms and the Drug History Questionnaire (DHQ).

13.2.7.1 ASSIST

The ASSIST is a screening instrument developed by a group of WHO researchers to help detect substance use and related problems in primary and general medical care. It can help health workers identify the level of risk for each substance identified. It seeks information on the use of all types of psychoactive substances, including tobacco, alcohol, cannabis, cocaine, amphetamine-type stimulants, sedatives, hallucinogens, inhalants, and opioids. It asks if any of these have ever been used and, if so, the frequency of use during the past three months; if the respondents have had a strong desire or urge to use the substance; the frequency of any problems they

Table 13.1 Screening instruments for drug use and drug use disorders

Instrument	Full name	References	Population studied	Time frame	No. of items	Administered by	Approx. time required	Score
(a) Instruments enquiring about different drug types in a disaggregated form								
ASSIST	Alcohol, Smoking and Substance Involvement Screening Test	World Health Organization (2002)	Adults	Lifetime Past 3 months	8 items	Clinician-administered interview Computer-administered format available Adolescent version available	10 min for administration, 5 min for scoring	0–3: low risk, no intervention (0–10 for alcohol) 4–26: moderate risk, brief intervention (11–26 for alcohol) 27+: high risk, more intensive intervention
DHQ PDHQ	Drug History Questionnaire Psychoactive Drug History Questionnaire	Sobell et al. (1995)	Adults	Lifetime Past 6 months	5 items	Self-administered	5–10 min	No specific cutoff

have had; if the substance has interfered with their responsibilities; if anyone has expressed concern about their substance use; if they have tried to decrease or discontinue use; and if they have ever used any substance by injection (WHO ASSIST Working Group 2002).

There are modified forms of the ASSIST – the NMASSIST (National Institute on Drug Abuse (NIDA)-modified ASSIST) (National Institute on Drug Abuse 2013); ASSIST-Lite (ultrarapid ASSIST) (Ali et al. 2013); ASSIST-Y for use in children and adolescents aged 10–17 years; and the electronic eASSIST (Drug and Alcohol Services South Australia (DASSA) 2012).

In a validation study among 1,047 participants in drug treatment and primary health-care settings in Australia, Brazil, India, Israel, Thailand, the UK, the USA, and Zimbabwe, the ASSIST showed high construct and concurrent validity and positive correlation with similar instruments ranging from 0.48 to 0.88 ($p < 0.001$) (Humeniuk et al. 2008). The sensitivity in the study ranged from 54 % to 97 %, specificity 50–96 %, depending on the drug type. The instrument was later tested in 214 patients with first episode psychoses and revealed satisfactory concurrent validity ($r = 0.41–0.63$; $p < 0.001$), with a sensitivity of 63–81 % and specificity of 62–76 % (Hides et al. 2009). Both studies also showed high validity in discriminating between nonproblematic use, abuse, and dependence and between those with and without illicit drug problems. A high internal consistency and good-to-excellent test–retest reliability (kappa, 0.58–0.90) were also reported (WHO ASSIST Working Group 2002). In a diagnostic accuracy study among 2,082 adults recruited from general medical and specialist mental health/addiction treatment services in nine countries, the ASSIST-LITE also showed high sensitivity (0.8–1.0) and specificity (0.7–0.8) (Ali et al. 2013).

13.2.8 Instruments Enquiring About Drug Use in an Aggregated Form

This group of instruments enquires about experiences of all drugs, including alcohol and tobacco. The word "drugs" is used in the questionnaire without reference to any specific substance. For example, a question in the CAGE-AID asks "Have you ever felt that you ought to cut down on your drinking *or drug use*?" Screening questionnaires of this type are not only quick to administer, but they also have the advantage that people who use multiple substances may be more likely to respond positively to a conjoint question than to questions about each specific drug. However, they have some disadvantages. For example, someone who uses only alcohol may not respond in the affirmative to a question that includes drugs. Also, conjoint questions do not detect specific substances. Examples of instruments of this type are CAGE-AID (Cut down, Annoyed, Guilty, Eye-opener – Adapted to Include Drugs), CRAFFT/RAFFT (below), the Drug Abuse Screening Test (DAST), and the Substance Abuse Subtle Screening Inventory (SASSI).

13.2.8.1 CRAFFT

CRAFFT is a mnemonic, based on its individual items: Car, Relax, Alone, Forget, Friends, and Trouble (Knight et al. 1999). It is the best studied instrument for screening for alcohol and drug use and related problems in adolescents (Pilowsky and Wu 2013). The six items are preceded by three preliminary questions that ask about the use of alcohol, cannabis, and other drugs. It evaluates certain lifetime events and behaviors, irrespective of when they occurred. The items were developed from the Problem-Oriented Screening Test for Teenagers (POSIT), Drug and Alcohol Problem (DAP) Quick Screen, and RAFFT questionnaire (Relax, Alone, Forget, Friends, Trouble). The CRAFFT was examined in several populations, including patients seen in hospital-based, sexually transmitted disease and substance use clinics, primary care, emergency departments, and the general population. The instrument was found to be suitable for distinguishing between alcohol and substance use, and problem use, abuse, and dependence, with a sensitivity ranging from 0.61 to 1.00, specificity from 0.33 to 0.97 (Dhalla et al. 2011).

13.2.8.2 Drug Abuse Screening Test (DAST)

The DAST-28 is an instrument used for screening and treatment evaluation research. Responses to the DAST are given as binary (0/1) items, yielding a total score ranging from 0 to 28. A cutoff score of 6 is generally used to indicate drug abuse or dependence (Yudko et al. 2007). It provides a measure of the severity of drug-related and other problems experienced during the respondent's lifetime. It has been used in various populations and has been found most useful in people who do not seek treatment.

The original test was adapted from the MAST (Michigan Alcoholism Screening Test), a screening instrument for problematic alcohol use. Like the MAST, the DAST cannot distinguish between active or inactive drug use or abstinence and low-risk use, abuse, or dependence. Alternate versions of the DAST-28 have been developed – the DAST-20, DAST-10, and DAST-A (for adolescents). DAST has moderate to high test–retest, inter-item and item–total reliability, sensitivity (41–96 %), and specificity (68–99 %), depending on the group studied (Yudko et al. 2007).

13.2.9 Instruments Specific to One Drug

Apart from instruments used to screen for alcohol, those most readily available are for cannabis, tobacco, and opioid use. Short instruments designed specifically for cannabis screening that have satisfactory psychometric properties and have been used in various populations include the Cannabis Abuse Screening Test (CAST), Cannabis Use Disorders Identification Test (CUDIT), and Problematic Use of Marijuana (PUM) (Piontek et al. 2008). The Fagerström Test for Nicotine Dependence (FTND) is the instrument most widely used to screen for nicotine use, while other available instruments are the Cigarette Dependence Scale (CDS) and Tobacco Dependence Screener (TDS). For opioids, most instruments, such as the Current

Opioid Misuse Measure (COMM), Opioid Risk Tool (ORT), and Opioid Assessment for Patients with Pain (SOAPP), were designed to elicit information to identify patients with chronic pain who are at risk of problems caused by their long-term analgesic treatment.

13.2.10 The Fagerström Test for Nicotine Dependence

The Fagerström Test for Nicotine Dependence (FTND) is also known as the Fagerström Test for Cigarette Dependence (FTCD), a revision of the Fagerström Tolerance Questionnaire (FTQ). It was designed to provide an ordinal measure of nicotine dependence. It contains six items that seek information on the number of cigarettes smoked, compulsion to smoke, and dependence. It provides a severity rating that can be used to help plan treatment and assess the prognosis. Its brevity and ease of scoring make it an efficient way of obtaining clinically meaningful information. It can be incorporated into general health and lifestyle screening questionnaires for use in clinical and nonclinical settings.

A modified version of the scale (modified Fagerström Tolerance Questionnaire, mFTQ) has been adapted for use in adolescents. The FTND was found to be reliable for evaluating smokers in different settings. It had a test–retest reliability ranging from 0.58 to 0.91, with the lowest value in smokers with schizophrenia, and a sensitivity of 0.75 and specificity of 0.80 in a study among patients with cancer in Japan. There was a weak ($r = 0.19$) to satisfactory ($r = 0.59$) correlation between the FTND score and breath carbon monoxide and saliva cotinine levels (Meneses-Gaya et al. 2009).

13.2.11 Instruments Enquiring About Multiple Problems, Including Comorbidity

These instruments help identify drug-related problems in mental and physical health, relationships, and adjustment at school or work. They may locate areas in need of further assessment and suggest services required. Examples include the Co-occurring Disorder Screening Instrument (COMM), Drug Use Screening Inventory – Revised (DUSI-R), Drug Check Problem List (PL), and Problem-Oriented Screening Instrument for Teenagers (POSIT).

13.2.11.1 Problem-Oriented Screening Instrument for Teenagers (POSIT)

The POSIT is a self-administered 139-item questionnaire, with fixed "yes/no" responses, designed for use in adolescents aged 12–19 (Rahdert 1991). It identifies problems in 10 domains that require further assessment and might need the provision of services; these domains include substance use/abuse, mental and physical health, family and peer relations, vocation, and special education. The instrument can be used by school personnel, juvenile and family court personnel, medical and

mental health-care staff, and staff working in substance use disorder treatment programs. The POSIT has been found to have strong internal consistency in several of its subscales and good test–retest reliability and overall validity (Knight et al. 2001, 2003).

13.3 Conclusion

Because of the high and increasing prevalence of substance use disorders and related comorbidity, screening for substances is important in many medical, psychiatric, and forensic services. There is a higher prevalence of use in some patient groups than others, such as those attending accident and emergency departments and pain clinics, and those who come into conflict with the law. Numerous screening instruments have been designed and validated. Factors that determine the choice of an instrument are not only its psychometric properties but also the practicality of employing it. The enormous pressures of working in a busy clinical unit often preclude the use of the lengthier instruments without special assistance. It should not be forgotten that screening is only the first step on a very long journey towards providing a successful outcome. It will be of limited value without the provision of treatment opportunities and encouraging substance users to accept and then adhere to any treatment offered. Finally, it is important to determine the success rate of using the instruments in terms of discontinuation or at least decreased use of substances compared with standard practice and to assess what effect they have in reducing long-term complications.

Clinical Assessment of Alcohol Use Disorders

14

Teresa Bobes-Bascarán, Teresa Bascarán, Paz García-Portilla, and Julio Bobes

Contents

Abstract

Clinical assessment of alcohol use disorders involves both a detailed initial interview and examination and monitoring of the patient's progress. There are no specific instruments to diagnose alcohol misuse, and so diagnostic assessment involves taking an accurate history from the patient and a meticulous clinical

examination. This chapter reviews the necessary attributes of a detailed clinical assessment, namely, (1) utility and purpose (screening, diagnosis, treatment planning, outcome evaluation), (2) time frame (current vs. chronic use), (3) specific target subgroup (age, gender, inpatient vs. outpatient, ethnicity), and (4) performance characteristics and adequate psychometric properties regarding validity and reliability. It also provides a description of the most relevant psychometric instruments to evaluate alcohol use disorders and related problems (historical and recent patterns of drinking; dependence and withdrawal symptomatology; craving and impulsiveness; legal, economic, and occupational problems; coping behaviors and confidence in relapse prevention; readiness to change), psychiatric comorbid symptomology (global and specific mental health measures), neurocognitive performance, social functioning, and quality of life and disability issues.

14.1 Introduction

Alcohol use disorders range from periodic consumption of hazardous quantities of alcohol to a pattern of drinking that is causing personal and health problems through to a disorder where the person is essentially disabled because of incessant drinking and recurrent withdrawal states. The starting point of assessment is to undertake screening and brief assessment so that the type and severity of alcohol use disorder is identified. This initial phase is addressed in a companion chapter in this book (see ▶ Chap. 12, "Screening, Early Detection and Brief Intervention for Alcohol Use Disorders").

After a person has been detected and diagnosed, an in-depth assessment, which involves both integrative comprehension of the patient and monitoring of the patient's progress, is needed. Ongoing assessment and monitoring is important because clients' symptoms and functioning may change throughout treatment, and so will priorities and targets of intervention. For instance, a patient may report anxiety symptoms or dysphoric mood upon entry into treatment and have these symptoms attenuated after achieving abstinence. By the same token, another person could enter treatment with apparently no mental health symptomatology but develop them after a period of reduced use, if he (or she) had been self-medicating with alcohol (Deady 2009). At the same time, it should be noted that recent alcohol abuse may influence neuropsychological performance, psychiatric symptomatology, and social and personal functioning, so it is strongly recommended to conduct further evaluations to determine a better approach of patient's underlying mental health and cognitive performance. It is fundamental to bear in mind that the primary benefit of assessment is not only to accurately and efficiently determine the treatment needs of the patient but also to build rapport. For this reason, it is the heart of the assessment to avoid confrontational approaches and adopt a motivational one instead (see ▶ Chap. 47, "Motivational Interviewing and Behaviour Change in Addiction Treatment").

An all-embracing evaluation should appraise multiple domains of need and explore the following areas:

- Alcohol consumption:
  - Historical and recent patterns of drinking
  - Dependence and withdrawal symptomatology
  - Alcohol craving and impulsiveness
  - Alcohol-related problems (i.e., legal, economic, occupational)
  - Self-efficacy and confidence in relapse prevention
  - Readiness to change
- Other drug misuse, including prescribed and under-the-counter medication
- Comorbid mental health disorders
- Comorbid physical health conditions
- Neurocognitive performance
- Social and personal functioning
- Quality of life and disability

This information may be obtained by a precise clinical interview, but standardized tools and measures may be administered as well (see Table 14.1).

This chapter will enumerate and briefly describe the most relevant psychometric instruments to evaluate alcohol use disorders and related problems, psychiatric comorbid symptomology, neurocognitive performance, and social functioning and quality of life issues. The reader is recommended to consult the companion ▶ Chap. 12, "Screening, Early Detection and Brief Intervention for Alcohol Use Disorders" and ▶ Chap. 15, "Drug Testing" for further information about complementary methods of assessment. Regarding physical and mental health comorbidities, Section VIII is an exhaustive revision on ▶ Medical Disorders and Complications of Alcohol and Other Drugs, Pain and Addiction, and Section IX addresses ▶ Psychiatric Comorbidities and Complications of Alcohol and Other Drugs.

14.2 Comprehensive Assessment of Alcohol Use and Related Problems

14.2.1 Evaluation of Alcohol Use

There are no specific instruments to diagnose alcohol misuse, so fundamental diagnostic methods consist of an accurate history from the patient and a thorough clinical examination. Notwithstanding this fact, psychometric tools are of considerable aid to appraise addictive disorders when used by trained specialists.

14.2.1.1 Clinical Severity of Addiction

Addiction Severity Index

The ASI is a semi-structured interview designed to address seven potential impairments and problem areas in substance-abusing patients: medical conditions, employment and support, drug use, alcohol use, legal issues, family/social relationships, and psychiatric disorders. It consists of 200 items, which gather information on recent (past 30 days) and lifetime problems in all of the problem areas. Last version (ASI 6.0) (Cacciola et al. 2011; McLellan et al. 2006) is composed of

Table 14.1 Distinctive features in instrument selection

Feature	Characteristics

	Inpatient versus outpatient
	Cultural issues/ethnicity
Sensitivity/positive predictive value (PPV)	Proportion of patients with the condition correctly classify as "diseased"
Specificity/negative predictive value (NPV)	Proportion of individuals without the condition who are correctly classified as "disease-free"
Validity (test measures what is intended to measure)	Content (comprehensiveness)
	Construct (conceptual components, internal structure)
	Convergent (similar to other tests to assess that construct)
	Discriminant (different to tests that assess other constructs)
	Criterion (correlation with gold standard measures)
	Concurrent (similar measures obtained to comparative tests at same time frame)
	Predictive (ability to predict future outcome)
Reliability (accuracy of assessment)	Test-retest (correlation at two different time points)
	Inter-rater (degree of agreement by different raters)
	Internal consistency (items of test measure same aspect)

15 scales: 9 primary scales (related to main problem areas) and 6 secondary scales (perceived support and conflicts with partner, family, and friends) (McLellan et al. 1980). There is a follow-up version (ASI-FU follow-up) designed to monitor patients' evolution and treatment outcomes and several adaptations to adolescent population: Teen-ASI (Kaminer et al. 1989) and T-ASI-2 (Brodey et al. 2008).

Alcohol Use Inventory

The AUI is a self-administered instrument which includes 24 scales that intend to describe different ways in which individuals use alcohol, benefits and negative consequences derive from such use, and awareness and readiness for help (Horn et al. 1987). It consists of 228 items grouped in primary scales regarding benefits, styles, consequences, and concerns and acknowledgments of alcohol use and other second-order factor scales.

Comprehensive Drinker Profile

The CDP is a structured interview that contains 88 questions inquiring different areas of interest: alcohol use, everyday problems, most common drinking settings, people with whom they drink, beverage preferences, reasons for drinking, effects and life problems related to alcohol use, and patient's concerns and issues (Miller and Marlatt 1984). Three instruments were derived from the CDP: the Brief Drinker Profile (BDP), the Follow-up Drinker Profile (FDP), and the Collateral Interview Form (CIF).

14.2.1.2 Dependence/Withdrawal Symptoms

Severity of Alcohol Dependence Questionnaire

The SADQ is a self-administered questionnaire designed to measure severity of dependence (Stockwell et al. 1979). There are four items in each of the five scales that gather information on a 6-month time frame: physical withdrawal, affective withdrawal, withdrawal relief drinking, alcohol consumption, and rapidity of reinstatement. Scores range between 0 and 60 points, and scores greater than 30 are suggestive of severe alcohol dependence. It has demonstrated adequate content and criterion (predictive) validity and test-retest reliability.

Alcohol Dependence Scale

The ADS consists of 25 items that interrogate alcohol withdrawal symptoms, impaired self-control over drinking, awareness of compulsive drinking, tolerance to alcohol, and salience of drink-seeking behavior (Skinner and Allen 1982; Skinner and Horn 1984). It has shown good predictive value, content and construct validity, and test-retest and internal consistency reliabilities. A computerized version is also available. It is an adequate instrument for clinical and research purposes.

Short Alcohol Dependence Data

This 15-item instrument was derived from the Alcohol Dependence Data (ADD) in order to accomplish an easier and faster measure profitable for seeking-help patients, current state dependence assessment, sensitive to change over time, and free of cultural influences. It can be self-administered or interviewer administered in about 2–5 min and has good reliability and validity parameters (Raistrick et al. 1983).

Clinical Institute Withdrawal Assessment

The CIWA-AD is an 8-item scale for clinical quantification of the severity of the alcohol withdrawal syndrome (Sullivan et al. 1989). It is useful to monitor patients undergoing alcohol withdrawal as it focuses on both intensity and severity of symptoms. Scores over 20 indicate a severe withdrawal syndrome, and inpatient detoxification is strongly recommended.

14.2.1.3 Craving/Impulsiveness

The Obsessive Compulsive Drinking Scale

The OCDS is a 14-item scale developed to reflect obsession and compulsion related to craving and drinking behavior such as drinking-related thoughts, urges to drink,

and the ability to resist those thoughts and urges (Anton et al. 1995). The OCDS has been shown to be a reliable and sensitive as a monitoring tool and has proved content and predictive validity for relapse drinking. There is an adolescent version, the A-OCDS (Deas et al. 2001), which discriminates between problem drinkers and experimenters and detects functional impairment associated with alcohol abuse.

Penn Alcohol Craving Scale

The PACS is a five-item self-administered instrument for assessing frequency, intensity, and duration of thoughts about drinking and the ability to resist drinking (Flannery et al. 1999). Although it was intended for adults, it may be used in adolescent population. Good reliability and validity measures have been obtained.

Alcohol Craving Questionnaire

The ACQ-NOW is a 47-item self-administered, multidimensional state measure of acute alcohol craving (Singleton et al. 1995). It measures four dimensions: emotionality, purposefulness, compulsivity, and expectancy. There is a 12-item short form, the ACQ-SF-R. It has demonstrated adequate reliability and is sensitive to change.

Impulsive Behavior Scale

The UPPS is a 45-item scale designed to measure impulsivity across dimensions of the Five-Factor Model of personality (Whiteside and Lynam 2001). It measures 4 domains: premeditation, urgency, sensation seeking, and perseverance. The revised version, UPPS-P, consists of 59 items and assesses an additional personality pathway to impulsive behavior, positive urgency (Cyders et al. 2007).

Barratt Impulsiveness Scale

The BIS is one of the oldest and most widely used measures of impulsive personality traits (Barratt 1959; Patton et al. 1995). The last version, BIS-11, contains 30 items grouped in three subscales: attentional impulsiveness, motor impulsiveness, and non-planning impulsiveness. This scale is intended to measure six factors: attention, motor impulsiveness, self-control, cognitive complexity, perseverance, and cognitive instability.

14.2.1.4 Self-Efficacy and Expectancy

Alcohol Abstinence Self-Efficacy Scale

The AASE was designed to evaluate self-efficacy in 20 situations that represent typical drinking cues associated to negative affect; social/positive, physical, and other concerns; and withdrawal and urges (DiClemente et al. 1994). It may be also used to assess an individual's temptation to drink. It has shown great utility to intervene over relapse potential situations, monitor progress in treatment, and assess outcomes.

Drinking Refusal Self-Efficacy Questionnaire

The DRSEQ is a 31-item measure of drinking-related self-efficacy (Young and Oei 1991). It is grouped in three factors: drinking in situations characterized by social

pressure, opportunistic drinking, and emotional relief. Adequate reliability and validity have been analyzed.

Alcohol Expectancy Questionnaire

The AEQ is an empirically derived self-report form designed to assess the domain of alcohol reinforcement expectancies (Brown et al. 1987). It consists of six subscales: positive global changes in experience, sexual enhancement, social and physical pleasure, assertiveness, relaxation/tension reduction, and arousal/interpersonal power. Total scores are predictive of current and future drinking practices, persistence and participation in treatment, and relapse following treatment.

Negative Alcohol Expectancy Questionnaire

The NAEQ is a 60-item questionnaire that assesses the extent to which negative consequences are expected to occur if that person were to "go for a drink now" (McMahon and Jones 1993a, b). The expected negative consequences are held to represent motivation to stop drinking. There are three different time frames: same day, next day, and long-term expected consequences. Responses are measured in terms of how likely it is that a person would expect them to occur and are measured on a 5-point Likert scale. A short version composed of 22 items is also available. This instrument is very useful at intake and during treatment to intervene over motivational factors during therapeutic process.

14.2.1.5 Motivation to Change

University of Rhode Island Change Assessment

The URICA is a 32-item self-report measure used to assess motivation for change that includes four subscales: precontemplation, contemplation, action, and maintenance (McConnaughy et al. 1983). These subscales can be combined in order to yield a second-order continuous readiness to change score (C + A + M-PC). It has demonstrated adequate internal consistency as well as content and criterion validity.

Readiness to Change Questionnaire

The RCQ is comprised of 12 items and focuses on readiness to change drinking behavior (Rollnick et al. 1992). It is based on the URICA questionnaire and is founded on Prochaska and DiClemente's theory on stages of change. It is clustered into three factors: precontemplation, contemplation, and action. It has good psychometric properties, including predictive validity. There is a treatment version, the RCQ (TV), for use in patients at treatment settings.

Stages of Change Readiness and Treatment Eagerness Scale

The SOCRATES consists of 40 items grouped in five stages of change: precontemplation, contemplation, determination/preparation, action, and maintenance (Miller and Tonigan 1996). The SOCRATES 8A is a 19-item version that yields three factorial-derived scale scores: recognition, ambivalence, and taking steps. There are other available forms of the SOCRATES: 8D 19-item drug/alcohol questionnaire for clients, 7A-SO-M 32-item alcohol questionnaire for significant

others of males, 7A-SO-F 32-item alcohol questionnaire for SOs of females, 7D-SO-F 32-item drug/alcohol questionnaire for SOs of females, and the 7D-SO-M 32-item drug/alcohol questionnaire for SOs of males. These SO forms are intended to measure motivation for change of significant others (rather than patient's motivation).

14.2.2 Psychiatric Comorbidity Assessment

Individuals with alcohol use disorders often suffer from one or more psychiatric disorders. This frequent phenomenon indicates the necessity of specific assessment and treatment in the field of addictive behaviors, which, historically, has been narrowed and focused on the addiction per se. This section yields over basic instruments to assess psychiatric comorbidity in patients with alcohol problems (see Table 14.2). For further information on psychiatric comorbidity, consult section IX of this book, ▶ Psychiatric Comorbidities and Complications of Alcohol and Other Drugs.

14.2.3 Neuropsychological Performance

Studies have long established that excessive alcohol use is associated with damage and impairment of brain structure and function, yielding to poor cognitive performance and behavior disturbances. Assessment of neuropsychological performance (and intervention where necessary) is fundamental, given that it determines assimilation and understanding of information, reasoning, and problem solving (in order to prevent relapse) and capacity to remember therapeutic guidelines, learn new skills, maintain abstinence, and develop more adaptive behaviors. This section enumerates the most relevant tests to evaluate neuropsychological performance (see Table 14.3).

14.2.4 Psychosocial Functioning and Quality of Life

Alcohol and other drug use disorders are increasingly viewed as chronic conditions. It is therefore important to assess their impact on the patient's overall well-being. From this perspective, the management of addictive behaviors should aim for the broad goal of recovery, which is defined as abstinence plus improved quality of life and psychosocial functioning. Assessing these social parameters is essential in treatment planning and outcome assessment as they represent the abilities and skills of the individual to function independently in the community.

14.2.4.1 Disability

Disability Assessment Schedule 2.0

The WHODAS 2.0 was developed through a collaborative international approach, with the aim of developing a single generic instrument for assessing health status and disability across different cultures and settings (World Health Organization 2010). It is short, simple, and easy to administer and one first-level general

Table 14.2 Psychometric instruments to evaluate psychiatric comorbidity

Construct	Instrument	Author
Psychiatric comorbidity	Psychiatric Research Interview for Substance and Mental Disorders (PRISM)	(Hasin et al. 1996)
	Composite International Diagnostic Interview (CIDI)	(World Health Organization 1990)
General symptoms	Symptom Checklist-90-Revised (SCL-90-R)	(Derogatis and Cleary 1977)
	Minnesota Multiphasic Personality Inventory (MMPI-2)	(Mc Kinley et al. 1948)
Affective symptoms	Hamilton Depression Rating Scale (HDRS)	(Hamilton 1960)
	Beck Depression Inventory-II (BDI-II)	(Beck et al. 1996)
	Young Mania Rating Scale (YMRS)	(Young et al. 1978)
Autolytic risk	Scale for Suicidal Ideation (SSI)	(Beck et al. 1979)
	Hopelessness Scale (HS)	(Beck et al. 1974)
Anxiety	Hamilton Anxiety Rating Scale (HARS)	(Hamilton 1959)
	State Trait Anxiety Inventory (STAI)	(Spielberger et al. 1970)
	Yale-Brown Obsessive Compulsive Scale (Y-BOCS)	(Goodman et al. 1989)
	Clinician Administered PTSD Scale (CAPS)	(Blake et al. 1995)
Psychotic spectrum	Brief Psychiatric Rating Scale (BPRS)	(Overall and Gorham 1962)
	Positive and Negative Syndrome Scale (PANSS)	(Kay et al. 1987)
Personality	International Personality Disorder Examination (IPDE)	(Loranger 1988)
	Eysenck Personality Questionnaire-Revised (EPQ-R)	(Eysenck and Eysenck 1975; Eysenck et al. 1985)
	Millon Clinical Multiaxial Inventory-III (MCMI-III)	(Millon 1983; Millon et al. 2004)
Eating behavior disorders	Eating Disorder Inventory (EDI)	(Garner and Olmsted 1986)
	Eating Disorder Examination (EDE)	(Cooper et al. 1989)
Sexual dysfunction	Changes in Sexual Functioning Questionnaire (CSFQ)	(Clayton et al. 1997)
	Derogatis Interview for Sexual Functioning-Self-Report (DISF-SR)	(Derogatis 1997; Derogatis and Melisaratos 1979)
ADHD	Conners' Adult ADHD Rating Scales	(Conners et al. 1999)
	The World Health Organization Adult ADHD Self-Report Scale (ASRS)	(Kessler et al. 2005)

disability factor, and 6 s-level standardized domains may be obtained: cognition, mobility, self-care, getting along, life activities, and participation.

14.2.4.2 Quality of Life

Quality of Life Enjoyment and Satisfaction Questionnaire

The Q-LES-Q is a self-administered scale of 93 items designed to measure satisfaction and enjoyment in various domains of functioning: physical health and activities, mood state, work, household duties, academic/occupational activities,

Table 14.3 Tests to assess neuropsychological performance

Function	Subcomponent	Instrument	Author
General mental function		Mini Mental State Examination (Mini Mental)	(Folstein et al. 1983)
Attention	**Span and control**	Digit span (WAIS-IV)	(Wechsler 1955, 2008)
		Mental control test	(Wechsler 1955, 2008)
	Sustained or vigilance	Visual Cancellation Test	(Weintraub and Mesulam 1988)
	Selective	Stroop Color and Word Test	(Golden 1976)
	Alternating	Trail Making Test – part B (TMT-B)	(Reitan 1955)
Executive function	**Dysexecutive syndrome**	Behavioral Assessment of the Dysexecutive Syndrome	(Wilson et al. 1996)

	Working memory	Letter-Number (WAIS-IV)	(Wechsler 1955, 2008)
	Flexibility and analogic reasoning	Wisconsin Card Sorting Test (WCST)	(Nelson 1976)
	Interference and inhibitory control	Go/no go task	
	Planning	Key Search and Zoo Map (BADS) plan	(Wilson et al. 1996)
	Decision making	Iowa Gambling Task (IGT)	(Bechara et al. 1994)
Memory	**Broad function**	Wechsler Memory Scale (WMS-III)	(Wechsler 1945, 1998)
	Short-term/working memory	Letter-Number, Arithmetic and Digit Span (WMS-III)	(Wechsler 1945, 1998)
	Episodic long term	Rey Auditory Verbal Learning Test (R-AVLT)	(Rey 1964)
	Semantic long term	Boston Naming Test	(Kaplan et al. 1983)
	Procedural	Rivermead Behavioral Memory Test (RBMT)	(Aldrich and Wilson 1991)
Visuospatial and perceptual abilities		Rey-Osterrieth Complex Figure	(Rey 1942)
Language and communication skills		Information and Comprehension (WAIS-IV)	(Wechsler 1955, 2008)
Premorbid and morbid intelligence		Wechsler Adult Intelligence Scale-IV (WAIS-IV)	(Wechsler 1955, 2008)
		National Adult Reading Test (NART)	(Nelson 1982; Nelson and Willison 1991)

leisure and hobbies, social relationships, and general activities (Endicott et al. 1993). There are various short forms available.

World Health Organization Quality of Life Assessment

The WHOQOL-100 includes 24 facets relating to quality of life, which are grouped into 4 larger domains: physical, psychological, social relationships, and environment (Power et al. 1999). It also includes 1 facet examining overall quality of life

and general health perceptions. There is an abbreviated, self-administered, 26-item version, the WHOQOL-BREF (Skevington et al. 2004), which produces only domain scores.

14.2.4.3 Functioning

Global Assessment of Function

The GAF is a 100-point tool rating overall psychological, social, and occupational functioning of people over 18 years of age and older (American Psychiatric Association 1994, 2013). It excludes physical and environmental impairment. This scale is included in the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV). However, in DSM-5, the multiaxial system and GAF assessment have been abandoned.

Personal and Social Performance Scale

The PSP is a global measure of personal and social functioning based on four domains of function: self-care, socially useful activities, personal and social relationships, and disturbing and aggressive behavior. Scores may vary from 0 to 100, with a higher score indicating a higher level of social and personal functioning (Morosini et al. 2000).

Abstract

Drug testing involves the analysis of urine or other body fluids for the presence of prescription drugs, illicit substances, and sometimes other toxins, together

with their metabolites, for the purpose of diagnosis and monitoring of progress and/or treatment in human subjects. Typically it is employed for clinical, medicolegal, or forensic purposes. This chapter reviews the approach to drug assays that would be undertaken in a hospital biochemistry or toxicology laboratory, where typically a sample of urine has been obtained from the patient. It does not specifically cover "benchtop" or "ward" testing, for which purpose a range of commercial dipstick-type tests have been introduced. The capacity of urine drug screening to determine the recent use of a psychoactive substance is often misunderstood by clinicians, and careful interpretation of the results is needed and should be undertaken in consultation with laboratory staff. The chapter reviews the techniques available for detecting the main classes of drugs including opioids, benzodiazepines, cannabinoids, and psychostimulants.

15.1 Introduction

A range of body fluids or tissues can be assayed for the presence of drugs. No single assay technology or assay strategy will detect all drugs of possible interest.

Comprehensive broad-spectrum analyses for drugs are labor-intensive. For this reason, most clinical laboratories that perform drug testing adopt a limited testing strategy that is designed to satisfy specific clinical needs. If this strategy is to succeed, it is essential that there is good communication between clinicians and laboratorians.

Clinicians should understand the technical limitations of the assay technology used in particular laboratories.

This chapter will discuss the pharmacokinetics of drugs of abuse and what assay technologies are available in the detection of these drugs in body fluids.

A common term used in a request to the laboratory is for a "drug screen." There is no single process that can identify all drugs. Screening processes will attempt to identify commonly abused substances, but many drugs and toxicants are not identified by "screening." Sometimes these drugs/toxicants will not be identified unless there is prior suspicion of their use and "targeted" assays are performed.

Drug screening is done in a number of different contexts. Some of these contexts are listed below:

1. Hospital toxicology
2. Workplace drug testing
3. Forensic toxicology
4. Postmortem toxicology
5. Sports toxicology
6. Drug-facilitated sexual assault
7. Drugs of abuse testing

Hospital toxicology is the investigation of deliberate or accidental overdose of prescription drugs or illicit substances and other toxins, in order to identify the toxicant so that "rational" therapy may be given to the patient. This was the raison

d'être for drug screening when this testing was first introduced into clinical laboratories in the 1970s. Interest in drug screening of this kind has receded over the years, and presently there is an emphasis on supportive therapy while the drug is metabolized and eliminated. The exceptions to this approach are when a specific antidote is available.[1]

Workplace drug testing is done to detect possible impairment of performance of tasks that are performed in the workplace. This testing is of particular importance when the occupation includes operation of dangerous equipment or the operation of vehicles, boats, and aircraft. A special case is the impairment of health-care practitioners who have access to drugs. Addicted individuals use potent synthetic opioids, such as fentanyl. Fentanyl is not detected in conventional screening protocols.

Forensic toxicology is done to provide evidence of a medicolegal nature where poisoning is alleged and may lead in evidence in criminal prosecutions.

Postmortem toxicology is toxicology done to help determine the cause of death.

Sports toxicology is drug testing done to detect the use of performance-enhancing drugs such as anabolic steroids and erythropoietin.

Investigation of drug-facilitated sexual assault involves targeted analysis of some toxicants that are not usually detected in broad-spectrum screening. These drugs include gamma-hydroxybutyrate and ketamine.

Drugs of abuse testing is a term used to indicate testing for the presence of drugs that have a potential for addiction. Sometimes this testing includes assays for drugs used in substitution therapy, such as methadone or buprenorphine, to assess compliance with prescribed therapy.

These different kinds of "drug screening" result in analytical protocols that vary according to the context. Most hospital-based laboratories have protocols that are a combination of "hospital toxicology" and "drugs of abuse testing." Most hospital laboratories do not document chain of custody of sample nor adhere to the rigorous practice demanded for medicolegal testing. Thus, testing that is done for "clinical purposes" does not satisfy the regulatory requirements applied to medicolegal testing.

Drugs of abuse include amphetamine and amphetamine derivatives, benzodiazepines, cocaine, cannabis, and opiates.

The presence of drugs can be determined in a variety of body fluids such as urine, blood, oral fluid, sweat, meconium, and vitreous humor. Drugs can also be detected in hair and body tissues (especially hepatic and renal tissue). All of these matrices offer various advantages and disadvantages.

Urine is the most commonly used matrix for drug detection. Urine samples can be obtained by noninvasive means. Urine offers a longer detection window compared to blood and oral fluid.

[1]Examples are paracetamol and digoxin overdose and methanol or ethylene glycol poisoning. In the case of paracetamol and digoxin toxicity, measurement of the concentration of the drug in serum is more useful than detection in urine.

Urine has the disadvantage that it may be adulterated or substituted at the time of collection. If the testing is to be reliable, the collection should be done under observation. The collection should be done in an area where there are no water sources such as taps and where a dye has been added to cistern water. The temperature of the urine should be tested immediately after collection to determine that the sample has been freshly voided. The creatinine concentration, pH, and the presence of oxidizing agents should also be tested to determine dilution or adulteration that can interfere with testing. Surreptitious adulteration with ammonia solution, bicarbonate, limewater, salt, vinegar, soap, detergents, and bleach can all interfere with immunoassays for drugs of abuse.

15.2 Drug Testing Features

15.2.1 Drug Testing Technologies

Drug testing technology can be classified into two major categories: immunoassay and chromatographic techniques of analysis. The chromatographic techniques of analysis may be further classified into thin-layer chromatography, gas chromatography, and liquid chromatography.

15.2.1.1 Immunoassay

The majority of clinical laboratories use immunoassay on high-capacity automated analyzers as first-line screening. All immunoassays are based on an antibody directed against the drug of interest. Binding of drug in the test sample to the antibody modulates an indicator system. The indicator system produces a signal that is a measure of the amount of drug in the sample. There a number of commercial immunoassays that vary in the indicator system used to indicate drug binding. A further variable is the specificity of the antibody. The cross-reactivity of the antibody to other structurally similar drugs and to drug metabolites is variable for different assay vendors.

The popularity of immunoassays is that most of them can be run on the same analyzers that are used to measure biochemical parameters in a routine biochemistry laboratory. The assays are rapid, do not require sample pretreatment, are supplied as “off-the-shelf” kits, are automated, and use a small volume of raw urine. The assays are validated by the manufacturer.

Four variations of immunoassays are in common use. These assays are:

- Enzyme multiplied immunoassay technique (EMIT, a Siemens trademark)
- Fluorescence polarization immunoassay (FPIA, an Abbott trademark)
- Cloned enzyme donor immunoassay (CEDIA, a Thermo trademark)
- Kinetic interaction of microparticles in solution (KIMS, a technique associated with Roche Abuscreen)

In Australasian laboratories, the CEDIA assays are the most commonly used immunoassays. In the CEDIA assay, ß-galactosidase is present as two inactive enzyme fragments which can reassociate to form the functional enzyme.

One of the inactive fragments is conjugated with drug (this fragment is designated as the "enzyme donor" fragment). If drug is present in the sample, it binds to the drug antibody and the enzyme fragment is free to associate and form the active enzyme. If drug is not present in the sample, the enzyme-drug fragment binds to the antibody and the fragment is not available to form an active enzyme.

Active enzyme cleaves chlorophenol red-ß-D-galactopyranoside to yield free chlorophenol red that can be detected photometrically.

Immunoassays for drugs suffer from the same disadvantages as any immunoassay. False-positive results for particular drugs of abuse can arise because of poor specificity for the drug. One of the popular assay systems uses an antibody to detect amphetamine that cross-reacts with pseudoephedrine.

The antibody used in screening assays for opiate drugs cannot distinguish between the presence of morphine and the presence of codeine. Thus, it is possible to have a positive opiate urine from the ingestion of a popular over-the-counter combination analgesic (paracetamol and codeine).

There is a commercial assay for methadone in urine that is specific for the parent drug and with limited cross-reactivity for the metabolites of methadone (EDDP and EMDP). There is a different assay from the same vendor that is specific for EDDP with low cross-reactivity for the parent drug methadone. This allows detection of a practice in where dispensed methadone was sold to other users. The person on-selling would spike their urine with pharmaceutical methadone to indicate that they had taken methadone and were compliant with the prescribed pharmacotherapy. Testing this urine for the presence of methadone metabolite would yield a negative result and thus rule out that the methadone in the urine resulted from ingestion of the prescribed drug.

Sometimes interpretation of a result depends on knowledge of the antibody specificity and metabolism of the drug.

The initial phase of drug excretion in the urine may have a higher proportion of parent drug than later phases of excretion where drug metabolites may predominate. Different individual may metabolize drug differently to others. Given that antibodies from different manufacturers have different specificities for parent drug and metabolites, any attempt to determine a quantitative result from immunoassay is fraught with difficulty. Further urine can range from dilute to concentrated depending on the state of hydration of individuals.

Clinicians should be aware that immunoassay screening is typically reported as a "negative" or "positive" result. A positive result means that the drug was detected at a concentration that exceeds a threshold concentration (often referred to as a "cutoff" concentration). A negative result does not mean that the drug is absent, rather that the concentration is less than the threshold concentration.

Cutoff concentrations are mandated in a range of jurisdictions, and there is some variability in the concentrations specified. There is an Australian and New Zealand Standard for Drugs of Abuse Testing in urine. The standard is jointly published by Standards Australia and Standards New Zealand and has the formal title of *AS/NZS 4308:2008 Procedures for specimen collection and the detection and quantitation of drugs of abuse in urine*.

This standard mandates the following cutoff concentrations:

- Amphetamine and related compounds, cutoff concentration is 300 μg/L.
- Benzodiazepines, cutoff concentration is 200 μg/L.
- Carboxy-THC (cannabis metabolite), cutoff concentration is 50 μg/L.
- Benzoylecgonine (cocaine metabolite), cutoff concentration is 300 μg/L.
- Morphine and related opiates, cutoff concentration is 300 μg/L.

So what is the rationale for these threshold concentrations? In the United States, there is a federal government-mandated drug testing regime for all federal employees. Regulation in most jurisdictions is based on the template provided by the Substance Abuse and Mental Health Services Administration of the United States (SAMHSA).

The SAMHSA testing has its origins in an Executive Order signed by President Ronald Reagan with the goal of establishing a drug-free federal workplace (Executive Order 12564, signed September 15, 1986). This was prompted by a crash of a military aircraft where drug use was implicated as a cause of the crash.

SAMHSA issues a regulation for testing for the presence of drugs of abuse in body fluids. This regulation is known as "Mandatory Guidelines for Federal Workplace Drug Testing Programs." The first version of the Mandatory Guidelines was promulgated in 1988.

AS/NZS 4308:2008 follows the cutoff concentrations specified by SAMHSA with the exception for amphetamine. For more than 20 years, the SAMHSA-specified cutoff for amphetamine was 1,000 μg/L. This was revised down to 500 μg/L in 2010.

The AS/NZS 4308 standard specifies 300 μg/L as the cutoff concentration for amphetamine, and this is a concentration that might produce a higher rate of false positives. The Preface to AS/NZ 4308:2008 specifically states that the role of the standard is to specify procedures for the testing of specimens "for medical-legal, workplace or court directed testing." The Preface contains an explicit disclaimer that testing for "clinical use or sport" is not covered by the standard. That is, the standard is specifically intended to apply to testing when the results of that testing may be presented in judicial or tribunal proceedings. The AS/NZS 4308 standard prescribes that all urines that test positive in the screening test must be confirmed by chromatographic analysis: thus, a high rate of false positives is of no consequence if there is mandatory confirmation testing.

Many clinical laboratories adopt the cutoff concentrations specified by AS/NZS 4308 even though the testing is performed in a different context to that intended for AS 4308. Clinical laboratories are not required to proceed to confirmatory testing (there are a few clinical laboratories that are accredited to AS 4308, and they would be obliged to perform confirmatory testing).

15.2.2 Chromatographic Techniques for Detecting Drugs of Abuse

Immunoassay depends on the specific of an antibody to bind to a drug molecule. Chromatography takes a different approach: chromatography is a process whereby individual components of a complex mixture are separated and identified.

There are three techniques that can be used to separate and identify drugs in a body fluid such as urine. They are thin-layer chromatography (TLC), gas

chromatography (GC), and liquid chromatography (LC). All of these kinds of chromatography involve a stationary phase and a mobile phase.

In TLC the stationary phase is a thin layer of a sorbent applied to a glass or plastic film as a backing medium or can even be specially formulated paper. The mobile phase is a liquid that migrates up the thin layer by capillary "wicking." The separation is achieved because of differential migration of drugs. Some drugs move rapidly because they have an affinity for the mobile phase, while others move slowly because of an affinity for the stationary phase.

In GC the stationary phase is a polymer that coats the inner wall of a silica capillary tube. The capillary tube is referred to as a column and typically has an internal diameter of 0.25 mm and a length of 30 m. The mobile phase is an inert gas such as helium. As in all forms of chromatography, the separation is achieved by a characteristic distribution of the drug between the stationary phase and the mobile phase. The constraint in gas chromatography is that the compound to be separated must be volatile. Most drugs are not volatile, and this means that they must be converted by chemical reaction into volatile analogues.

In LC the stationary phase consists of small spherical particles of silica. The particles are packed into a stainless steel column (75–150 mm long). In high-performance columns, the beads are 2 μm in diameter. The beads are usually coated with hydrocarbon "whiskers" that are chemically bonded to the underlying silica. The mobile phase is usually water based but with varying amounts of an organic modifier such as methanol or acetonitrile that are used to vary the polarity of the mobile phase. In common with all chromatographic separations, components of a mixture are separated based on their differential distribution between stationary phase and mobile phase.

Prior to performing a chromatographic separation, there is usually some form of sample pretreatment. This pretreatment involves extracting the drug of interest from urine by mixing with a nonmiscible solvent into which the drug is preferentially distributed.[2] This treatment provides a first stage of purification and can be used to concentrate the drug to enhance detection.

Drugs are detected using TLC by direct visualization of a spot after sequentially dipping in or spraying with a range of "visualization" reagents. These visualization reagents react with drugs of interest to give color reactions. Thus, identification of a drug depends on the degree of migration through the stationary phase and the pattern of reaction colors. The advantage of TLC is that it uses simple equipment. The disadvantages of TLC are that it requires extensive training to acquire the pattern recognition skills, it is relatively insensitive, and it does not provide any quantitation of the amount of drug present in the sample.

GC and LC are "instrumental" techniques of analysis, and the equipment is expensive. There are a number of different detectors that can be used to detect the presence of drug that is eluted from the chromatographic column. For drug analysis, the preferred detectors are mass spectrometers (MS).

[2]There is a variation on this procedure that is called solid-phase extraction; this technique will not be discussed here.

Mass spectrometry involves the formation of charged ion(s) from the drug molecule. These charged ions can be sorted in the mass spectrometer and the mass of each ion determined. Hard ionization, such as that produced by subjecting the drug molecule to a beam of electrons, results in extensive fragmentation of the drug molecule. Soft ionization, such that produced using an electrospray ion source,[3] produces limited fragmentation. Different drugs give rise to a distinctive ion "fingerprint."

There is now a trend to the use of "tandem mass spectrometry." In tandem mass spectrometry, one of the ions generated in the ion source is selectively introduced in a collision cell where it collides with inert gas molecules. These collisions induce further fragmentation. The daughter ions produced from the selected precursor ion can be separated and characterized. The two stages of fragmentation of the drug molecule in a tandem mass spectrometer provide greater specificity in the identification of the drug. Thus, drugs are identified based on the time it takes to elute the drug from the chromatographic column (retention time) and the pattern of ions formed after ionization of the drug molecule.

Gas chromatography has the highest resolution of all these modes of chromatography and can typically resolve 100 or more compound in a single chromatographic run. The disadvantage of GC is that it can only be applied to volatile substances so that most drugs have to be derivatized before they can be chromatographed. This is a labor-intensive process.

LC can be used for nonvolatile drugs and does not require chemical derivatization. LC lacks some of the resolving power of GC. Ionization of drugs in the liquid phase results in soft ionization with limited fragmentation, and for this reason tandem mass spectrometry is usually required to give the desired specificity to the analysis. LC-TMS analyzers double the cost of GC-MS analyzers.

15.2.3 Pharmacokinetics and Metabolism

A basic understanding of pharmacokinetics and metabolism is required to estimate windows of opportunity to detect drugs in urine.

15.2.4 Amphetamine

Amphetamine (1-phenylpropan-2-amine) is a molecule consisting of a benzene ring with a 3-carbon side chain; an amino group is substituted on the second carbon of the side chain. The amino group on the side chain confers basic characteristics for this drug, and consequently the rate of renal excretion of the unchanged drug is dependent on urine pH.

[3]Electrospray ionization occurs when solvent is eluted from a chromatographic column and nebulised from a jet, maintained at a high voltage, into a heated gas stream.

Acidic urine inhibits tubular reabsorption and promotes net excretion of amphetamine because the drug is charged at an acidic pH and less likely to diffuse back across the plasma membrane of the tubular epithelium. When the pH of urine is uncontrolled, about 30 % of the drug is excreted unchanged in the first 24 h; if the urine is acidified, this rises to 75 %, and if the urine is alkalinized, the amount excreted unchanged can fall to less than 5 %.

The plasma half-life of amphetamine can vary from 4 h (acidic urine) to 12 h (uncontrolled urinary pH).

The major route of metabolism is oxidative deamination to form phenylacetone which is then hydroxylated to benzoic acid which in turn is converted to hippuric acid. When urine pH is not manipulated, about 50 % of the dose is excreted in the urine as benzoic and hippuric acids.

There are many compounds that are structurally related to amphetamine that have psychoactive properties. These include methamphetamine (crystal meth), methylenedioxyamphetamine (MDA), and methylenedioxymethylamphetamine (MDMA or Ecstasy).

Methamphetamine is the molecule formed when the amino group of amphetamine is substituted with a methyl group to form a secondary amine. MDMA is the molecule formed when there is a methylenedioxy bridge attached to the benzene ring on carbon atoms 3 and 4.

Historically, immunoassays for amphetamines in urine were prone to interference from a range of other drugs including over-the-counter drugs such as pseudoephedrine. The more recent formulations of these kits are less likely to exhibit these cross-reactions. When there is doubt about the veracity of a laboratory result, enquiry should be made of the individual laboratories to determine the performance characteristics of the particular assay that is used.

There is some variation in the performance of immunoassays for amphetamines and related compounds. The most common immunoassay system used in Australia offers two versions of the assay to detect these psychoactive amines. Both versions give 100 % cross-reactivity with amphetamine but have different cross-reactivity for the analogues of amphetamine.

One of the assay systems shows 100 % reactivity for methamphetamine, 2 % reactivity for MDA, and 70 % reactivity for MDMA. The alternate assay system shows 80 % reactivity for methamphetamine, 115 % reactivity for MDA, and 200 % reactivity for MDMA. Assays from other vendors have different patterns of reactivity.

Despite all of these variables, amphetamine and related compounds should be detected in the urine for 48 h after administration of the drug.

15.2.5 Benzodiazepines

Benzodiazepines are drugs that have hypnotic, anxiolytic, and anticonvulsant activity. There are many compounds fall within this class of drugs. They vary in their patterns of metabolism and their spectrum of physiological effects. The pharmacology of benzodiazepines is complex because many of the metabolites of the parent drugs are biologically active themselves.

The variety of chemical structures that possess these properties is extensive. This chapter will restrict discussion to the 12 compounds of this class that are used clinically in Australia. They are shown in Table 15.1.

The chemical structures of these compounds are shown in Fig. 15.1.

All of these compounds include a benzene ring fused with a diazepine ring. A diazepine ring is a 7-member heterocyclic compound that contains two nitrogen atoms. The atoms of the diazepine ring are numbered 1–5 starting with the nitrogen atom closest to the benzene ring (atoms involved in the fusion of the two rings are not counted).

In all of these compounds, the nitrogen atoms are located at positions 1 and 4 (called a 1, 4-benzodiazepine). The exception is clobazam where the nitrogen atoms are in positions 1 and 5 (a 1, 5-benzodiazepine).

With the exception of bromazepam, all of these benzodiazepines have an aryl substituent attached to position 5 in the diazepine ring. Bromazepam is substituted at position 5 with a pyridine ring.

Midazolam includes a fused diazolo ring. A diazolo ring is a five-member heterocyclic ring that includes two nitrogen atoms.

Alprazolam and triazolam include a fused triazolo ring. A triazolo ring is a five-member heterocyclic ring that includes three nitrogen atoms.

All of these benzodiazepines include substitution of a carbon atom in the fused benzene ring. This carbon atom is the para position relative to the carbon closest to the nitrogen in the diazepine ring. This position is sometimes numbered as carbon 7, sometimes as carbon 8, and sometimes as carbon 9.

This carbon is variously numbered because of the convention in numbering atoms in fused ring systems.

In six of the benzodiazepines, this "para" carbon atom is numbered as atom 7 (bromazepam, clobazam, clonazepam, diazepam, oxazepam, and temazepam).

In three of the benzodiazepines, this carbon atom is numbered as atom 8 (alprazolam, midazolam, and triazolam).

Table 15.1

Benzodiazepine	Duration of action[4]
Alprazolam	Intermediate acting
Bromazepam	Intermediate acting
Clobazam	Long acting
Clonazepam	Long acting
Diazepam	Long acting
Flunitrazepam	Long acting
Lorazepam	Intermediate acting
Midazolam	Short acting
Nitrazepam	Long acting
Oxazepam	Intermediate acting
Temazepam	Intermediate acting
Triazolam	Short acting

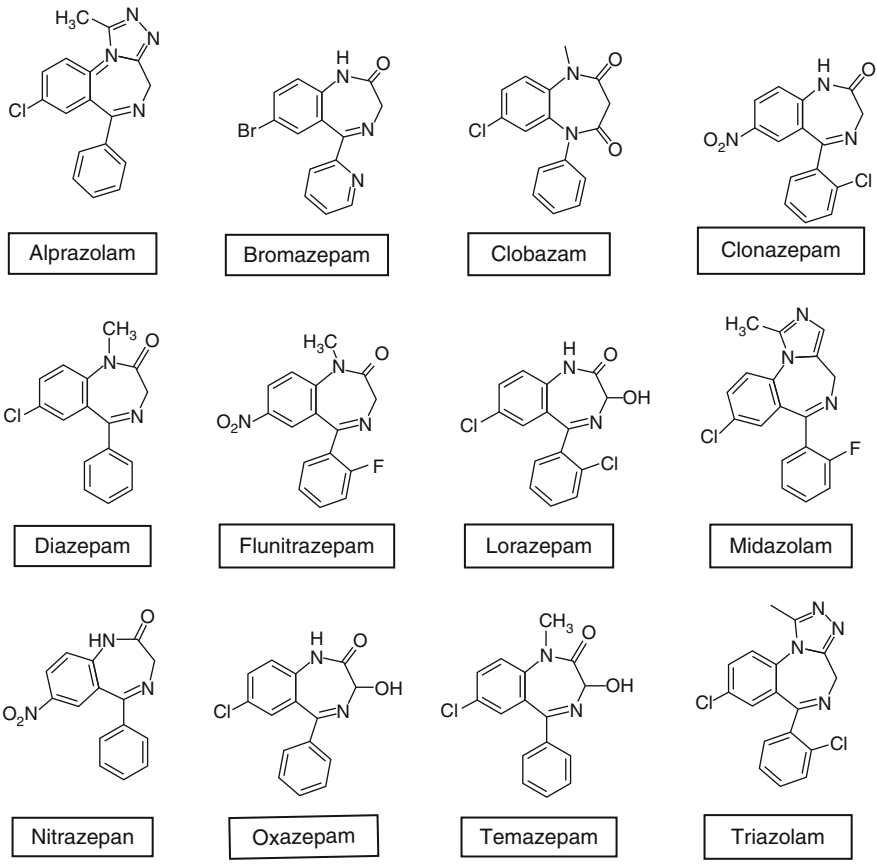

Fig. 15.1

In three of the benzodiazepines, this carbon atom is numbered as atom 9 (flunitrazepam, lorazepam, and nitrazepam).

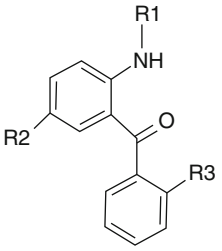
Eight of the twelve benzodiazepines have a chlorine substituent in the para position. Bromazepam is substituted with a bromine atom in this position. Clonazepam, flunitrazepam, and nitrazepam are substituted with a nitro group in the para position.

15.2.6 Metabolism

The metabolism of the benzodiazepines involves three main reactions:

- Hydroxylation at carbon 3 of the diazepine ring
- Dealkylation of the 2-methyl group of diazepam, flunitrazepam, midazolam, and temazepam

- Dealkylation of the methyl substituent of the diazolo ring of midazolam
- Dealkylation of the methyl substituent of the triazolo ring of alprazolam
- Hydroxylation of the methyl substituent of the diazolo or triazolo benzodiazepines
- Reduction of the nitro group of clonazepam, flunitrazepam, and nitrazepam to form amino metabolites of these benzodiazepines
- Hydrolytic cleavage of the diazepine ring to form an amino-benzophenone with the elimination of glycine



Aminobenzophenone

There is extensive glucuronidation all of these metabolites.

There is minimal or no excretion of the unconjugated parent drug. Most of the benzodiazepines undergo significant metabolism. The exceptions are oxazepam, temazepam, and lorazepam that are excreted largely as the glucuronide.

15.2.7 Alprazolam

The two major metabolites are α-hydroxyalprazolam (where the methyl substituent of the triazolo ring is hydroxylated) and 4-hydroxyalprazolam where carbon 4 of the diazepine ring is hydroxylated. Both metabolites are active. The α-hydroxyalprazolam represents 15 % of the dose of the parent drug and the 4-hydroxyalprazolam represents about 60 % of the dose. The remainder is made up of minor metabolites such as the benzophenone derivative and desmethylalprazolam.

15.2.8 Bromazepam

The two major metabolites are 3-hydroxybromazepam (30 %) and the benzophenone derivative (40 %). These two metabolites are extensively conjugated.

15.2.9 Clobazam

Clobazam is highly lipophilic and is metabolized slowly: about 90 % of a dose is excreted in the urine in 17 days. It is metabolized by demethylation and

hydroxylation. The metabolites are desmethylclobazam (an active metabolite) and 4-hydroxyclobazam and 4-hydroxydesmethylclobazam.

15.2.10 Clonazepam

The major metabolic reaction is reduction of the nitro group to 7-aminoclonazepam, followed by acetylation to 7-acetamidoclonazepam. Hydroxylation of clonazepam and its 2 metabolites also occurs. All metabolites are extensively conjugated. 70 % of the dose is excreted as 7-aminoclonazepam and 7-acetamidoclonazepam.

15.2.11 Diazepam

The major routes of metabolism are demethylation to form desmethyldiazepam and 3-hydroxylation. Desmethyldiazepam (nordiazepam) is an active metabolite that accumulates during chronic dosing. Desmethyldiazepam can be further metabolized to form oxazepam (an active metabolite). Diazepam can also be hydroxylated to form temazepam, another active metabolite. There is considerable interperson variation in the proportion of the metabolites formed although oxazepam is the major metabolite and is excreted as the glucuronide.

15.2.12 Flunitrazepam

Flunitrazepam is extensively metabolized to desmethylflunitrazepam and 7-aminoflunitrazepam. Other metabolites include 3-hydroxyflunitrazepam, 3-hydroxy-7-acetamidoflunitrazepam, and 7-amino-1-desmethylflunitrazepam.

15.2.13 Lorazepam

Lorazepam is excreted in the urine as the inactive glucuronide. There is no other metabolism of any significance.

15.2.14 Midazolam

Midazolam is metabolized by hydroxylation to 1-hydroxymethylmidazolam and 4-hydroxymidazolam. These hydroxy metabolites are then conjugated with glucuronic acid and cleared rapidly (90 % of a dose is excreted in the urine in 24 h).

15.2.15 Nitrazepam

Nitrazepam is metabolized to 7-aminonitrazepam and then to the 7-acetamido derivative. There is some formation of 3-hydroxy derivatives of these metabolites.

There is also cleavage of the diazepine ring to yield 2-amino-5-nitrobenzophenone and 2-amino-3-hydroxy-5-nitrobenzophenone. All the metabolites are inactive.

15.2.16 Oxazepam

Oxazepam is glucuronidated and excreted in the urine. Only traces of unchanged oxazepam and other minor metabolites can be detected in the urine. Oxazepam is a metabolite of diazepam and temazepam.

15.2.17 Temazepam

Temazepam is largely excreted as the glucuronide. There is limited demethylation to form oxazepam. Temazepam is a metabolite of diazepam.

15.2.18 Triazolam

The major metabolite of triazolam is 1-hydroxymethyltriazolam which has similar activity to the parent drug. Minor metabolites are 4-hydroxytriazolam, 1-hydroxymethyl-4-hydroxytriazolam, and dichlorotriazolylbenzophenone derivatives.

15.2.19 Immunoassay Detection of Benzodiazepines

Table 15.2 shows the specificity of a commonly used immunoassay for benzodiazepines.

The assay has probably been standardized to nitrazepam because this drug shows 1,005 cross-reactivity. Diazepam shows 247 % cross-reactivity, and clobazam shows 62 % cross-reactivity. The glucuronides of temazepam, oxazepam, and lorazepam exhibited minimal reaction in the assay system unless the urine was treated with ß-glucuronidase to hydrolyze the conjugate and release free drug or metabolite. Glucuronidation is the major route of biotransformation of these 3 benzodiazepines so treatment with ß-glucuronidase is essential to detect these drugs.

15.2.20 Cannabinoids

The hemp plant C*annabis sativa* synthesizes a psychoactive compound called tetrahydrocannabinol. Tetrahydrocannabinol is the main psychoactive compound found in the plant, but it is one of over 60 closely related compounds that are collectively referred to as cannabinoids.

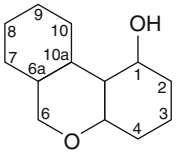
Table 15.2 Specificity of the CEDIA® Benzodiazepine Assay for various benzodiazepines and their metabolites[a]

Drug/metabolite	Percent cross-reactivity without ß-glucuronidase treatment	Percent cross-reactivity with ß-glucuronidase treatment
7-aminoflunitrazepam	Not tested	99
7-aminonitrazepam	Not tested	83
α-Hydroxyalprazolam	188	167
α-Hydroxytriazolam	193	155
Alprazolam	205	220
Alprazolam glucuronide	Not tested	100
Bromazepam	110	104
Clobazam	62	59
Clonazepam	140	71
Desalkylflurazepam	210	173
Diazepam	247	154
Flunitrazepam	135	109
Lorazepam	122	115
Lorazepam glucuronide	1	45
Aminoclonazepam	Not tested	96
Nitrazepam	100	100
Desmethyldiazepam	211	173
Oxazepam	107	125
Oxazepam glucuronide	1	25
Temazepam	144	93
Temazepam glucuronide	1	25
Triazolam	191	217

[a]Adapted from the Thermo Scientific Benzodiazepine Assay Package Insert dated November 2002

It is difficult to follow the metabolism of tetrahydrocannabinol without a basic understanding of the structure of the molecule. Tetrahydrocannabinol is the derivative of a fused ring system named tetrahydrobenzo[c]chromen-1-ol. The chromen-1-ol part of the name refers to a benzene ring fused to a furan (a 6-membered heterocyclic ring containing an oxygen atom), and the benzene ring is substituted with a hydroxyl group at carbon number 1. The tetrahydrobenzo group is the third ring structure fused to the chromen-1-ol system; the tetrahydrobenzo ring is a 6-membered carbon ring that is not an aromatic ring (it has four extra hydrogen atoms attached to the ring carbons that prevent the ring from displaying aromatic character).

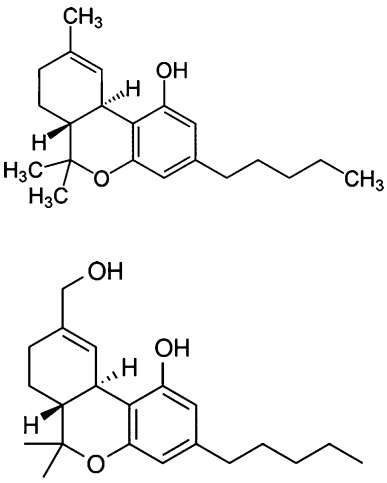
The numbering convention is shown below:



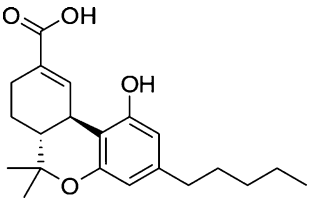
Tetrahydrocannabinol has the structure shown below.

The formal chemical name of tetrahydrocannabinol (THC) is 6,6,9-trimethyl-3-pentyl-6a,7,8,10a-tetrahydro-6H-benzo[c]chromen-1-ol. There are 2 methyl substituents on the benzene ring at ring position 6 and a further methyl group attached at position 9. There is a pentyl substituent on carbon number 3. The nonaromatic ring has 2 hydrogen atoms bonded to carbon atom numbers 6a, 7, 8, and 10a.

The first step in the metabolism of tetrahydrocannabinol is the hydroxylation of the methyl group attached to the carbon in position 9 of the ring system. The formal name of this metabolite is 9-(hydroxymethyl)-6,6-dimethyl-3-pentyl-6a,7,8,10a-tetrahydro-6H-benzo[c]chromen-1-ol. Simpler nomenclature calls this compound 11-hydroxy-tetrahydrocannabinol or 11-OH-THC; the structure is shown below.



11-Hydroxy-tetrahydrocannabinol is known to be psychoactive but has a limited role in the pharmacology of cannabis. Hydroxy-THC is rapidly metabolized to form a carboxylated metabolite. The carboxylated metabolite has the formal name 1-hydroxy-6,6-dimethyl-3-pentyl-6a,7,8,10a-tetrahydrobenzo [c]chromene-9-carboxylic acid, but this name is conveniently shortened to 11-*nor*-9-carboxy-delta-9-tetrahydrocannabinol or simply carboxy-THC. The structure is shown below:



Carboxy-THC is not psychoactive and is extensively conjugated with glucuronic acid before excretion into urine. The cutoff concentration for immunoassay of "cannabis metabolites" is set at 50 μg/L in the Australasian Standard AS/NZS 43008. This standard prescribes a negative report if the immunoassay screening is less than the cutoff concentration and confirmatory testing does not proceed. If a positive result is obtained in the immunoassay screen, it is then mandatory to confirm by chromatographic testing, and the confirmatory cutoff concentration nominated by the standard specifically for carboxy-THC is 15 μg/L. Hydrolysis of the glucuronide of carboxy-THC is rarely performed prior to immunoassay but is mandatory before confirmatory chromatographic analysis. One of the commonly used immunoassays is calibrated with carboxy-THC (i.e., carboxy-THC shows 100 % cross-reactivity); the assay shows a 63 % cross-reactivity to the glucuronide of carboxy-THC. By way of contrast, the parent psychoactive compound THC shows a 28 % cross-reactivity and hydroxy-THC shows a 42 % cross-reactivity.

The specified cutoff concentrations are a compromise: if the cutoff is set too low, it could produce a "positive" result from passive smoking. If the cutoff is set too high, then true positives might not be detected. The effect of passive smoking has been the subject of a number of studies, and the consensus is that passive smoking is unlikely to result in a urinary concentration of cannabis metabolites that exceeds 50 μg/L.

The half-life for elimination of carboxy-THC is about six days. The precursor compound THC is lipophilic and has a high volume of distribution of about 10 L per kilogram of bodyweight. Chronic users of cannabis establish a significant reservoir of carboxy-THC in the adipose tissue. During periods of abstinence, THC is slowly released into the systemic circulation and metabolized to hydroxy-THC and carboxy-THC: about 70 % of these metabolites are excreted in the feces and about 30 % is eliminated in the urine. The time taken for carboxy-THC to fall below the cutoff concentrations of the metabolite in the urine is therefore dependent on the amount of THC stored in tissue lipids.

Following a single occasion of cannabis use, the urinary concentration of carboxy-THC, determined by GC-MS, falls below a cutoff concentration of 50 μg/L within 72 h. Moderate users of cannabis (defined as four occasions per week) typically fall to the cutoff concentration within 5–7 days after ceasing use of the drug. Daily use of cannabis typically exhibits a fall to the cutoff concentration within 12 days of ceasing use. Carboxy-THC may be detected in the urine of chronic heavy users for greater than 30 days after cessation of use.

Given the extended period of detection of carboxy-THC in the urine of long-term heavy users of the drug, the question is often posed if there is continued use. This may be a pertinent question in persons on drug rehabilitation programs, which require abstinence, or when use is proscribed by judicial proceedings. One approach to this issue is to determine a carboxy-THC to creatinine ratio for urine samples collected at different times. A comparison of these two ratios and consideration of the time elapsed between the two samples taken allow an assessment of continued use. The stringency of the criteria that are applied in comparing these ratios influences the

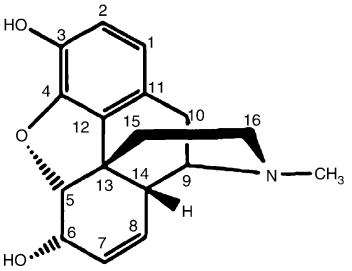
reliability of the assessment. Stringent criteria will give a high probability of a true positive result, whereas less stringent criteria may detect more recidivist behavior but at the risk of false-positive results (Identifying New Cannabis Use with Urine Creatinine-Normalized THCCOOH Concentrations and Time Intervals between Specimen Collections, M. L. Smith, A. J. Barnes, and M. A. Huestis, Journal of Analytical Toxicology, volume 33, May 2009, page 185). Clinicians should contact their local provider of laboratory testing to determine an appropriate testing strategy for the care of their patients.

15.2.21 Opiates and Opioids

Opium is the dried sap that is exuded when the seedpods of the opium poppy (*Papaver somniferum*) are scored. Crude opium contains about 25 alkaloids. Alkaloids are plant products that are bases because they contain a heterocyclic ring that includes a nitrogen atom. Many alkaloids have pharmacological activity. The main alkaloids in opium are morphine, codeine, and thebaine.

Morphine can be isolated in pure form from opium. Both licit and illicit sources of morphine are derived from the cultivation of poppies. The term opiates is used to describe drug substances that are purified from opium or are simple derivatives of the opium alkaloids: this includes morphine, codeine, and heroin. The term opioids includes all substances that have a morphine-like activity whether they are naturally occurring alkaloids, semisynthetic drugs such as hydrocodone and hydromorphone, or synthetic drugs that include buprenorphine, fentanyl, methadone, and oxycodone.

The morphine molecule consists of five fused rings. There is a benzene ring fused to a cyclohexane ring (6 carbon unsaturated ring) which in turn is fused to a cyclohexene ring (6 carbon unsaturated ring). The benzene ring and the cyclohexene ring are joined by a tetrahydrofuran ring (5 atom ring containing an oxygen atom). These four fused rings form a rigid structure in one plane; above this plane is a piperidine ring (6-membered ring containing a nitrogen atom). Piperidine shares carbon atoms with the four ring systems at positions 9, 13, and 14 (see the structure below).



Morphine has two hydroxyl groups, one at position 3 and one at position 6. These two hydroxyl groups can react with acetic acid (or acetic anhydride) so that two acetyl groups are added to the molecule via an ester link. The resulting

molecule is 3,6-diacetylmorphine (diamorphine or heroin). Codeine has the same structure as morphine excepting the 3-hydroxyl group is replaced by a methoxy (CH_3O–) group.

Heroin is rapidly metabolized to both 3-monoacetylmorphine and 6-monoacetylmorphine. The half-life of heroin in the systemic circulation is about 3 min.

The 3-monoacetylmorphine is inactive because it lacks a free hydroxy group at position 3 that is essential for receptor binding; 6-monoacetyl has double the potency of morphine but it too is rapidly deacetylated to morphine with a half-life of about 5 min.

Diamorphine and 6-monoacetylmorphine both are more lipophilic than morphine and cross the blood-brain barrier more easily than morphine. Diamorphine can be detected in CSF within 15–20 s of intravenous administration.

After parenteral administration of morphine, 90 % of the drug is excreted in the urine in the following 24 h. Morphine is mainly excreted as the 3-glucuronide and the 6-glucuronide. The plasma half-life is about 3 h.

Intact codeine has minimal analgesic activity; the analgesic effect exerted by codeine only occurs after the drug has been O-demethylated to yield morphine. The demethylation occurs mainly in the liver due to the action of the CYP2D6 cytochrome (this is a polymorphic enzyme with significant interindividual variation in the rate of demethylation). Following oral administration, about 60 % of the dose is excreted as free or conjugated codeine, and about 20 % is excreted as free or conjugated morphine. The plasma half-life of codeine is about two hours.

There are several issues with the interpretation of immunoassays of urine that are positive for opiates. Most immunoassays do not distinguish between codeine and morphine. Codeine is present in some over-the-counter analgesic, whereas morphine is subject to more intense regulation (regulated as a Schedule 8 Controlled Drug in Australia) or morphine may be present in urine because of the illicit use of heroin.

Standard AS/NZS 4308 prescribes a cutoff of 300 μg/L for immunoassay screening for the presence of an opiate in urine. Most Australian clinical laboratories, whether accredited to the standard or not, continue to report a positive opiate when this cutoff is exceeded. This 300 μg/L cutoff was originally specified by SAMHSA but was increased to 2,000 μg/L in 1998 because the threshold as originally set could be exceeded by ingestion of poppy seed legitimately used in food products.

Urines that test positive to an immunoassay for opiates can be tested using chromatographic techniques where it is easy to quantify individual opiates. When these data are available, some rules can be applied to contribute the source of the opiate:

- If the total codeine concentration in the urine sample is >300 μg/L and the ratio of the morphine concentration to the codeine concentration >2, then it is probable that these opiates occur in the urine because of ingestion of codeine alone.

- If the total morphine concentration in the urine sample is greater than 1,000 μg/L and the ratio of the morphine concentration to the codeine concentration is $1 < 2$, then poppy seeds can be excluded as the sole source for the positive opiate test result.
- If the total morphine concentration in the urine sample is greater than 1,000 μg per ml and no codeine is detected, then it is likely that the positive opiate result is due to the use of morphine or heroin (The Clinical Toxicology Laboratory, Page 87, AACC Press, 2001).

Table 15.3 shows the cross-reactivity of a commercial reagent system for detection of opiates (Cedia Opiates, Thermo Scientific).

The assay is calibrated to morphine, and codeine shows 125 % cross-reactivity, whereas diacetylmorphine and other morphine metabolites show a cross-reactivity between 48 % and 57 % (Table 15.3). It should be noted that some semisynthetic opiate agonists such as pethidine, oxymorphone, and oxycodone show minimal activity in the immunoassay system, whereas other semisynthetic agonists show 50–57 % cross-reactivity.

Thus, a "negative" screen for "opiates" does not exclude abuse of a number of opiates and opioids. If this is an issue of concern, practitioners should enquire of their service provider to determine the specificity of the immunoassay used.

It should be noted that a number of assay vendors offer immunoassays that are directed at a particular opiate or opioid and are relatively specific for the compound of interest. These assays may not be offered by hospital biochemistry laboratories on a routine basis. The sample may need to be forwarded to a specialist drug assay laboratory. Such opioids include buprenorphine, pethidine, oxycodone, tramadol, and methadone.

The general rule is that opiates that react in screening assay can be detected for 2 days after a single occasion of use.

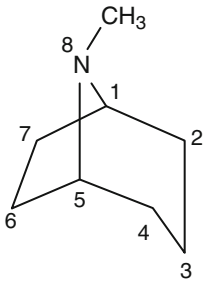
Table 15.3

Drug/metabolite	Cross-reactivity
Morphine	100
Codeine	125
Diacetylmorphine	53
Dihydrocodeine	50
Hydrocodone	48
Hydromorphone	57
Morphine-3-glucuronide	81
Morphine-6-glucuronide	47
6-Monoacetylmorphine	81
Pethidine (meperidine)	0
Oxymorphone	2
Oxycodone	3

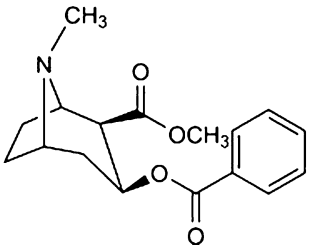
Fentanyl deserves special comment: it is a very potent opioid which means concentrations of the drug in the urine are quite low following licit or illicit use. Detection requires sophisticated technique and sensitive analyzers that will not be available in many laboratories. These technical challenges are known to health professionals who have access to this drug, and fentanyl may become their drug of choice if inclined to drug abuse. There has been a substantial increase in the use of sustained-release transcutaneous patches of fentanyl in treatment of chronic pain or in a palliative care context. It is a relatively simple matter to extract the drug from these patches for intravenous injection and there evidence of a black market for these patches in some jurisdictions.

15.2.22 Cocaine

Cocaine, scopolamine, hyoscyamine, and atropine are examples of tropane alkaloids that occur in the plants. Two families of plants contain tropane alkaloids: Erythroxylaceae (coca) and Solanaceae. These compounds contain a bicyclic 8-membered ring with a nitrogen bridge joining carbon atom 1 and carbon atom 5.



Cocaine has a methyl ester attached at carbon 2 of the tropane ring and a benzoyl ester attached to carbon 3. A trivial name for cocaine is methylbenzoylecgonine.

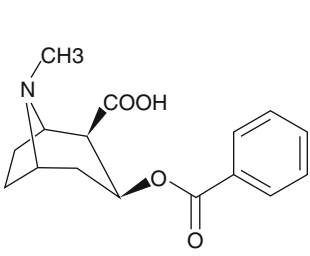


The metabolism of cocaine involves hydrolysis of the two ester bonds in the drug. The major metabolite is benzoylecgonine formed when the methyl ester is hydrolyzed to yield a carboxyl on carbon 2 of the tropane ring. About 45 % of the dose is excreted in the urine as benzoylecgonine.

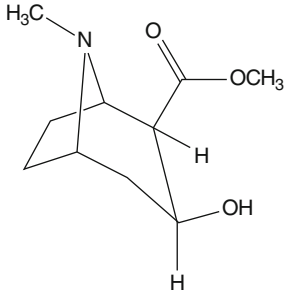
Table 15.4

Drug/metabolite	Cross-reactivity
Benzoylecgonine	100
Cocaine	54
Ecgonine	1
Methylecgonine	0

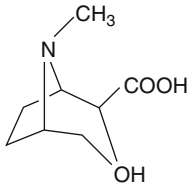
Methyl ecgonine is formed when the benzoyl ester is hydrolyzed to yield an hydroxyl group on carbon 3 of the tropane ring. About 40 % of the dose is excreted in the urine as methyl ecgonine. Both ester links of cocaine may be hydrolyzed to yield ecgonine which is a minor metabolite of cocaine. Only a small proportion of the dose, about 55 %, is excreted as the parent drug.



Benzoylecgonine



Methylecgonine



Ecgonine

Table 15.4 shows the specificity of a commonly used immunoassay for cocaine. The assay is calibrated to the major metabolite, benzoylecgonine. There is limited reaction to cocaine (54 %) and virtually no reaction to the minor metabolites of cocaine.

The cutoff concentration for immunoassay screening is specified as 300 μg/L of "cocaine metabolite"; given the specificity of most assays and the pattern of urinary excretion of metabolites, this equates to a concentration of 300 μg/L of benzoylecgonine.

The standard specifies a lower cutoff concentration for chromatographic confirmatory assays. The confirmatory test is reported as positive if benzoylecgonine is detected at a concentration $\geq$150 μg/L or if methylecgonine is detected at a concentration $\geq$150 μg/L.

Benzoylecgonine can be detected in the urine after a single occasion of use for about 72 h.

Biological State Marker for Alcohol Consumption

Abstract

Alcohol-related disorders are common, expensive in their entire course, and often underdiagnosed. To facilitate early diagnosis and therapy of alcohol-related disorders and thus prevent later complications, questionnaires and biomarkers are useful. Indirect state markers like gamma-glutamyl transpeptidase (GGT), mean corpuscular volume (MCV), and carbohydrate deficiency transferrin (CDT) are influenced by age, gender, various substances, and non-alcohol-related illnesses and do not cover the entire timeline for alcohol consumption. Direct state markers as ethyl glucuronide (EtG), phosphatidylethanol (PEth), and fatty acid ethyl esters (FAEEs) have gained enormous interest in the last decades as they are metabolites of alcohol becoming only positive in the presence of alcohol. As biomarkers with high sensitivity and specificity covering the complimentary timeline, they are already routinely in use and contribute to new perspectives in prevention, interdisciplinary cooperation, diagnosis, and therapy of alcohol-related disorders.

16.1 Introduction

Alcohol-related disorders are in the top ten of the most common diseases worldwide (World Health Organization (WHO) 2011). The point prevalence for alcohol dependence in Germany, as in other comparable countries, is 5 % and the lifetime prevalence is 10 % (Mann 2002). Worldwide, approximately 4 % of deaths are attributable to alcohol, greater than deaths caused by HIV, violence, or tuberculosis (World Health Organization (WHO) 2011). The yearly costs attributable to alcohol in Europe are approximately 270 billion € and in Germany 26.7 billion € (DHS). The costs include medical care; decreased productivity caused by illness, accidents, and death; and the social burden, e.g., in the family (World Health Organization (WHO) 2011).

In general hospitals, a rate of up to 20 % of all inpatients having an alcohol use disorder was found; in surgical departments rates from 16 % to 35 % in patients with multiple trauma were described (Tonnesen and Kehlet 1999; Spies et al. 2001). These patients have a prolonged hospital stay (Tonnesen and Kehlet 1999; Spies et al. 2001; Rubinsky et al. 2012); they have to be treated 1.5 days longer in ICUs

(Rubinsky et al. 2012) and are twice likely to return to OR due to complications (Rubinsky et al. 2012). The post-traumatic lethality is up to four times higher in individuals with alcohol use disorders (Tonnesen and Kehlet 1999; Spies et al. 2001). Of all alcohol-dependent individuals, 80 % are treated by general practitioners and only 34 % in general hospitals (Mann 2002). Thus, alcohol-related disorders are common, expensive in their entire course (Rehm et al. 2009), and often underdiagnosed (Moore et al. 1989).

To facilitate early diagnosis and therapy of alcohol-related disorders and thus prevent later complications, questionnaires like the CAGE questionnaire (Ewing 1984) or the Alcohol Use Disorders Identification Test (AUDIT) (Saunders et al. 1993) and biomarkers are useful.

Indirect state markers as well as direct state markers are routinely used to detect alcohol. The indirect state markers like gamma-glutamyl transpeptidase (GGT), mean corpuscular volume (MCV), and carbohydrate deficiency transferrin (CDT) are influenced by age, gender, various substances, and non-alcohol-related illnesses and do not cover the entire timeline for alcohol consumption (Conigrave et al. 2002; Laposata 1999; Helander 2003a; Hannuksela et al. 2007; Niemelä 2007; Allen et al. 2009).

Direct state markers have gained enormous interest in the last decades as they are metabolites of alcohol becoming only positive in the presence of alcohol. As biomarkers with high sensitivity and specificity covering the complimentary timeline, they are already routinely in use and contribute to new perspectives in prevention, interdisciplinary cooperation, diagnosis, and therapy of alcohol-related disorders.

16.2 Direct Ethanol Metabolites

Routinely used direct ethanol metabolites are:

- Ethyl glucuronide (EtG), in serum, urine, and hair (Alt et al. 2000; Dahl et al. 2002, 2011a; Schmitt et al. 1995; Skipper et al. 2004a; Schlögel et al. 2005; Wurst et al. 1999a, b; Wurst and Metzger 2002; Wurst et al. 2003a, b, 2004a, 2008a, b, c, d, 2011; Politi et al. 2006; Junghanns et al. 2009; Halter et al. 2008; Wiens et al. 2008; Albermann et al. 2012a; Ferreira et al. 2012; Hoiseth et al. 2012, 2013; Hagström et al. 2012; McDonell et al. 2012; Stewart et al. 2013; Redondo et al. 2012)
- Ethyl sulfate (EtS), in urine and serum (Dresen et al. 2004; Helander and Beck 2004; Wurst et al. 2006)
- Phosphatidylethanol (PEth) in whole blood (Alling et al. 1983; Aradottir et al. 2006; Varga et al. 1998; Hartmann et al. 2007; Marques et al. 2010, 2011; Kip et al. 2008; Gnann et al. 2009, 2012; Zheng et al. 2011; Nissinen et al. 2012; Isaksson et al. 2011; Wurst et al. 2010; Wurst and Thon 2012; Loftus et al. 2011; Stewart et al. 2009, 2010; Faller et al. 2011)

- Fatty acid ethyl ester (FAEEs) especially in hair (Auwärter et al. 2001; Pragst et al. 2001; Appenzeller et al. 2007a; Pragst and Yegles 2007)

Direct ethanol metabolites are detectable in serum for hours, in urine for up to 7 days, in whole blood over 2 weeks, and in hair over months.

16.2.1 Ethyl Glucuronide

Ethyl glucuronide (EtG) is a phase II metabolite of ethanol and has a molecular weight of 222 g/mol. It is metabolized by the UDP-glucuronosyltransferase (Foti and Fisher 2005).

It is not relevant for the alcohol elimination (less than 0.1 %), but it can function as a biomarker as it is only detectable in the presence of ethanol. EtG is nonvolatile, water soluble, and stable in storage and can, depending on the amount consumed and time spent for consumption, still be detectable in the body long after completion of alcohol elimination (Wurst et al. 2004a; Borucki et al. 2005). According to Walsham and Sherwood (2012), EtG can be detected of up to 90 h in urine. There is no difference regarding the elimination rate between a healthy population and heavy alcohol consumers at the beginning of detoxification treatment (Høiseth et al. 2009).

Ethyl glucuronide can also be detected in postmortem body fluids and tissues like gluteal and abdominal fat, liver, brain, and cerebrospinal liquor (Wurst et al. 1999b), even in bone marrow and muscle tissue (Schlögel et al. 2005).

Even small amounts like 0.1 l champagne can be detected up to 27 h. Experiments with 1 g ethanol (champagne, whisky) (Thierauf et al. 2009a) as well as use of mouthwash (Costantino et al. 2006) and hand sanitizer gels (Rohrig et al. 2006) yielded ethyl glucuronide concentrations of less than 1 mg/L in urine. Measurable concentrations in urine were found up to 11 h. This aspect is of relevance regarding unintentional exposure of alcohol. Pralines, nonalcoholic beer, pharmaceutical products, fruit juice, sauerkraut, mouthwash products, and hand sanitizer gels may contain small amounts of alcohol. Even the intake of 21–42 g yeast with approximately 50 g sugar leads to measureable EtG and EtS concentrations in urine (Thierauf et al. 2010).

Therefore, a patients' claim not having consumed alcohol may be the truth even when EtG is detectable in urine. Since patients in withdrawal treatment should avoid even the smallest amount of alcohol, they have to be informed of such hidden sources of ethanol to avoid unintentional alcohol intake. A differential cutoff of 0.1 mg/L in cases where total abstinence is the goal, and 1.0 mg/L if small amounts of alcohol intake are tolerated, has been recommended for practical reasons (Costantino et al. 2006).

Selected applications for the use of EtG:

1. Specific high-risk group:

Many patients in opioid-maintenance therapy suffer from hepatitis C (HCV) infection. Alcohol consumption, especially in large amounts, leads to the progression of cirrhosis (Gitto et al. 2009; Safdar and Schiff 2004). One study in Sydney (Wurst et al. 2008d) and one in Basel (Wurst et al. 2011) showed the usefulness

and necessity of the determination of ethyl glucuronide in patients in opioid-maintenance therapy. In the former study, of all EtG-positive patients, 42 % (n = 8 of 19) would have not reported the alcohol consumption (Wurst et al. 2011). In the latter one, 75 % consumed alcohol according to the hair analysis for EtG; however, two thirds did not report about it (Wurst et al. 2011).

The use of direct ethanol metabolites in high-risk groups therefore allows more possibilities for therapeutic interventions, consequently leading to improvement in the quality of life.

2. Monitoring programs:

One example for using ethyl glucuronide successfully in monitoring programs are the Physician Health Programs in the USA which provide a nondisciplinary therapeutic program for physicians with potentially impairing health conditions as, for example, substance-related disorders. Being in the monitoring program, physicians with substance-related disorders are allowed to keep on working, whereas a regularly proof of abstinence has to be shown. Measuring EtG in urine, Skipper and colleagues (Skipper et al. 2004b) showed that of 100 random samples collected, no sample was positive for alcohol using standard testing; however, seven were positive for EtG (0.5–196 mg/l), suggesting recent alcohol use. EtG testing can provide additional information and, consequently, may lead to further treatment and improvement for the patient (Skipper et al. 2004b).

3. Pharmacotherapeutic studies:

As an objective outcome parameter, EtG testing has shown to be useful in pharmacotherapeutic studies (Dahl et al. 2011b; Mitchell et al. 2012).

4. Liver transplantation:

Liver transplantations are in 20–30 % related to alcohol (Burroughs et al. 2006). Postoperatively, 20–25 % of the patients lapse or relapse to alcohol intake (Kelly et al. 2006; DiMartini et al. 2006). In 18 patients with ALD (alcohol liver disease), Erim et al. (2007) found no self-report on alcohol consumption. One out of 127 tests for breath alcohol was positive, whereas 24 of 49 urine samples were positive for EtG. Comparable results were reported by Webzell et al. (2011) who found self-reported alcohol consumption in 3 % in contrast to 20 % positive urine EtG and EtS tests.

The applications mentioned above show that ethyl glucuronide tests are complementary to self-reports and questionnaires, yielding valuable information on alcohol consumption which is relevant to diagnosis and therapy.

16.2.1.1 Methodical Aspects

A DRI ethyl glucuronide enzyme immunoassay (DRI-EtG EIA) is commercially available. The first study showed satisfying but not convincing results (Böttcher et al. 2008). Therefore, enquiries with medicolegal relevance need further confirmation with forensic-toxicologically acceptable methods like LC/MS-MS (Weinmann et al. 2004). The use of penta-deuterium-labeled ethyl glucuronide as internal standard and liquid chromatography-tandem mass spectrometry (LC/MS-MS) must be considered to be a gold standard. The ionic transitions observed are m/z 221 -> 75 for EtG and m/z 226 -> 75 for d5-EtG. A simple mass spectrometry would provide less reliable evidence.

In addition, EtG can also be detected in specimen of dried blood which is of relevance for forensic investigations (Kaufmann and Alt 2008; Winkler et al. 2011).

16.2.1.2 Limitations

In recent years, the potential in vitro formation and degradation of EtG and EtS have gained attention (Helander et al. 2009; Helander and Dahl 2005; Baranowski et al. 2008; Halter et al. 2009): At first, hydrolysis of EtG caused by microbes in urinary tract infections, especially *E. coli*, was reported (Helander and Dahl 2005). Complete degradation of EtG within 3–4 days by *E. coli* and C. sordellii was confirmed by Baranowski et al. (2008). In contrast, the stability of EtS for up to 11 days could be shown (Baranowski et al. 2008). Further studies with standardized test procedures for biodegradation showed that EtS in closed bottle test (OECD 301 D) remained stable for even longer periods, whereas in the context of a higher bacterial density such as in the Manometric Respiratory Test (MRT), a reduction after 6 days was detected (Halter et al. 2009). This problem could be countered by cooling and the addition of stabilizers.

Furthermore, a recent study reported that the bacterial degradation of EtG by *E. coli* can be prevented by the use of dried urine on filter paper (Redondo et al. 2012).

16.2.1.3 Possible Influences on EtG Levels

The WHO/ISBRA Study showed that EtG urine concentrations are influenced by age, gender, cannabis consumption, and renal function. In contrast, race, nicotine consumption, body mass index, liver cirrhosis, and body water content had no significant influence on EtG concentrations (Wurst et al. 2004a). The results concerning renal and liver functions have recently been confirmed:

(a) In 14 patients with reduced renal function (Høiseth et al. 2013), prolonged elimination has been reported.
(b) In a study on 120 patients with liver diseases, severity of disease had no influence on the validity of ethyl glucuronide (Stewart et al. 2013).

The positive predictive values for patients who claimed abstinence in the last 3 days for ethyl glucuronide and ethyl sulfate were 81 % and 70 %, respectively. The negative predictive values were 91 % and 93 %, respectively. Had the patients claimed abstinence in the last 7 days, the positive predictive values would be 97 % and 80 %, respectively; the negative predictive values would each be 85 % (Stewart et al. 2013).

16.2.2 Ethyl Sulfate

Ethyl sulfate (EtS) presents a secondary elimination pathway for alcohol and is usually detectable in varying interindividual concentrations. An immunochemical detection test is currently not commercially available for EtS. For combined detection of EtS and EtG, the use of rapid LC/MS-MS procedures is routinely applied.

The formation is effected by sulfonyl transferase and the breakdown by sulfatases. The molecular weight is 126 g/mol and the molecular formula $C_2H_5SO_4H$.

Ethyl sulfate formed through conjugation of activated sulfate and ethanol in rat liver was described by Boström and Vestermark in 1960 (Boström and Vestermark 1960). Its detection in rat urine was conducted after application of ^{35}S-sulfate and ethanol on rats, with thin slice chromatography and autoradiographic proof on radiographic film (Boström and Vestermark 1960).

Schneider and Glatt (2004) developed a liquid chromatography-tandem mass spectrometry method with 2-propylsulfates as internal standard. Helander and Beck (2004) used liquid chromatography-electrospray ionization-mass spectrometry (LC-ESI-MS) in a single-quadrupole modus and D_5-ethylsulfate as internal standards for the quantification of EtS in urine samples. The disadvantage of this method is a longer period of chromatographic separation. Furthermore, the exclusive monitoring of de-protonated molecules in a single MS does not meet forensic standards (Aderjan et al. 2000; Society of Forensic Toxicologists and American Academy of Forensic Sciences and SOFT/AAFS 2006). At any rate, an additional fragment ion would be required for the verification analyses according to forensic guidelines (Society of Forensic Toxicologists and American Academy of Forensic Sciences and SOFT/AAFS 2006). Even when this requirement from forensic guidelines must not be met in clinical diagnostic, it is still in demand in workplace drug testing in the USA (SAMHSA. Mandatory Guidelines for Federal Workplace Drug Testing. Federal Register 2004). In this context, an LC-tandem-MS method with penta-deuterium EtS as internal standard and two ion transitions (Dresen et al. 2004), which can be used in forensic and medicolegal cases as well as in clinical routine (Skipper et al. 2004a), raises particular interest.

In summary, a cutoff of 0.05 mg/l for repeated alcohol intake was suggested (Albermann et al. 2012b). As for ethyl glucuronide, there is evidence of prolonged elimination in reduced renal function (Høiseth et al. 2013).

16.2.3 Fatty Acid Ethyl Esters

In recent years, the existence of fatty acid ethyl esters, non-oxidative metabolic products of ethanol in blood and various organs with reduced or deficient capacity to oxidize ethanol after consumption has been proven. Since these esters were proven to cause damage to subcellular structures, they were postulated to be mediators of organ damage.

Two enzymes catalyze the formation of FAEE: acetyl-coenzyme A:ethanol o-acyltransferase (AEAT) and fatty acid ethyl ester-synthase. FAEE synthase can be isolated from rabbit myocardium, human brain, and rat fat tissue. Two of these FAEE synthases were shown to be identical to rat liver carboxyl esterase (Tsujita and Okuda 1992; Bora et al. 1996). Furthermore, pancreatic lipase, lipoprotein lipase, and glutathione transferase were shown to possess FAEE synthase activity (Tsujita and Okuda 1992; Bora et al. 1996; Bora et al. 1989).

Fatty acid ethyl esters are formed in the presence of ethanol from free fatty acids, triglycerides, lipoproteins, or phospholipids affected by specific cytosolic or microsomal FAEE synthases or through acyl-coenzyme A-ethanol o-acyltransferase.

Detectable levels are found in blood shortly after alcohol consumption and remain positive for more than 24 h (Borucki et al. 2005).

Of 15 different FAEEs in the hair, the sum of four of these (ethyl stearate, ethyl oleate, ethyl myristate, and ethyl palmitate) is shown to function as a marker in hair analysis (Pragst and Yegles 2007). With a cutoff of 0.5 ng/ml, a sensitivity and a specificity of 90 % were reported. A differentiation between abstinent, social, and excessive drinkers appears possible (Yegles et al. 2004; González-Illán et al. 2011). However, the complex GC/MS method lacks practicability for routine use.

16.2.4 Phosphatidylethanol

Phosphatidylethanol, a phospholipid, is formed in the presence of alcohol via the action of phospholipase-D. The precursor is naturally existing lipid-phosphatidylcholine. The lipid-PEth consists of glycerol which is substituted at positions sn1 and sn2 by fatty acids and is esterified at position sn3 with phosphoethanol (Gustavsson and Alling 1987). Due to the variations of the fatty acids, various homologues of PEth can be detected. In 2010, 48 PEth homologues were described in the blood of a deceased alcohol-dependent individual for the first time (Gnann et al. 2010). The PEth homologues 16:0/18:1 and 16:0/18:2 are most prevalent, and their combined sum correlates better with PEth than PEth 16:0/18:1 or PEth 16:0/18:2 alone (Zheng et al. 2011).

Using the original HPLC methods, repeated consumption of more than 50 g alcohol over 2–3 weeks yielded positive results (Varga et al. 1998), lately even with daily consumption over 40 g (Aradóttir et al. 2004).

A recent drinking experiment with healthy persons with an alcohol consumption of 1 g/kg body weight on 5 consecutive days yielded PEth values up to 237 ng/ml (Gnann et al. 2012). Measurements were made with LC-MS/MS. In contrast in alcohol-dependent patients, the values were reported to be up to 4200 ng/ml (Helander and Zheng 2009).

Various studies found no false-positive results (Wurst et al. 2003a; Hartmann et al. 2007; Wurst et al. 2004b). A linear relationship between consumed amounts of alcohol with phosphatidylethanol values has been described (Aradottir et al. 2006; Stewart et al. 2009, 2010).

In 144 patients, Aradottir et al. (2004) reported sensitivity of PEth to be 99 %, of CDT, MCV, and GGT to be between 40 % and 77 %, as well as a correlation between the amount consumed and the PEth value. In a receiver operating characteristics (ROC) curve analysis with consumption status (active drinkers vs. abstinent drinkers) as a state variable and with phosphatidylethanol, MCV, and gamma-GT as test variables, an area under the curve (AUC) of 0.973 for phosphatidylethanol could be found; the sensitivity was 94.5 % and the specificity 100 % (Hartmann et al. 2007). The findings were confirmed in further publications (Wurst et al. 2010; Wurst and Thon 2012; Stewart et al. 2010; Hahn et al. 2012). PEth values were not influenced by liver diseases and hypertension (Stewart et al. 2009).

16.2.4.1 Methodical Aspects

Concerning the interpretation of results, it is important to acknowledge that publications before 2009 used the HPLC method in combination with evaporative light scattering detection. This method detects a sum of all PEth homologues. In contrast, the new approach is the use of LC-MS- and LC-MS/MS methods (Gnann et al. 2009). These methods facilitate detection and quantification of single homologues, if a reference is available. Furthermore, recent publications suggested LC-HRMS (liquid chromatography high-resolution mass spectrometry) method (Nalesso et al. 2011) and a metabolic approach using LC-MS-IT-TOF (liquid chromatography with quadrupole ion trap-time-of-flight-mass spectrometry) (Loftus et al. 2011). Another publication presented specific PEth antibodies which were decreased in alcohol-dependent subjects or subjects with alcohol-induced pancreatitis (Nissinen et al. 2012).

For everyday practical use, the use of dried blood spots may be of significant relevance (Faller et al. 2011). This method is suggested to have results similar to whole blood measures. Furthermore, obtaining specimen is simplified since nonmedical staff can obtain capillary blood, the risks for HIV and hepatitis C infections are decreased, and storage and transport are simplified.

16.2.4.2 Limitations

In blood and tissues containing ethanol, the formation of PEth under certain conditions may be feasible. Without influencing the PEth levels, blood samples can be stored in refrigerators for up to 72 h or frozen at −80 °C.

In vitro formation of PEth in erythrocytes has been reported after addition of ethanol (Varga and Alling 2002). Further experimental studies in rats showed that ceramide is able to block the activity of phospholipase- D and inhibits the synthesis of PEth (Pragst and Yegles 2008).

16.2.5 Hair Analyses

Hair analysis has been established to assess ethanol intake. FAEE and ethyl glucuronide (EtG), two metabolic by-products of ethanol, are gaining attention as alcohol markers in hair (Auwärter et al. 2001; Pragst et al. 2001; Appenzeller et al. 2007a; Pragst and Yegles 2007; Yegles et al. 2004; Wurst et al. 2004b; Pragst and Yegles 2008; Pragst 2006).

The time frame for the detection of alcohol consumption is longer in hair compared to blood or urine. Due to head hair growth of 1 cm per month, depending on the hair length, evidence of alcohol consumption can be found for the respective time period. The deposit of lipophilic FAEE in hair occurs in sebum (Auwärter et al. 2004), whereas hydrophilic EtG is incorporated through perspiration and/or from blood (Pragst and Yegles 2007).

Measurement of FAEE and EtG allows differentiation between chronic excessive and moderate alcohol consumption as well as abstinence or very low levels of alcohol consumption.

In a consensus from the Society of Hair Testing, an FAEE concentration of over 0.5 ng/ml hair and/or an EtG concentration of over 30 pg/ml hair is interpreted as definite evidence for excessive and regular alcohol consumption (>60 g EtOH per day) (Society of Forensic Toxicologists and American Academy of Forensic Sciences (SOFT/AAFS). Forensic Toxicology Laboratory Guidelines 2006). EtG concentration of more than 7 pg/mg is a marker for frequent alcohol use (Society of Forensic Toxicologists and American Academy of Forensic Sciences (SOFT/AAFS). Forensic Toxicology Laboratory Guidelines 2006).

The combined use of FAEE and EtG can be recommended to increase the validity of hair analysis (Pragst and Yegles 2008).

In an alcohol drinking experiment, 32 women who consumed 16 g alcohol per day had EtG values of less than 7 pg in their scalp hair (Kronstrand et al. 2012). These divergent results may be explained by the fact that EtG values lower than 7 pg/mg do not exclude alcohol ingestion. Furthermore, scalp hair was pre-analytically cut in this study, while previous studies pulverized the specimen: The preparation pre-analytically has been reported to influence the results significantly (Albermann et al. 2012a).

16.2.5.1 Other Influencing Factors

Whereas only in one case a false-positive result for EtG in hair after use of EtG containing shampoo has been reported (Sporkert et al. 2012), regular use of alcohol-containing hair tonic can lead to false-positive FAEE results (Hartwig et al. 2003). No such false-positive results are reported for EtG (Ferreira et al. 2012). Impaired kidney function may lead to higher EtG levels, as preliminary results indicate (Høiseth et al. 2013).

False-negative results for both alcohol markers can also be caused by use of hair cosmetics (Yegles et al. 2004; Hartwig et al. 2003) like alkaline hair cosmetics for FSEE or bleaching substances for EtG (Yegles et al. 2004).

The hair color and melanin content in the hair play no role, in contrast to drugs and medications (Kulaga et al. 2009; Appenzeller et al. 2007b). In segmental investigations of hair samples, a chronological correlation to drink or abstinent phase with FAEE is not possible (Auwärter et al. 2004), but for EtG, two studies have shown this to be feasible (Wurst et al. 2008d; Kulaga et al. 2009).

Altogether, hair analysis for FAEE or EtG is currently a sensible tool to clarify retrospective alcohol consumption, as shown in many studies.

16.2.5.2 Practical Use

Hair analysis for FSEE or EtG is applicable in several contexts including judging driving ability and forensic psychiatry (Wurst et al. 2008a, b; Liniger et al. 2010). Another clinical use of alcohol metabolite measures is the screening for alcohol use in medication-assisted treatment of opioid-dependent subjects (Wurst et al. 2008b, d) as mentioned above.

16.2.5.3 Alcohol Metabolites and Fetal Alcohol Syndrome (FAS)

Consumption during pregnancy can have significant consequences: the fetal alcohol syndrome (FAS) and the fetal alcohol spectrum disorder (FASD) characterized by congenital abnormalities, cognitive dysfunction, and developmental disorders. Estimations report that the prevalence of FAS and FASD is 0.2 to 1/100 live births in industrialized countries (Sampson et al. 1997; Stade et al. 2009). Direct and indirect costs add up to 24,000 Canadian dollars per affected individual as estimated by Stade et al. (2009). Total costs of FASD in Canada are estimated to amount to 5.3 billion Canadian dollars (Stade et al. 2009).

A recent study about Italian and Spanish neonatologists show the relevance: 50 % Italian and 40 % Spanish participants reported to have permitted women occasional alcohol use during pregnancy (Vagnarelli et al. 2011). Alcohol intake during pregnancy can be investigated in maternal (including hair, blood, urine) and fetal specimens (meconium) (Joya et al. 2012).

To date there is only one study from Wurst et al. (2008a) employing EtG in urine and hair in pregnant women assessing alcohol intake compared with self-reports: Women at the end of the second trimester were included. The AUDIT identified 25.2 % women consuming alcohol during the pregnancy. None of the participants scored above the gender-specific AUDIT score higher than the cutoff value of 4 points. However, according to the hair analysis, 12 women drunk more than 20–40 g alcohol per day, and four had an intake over 60 g/day (Wurst et al. 2008a).

These results support the use of direct alcohol metabolites in pregnant women since increases of % CDT (percent of carbohydrate-deficient transferrin vs. total transferrin) and its isoforms were reported for this specific population (Bianchi et al. 2011; Kenan et al. 2011). The usefulness of PEth measures during pregnancy was described in only one study so far (Stewart et al. 2010).

Studies on fetal specimen include current measures of meconium. These measures are a cumulative indicator of alcohol consumption, since it is formed between the 12th and 16th weeks of pregnancy. While the first studies investigated FAEEs concentrations, recent research focused on EtG and EtS. The largest study investigated meconium of 607 newborns. 7.9 % of specimens indicated maternal alcohol intake during pregnancy (Pichini et al. 2012). Low maternal education level and age were associated with biomarker values above the cutoff (Pichini et al. 2012). Regarding FAEEs detection, the specimen has to be investigated promptly. One study reported that negative meconium values in 19 babies turned positive within 59 h (Zelner et al. 2012). Following the authors' in vivo and in vitro studies, this change may be caused by contamination through nutritional components, postnatal feces, and ethanol-producing germs (Zelner et al. 2012). This may also be the cause for 82.8 % EtG and 22.2 % FSEE positive values in meconium, reported by another study (Morini et al. 2010a).

16.2.6 The Value of Ethanol Metabolites

In summary, specific ethanol metabolites are available which can detect the spectrum between short-term intake of small amounts and long-term use of large amounts of alcohol (Table 16.1). Cutoff values and influencing factors are summarized in Tables 16.2 and 16.3.

Appropriate methods of analysis and pre-analytics are crucial for a valid and reliable detection of markers. For ethyl glucuronide (EtG), the most frequently used marker, the best method for detection is chromatographic approach which is considered a standard method especially in forensic cases. A commercial test kit is available and contributed to wide distribution of the test. Of course, lab values always require critical reappraisal. However, EtG is detectable in urine using LC-MS/Ms even after an ingestion of low amounts of alcohol (1 g), which also occurs in some foods, drugs, and disinfectants. Individuals with the motivation to or obligation for abstinence have to be informed about these "hidden contents" to avoid involuntary intake of alcohol. For forensic purposes, the current cutoff value of 0.1 mg/L should be adapted to exclude cases of involuntary alcohol use. With respect to differences in formation and degradation, EtG and ethyl sulfate (EtS) should be analyzed together, if possible. In the absence of known influencing factors, EtG in the hair can be recommended as a marker for alcohol intake for the last 3 months. Further, guidelines for interpretations of values from international society (SOHT) are available. While positive urine values of EtG and EtS can be in accord with innocent/unintentional alcohol intake, positive values of PEth are related to previous intoxications of 0.5 % and more.

The use of dried blood spots is promising and may facilitate sample taking, storage, distribution, and decrease of infection risk.

Table 16.1 Clinically relevant options for the determination of direct biomarkers, with respect to amount and duration of alcohol intake (Modified according to Thon et al. (2013))

Duration of consumption	Amount of consumption	
	>1 g/d	>40–60 g/d
<1 day	Serum, urine: EtOH, EtG, EtS	Serum and urine: EtOH, EtG, EtS; PEth in whole blood and dried blood spots (LC-MS/MS)
>1 day	Serum, urine: EtOH, EtG, EtS	Serum and urine: EtOH, EtG, EtS; PEth in whole blood and dried blood spots (LC-MS/MS)
>14 days	Serum, urine: EtOH, EtG, EtS	Serum and urine: EtOH, EtG, EtS; PEth in whole blood and dried blood spots (HPLC LC-MS/MS)
Weeks to months	Serum, urine: EtOH, EtG, EtS	Serum and urine: EtOH, EtG, EtS; PEth in whole blood and dried blood spots (HPLC LC-MS/MS), EtG and FAEEs in hair

Table 16.2 Clinically relevant options for the determination of direct biomarkers, with respect to amount and duration of alcohol intake (Modified according to Thon et al. (2013))

Biomarkers	Amount of consumption	Cutoff	Reference
EtG in hair	Abstinence and low intake (<10 g alc/d)	<7 pg/mg	Society of Hair Testing (2009)
	Social consumption (20–40 g/d)	7–30 pg/mg	
	Excessive drinking (>60 g/d)	>30 pg/mg	
FAEEs in hair	Repeated alcohol intake	≥200 pg/mg	Society of Hair Testing (2009)
	Excessive intake	≥500 pg/mg	
EtG in urine	Total abstinence	0.1 mg/L	Thierauf et al. (2009a, b)
	- Unintentional intake - Recent alcohol use - Longer back-dated alcohol intake in larger amounts	0.1 mg/l–0.5 mg/L	
	Unintentional intake unlikely, but possible, active alcohol intake probable	0.5–1 mg/L	
EtS in urine	Total abstinence	0.05 mg/L	Weinmann et al. (2004)
PEth	>40 g/d, more than 2 weeks of alcohol intake at least once with 1 % detectable	HPLC: 0.22 μM, LC/MS-MS: 20/30 ng/ml PEth 16:0/18:1 or 0.05 μM	Varga et al. (1998), Gnann et al. (2012), Aradóttir et al. (2004)

EtG ethyl glucuronide, *FAEEs* fatty acid ethyl esters in hair, *EtS* ethyl sulfate, *PEth* phosphatidylethanol

16.3 Traditional Biomarkers for Alcohol Consumption

Many clinical-chemical parameters show pathological changes as evidence of the biochemical burden of ethanol metabolism. None of these conventional indicators show 100 % sensitivity or specificity. Nonetheless, evidence of long-term alcohol consumption can be obtained from these state markers, especially a combination of several individual indicators.

16.3.1 Gamma-Glutamyl Transferase (γ-GT)

γ-GT is a membrane-bound glycoprotein enzyme which occurs ubiquitous in the organism, but mainly in the liver, pancreas, and renal proximal tubules. γ-GT detectable in serum arises mainly from the liver so that an increase in serum enzyme activity would be a sensitive indicator for hepatobiliary diseases. Chronic alcohol consumption induces an increase in enzyme synthesis and, through direct activation of the enzyme from membrane binding, leads to increase of γ-GT in serum. The release of enzymes through liver parenchymal damage also presents a secondary mechanism in chronic alcoholic hepatitis (Conigrave et al. 2003). To exceed the

Table 16.3 Detection of direct biomarker, with respect to amount and duration of alcohol intake (Modified according to Thon et al. (2013))

Direct biomarkers	Potential influencing factor	Influence	Reference
EtG in urine	*E. coli*, dried urine spots	No	Redondo et al. (2012)
	Grade of liver disease, smoking, BMI, body water content reduced kidney function	No	Wurst et al. (2004a), Stewart et al. (2013)
EtS in urine	*E. coli*, dried urine spots	No	Hoiseth et al. (2012)
PEth	Liver disease	No	Stewart et al. (2009)
	Hypertension	No	
	Storage of ethanol blood samples	No	Aradóttir et al. (2004)
	Refrigerator temperature, −80 °C		
EtG in hair	Hairsprays with ethanol, hair color, melanin content, age, gender, BMI	No	Ferreira et al. (2012), Kulaga et al. (2009), Appenzeller et al. (2007b), Kharbouche et al. (2010)
EtG in urine	*E. coli*, *C. sordellii*	Decrease	Helander and Dahl (2005), Baranowski et al. (2008)
	Reduced kidney function	Longer detection	Wurst et al. (2004a), Hoiseth et al. (2012)
	Chloral hydrate	False positives	Arndt et al. (2009)
EtS in urine	Reduced kidney function	Longer detection	Hoiseth et al. (2012)
	Closed bottle test (OECD 301 D)	28 days stable detection, depletion after 6 days	Halter et al. (2009)
	Manometer Respiratory Test (MRT)		
FAEEs in hair	Aggressive alkaline hairsprays	False negative	Sampson et al. (1997)
	Hairsprays with ethanol	False positives	
PEth	Ethanol-containing blood samples, storage of ethanol blood samples at RT and −20 °C	Increase	Aradóttir et al. (2004)
EtG in hair	Hairspray with EtG	Increase	Sporkert et al. (2012)
	Reduced kidney function	Increase	Høiseth et al. (2013)
	Bleaching, hair styling products	False negative	Yegles et al. (2004), Morini et al. (2010b)

EtG ethyl glucuronide, *FAEE* fatty acid ethyl esters, *EtS* ethyl sulfate, *PEth* phosphatidylethanol, *BMI* body mass index, *RT* room ambient temperature, *E. coli* Escherichia coli, *C. sordellii* Clostridium sordellii

normal values (according to Szasz, 4–18 U/l in women and, 6–28 U/l in men) requires the chronic, daily alcohol intake over at least four to six weeks. A short-term, higher alcohol burden causes no such increase (Haffner et al. 1988). Nevertheless, Anton et al. (1998) showed that the drinking intensity has more influence on γ-GT than drinking frequency. In absolute alcohol abstinence, normalization of the values occurs within three weeks to 60 days (Haffner et al. 1988).

The sensitivity of γ-GT varies, according to age, gender, and body weight, from 35 % to 85 % (von Herbay and Strohmeyer 1994). Puukka et al. (2006a) showed that γ-GT increased with age in heavy alcohol drinkers as well as moderate drinkers. In contrast, in young adults less than 30 years, even when these are alcohol dependent, the sensitivity of the markers is very low (Bisson and Milford-Ward 1994). Chan et al. (1989) traced this back to higher resistance in younger patients to damaging alcohol effects. In addition, the higher vulnerability of women to alcohol-associated liver diseases is well known (Puukka et al. 2006b). Other studies have shown a relationship between being overweight (BMI > 25) and an increase in γ-GT (Puukka et al. 2006b). γ-GT levels can also be increased by various other causes, for example, the effect of medication (such as enzyme-inducing drugs, e.g., phenytoin) and teratogens, obesity, diabetes, and cholestatic or inflammatory liver diseases. Accordingly, the specificity of 63–85 % is only relatively satisfactory, and γ-GT, in spite of its practicality as single indicator of chronic alcohol misuse and current liver diseases, is a relatively poor alcohol biomarker (Cushman et al. 1984; Neumann and Spies 2003).

16.3.2 Mean Corpuscular Erythrocyte Volume (MCV)

Measurements of MCV are common in standard investigations; an increase occurs in 4 % of the general population and in 40–60 % of patients with alcohol misuse (Wymer and Becker 1990; Morgan et al. 1981). Koivisto et al. (2006) reported definite evidence of marked dose-dependent relationship between MCV and the intensity of alcohol consumption. Increase in MCV is to be expected in long-term alcohol consumption; by contrast the values normalize slowly during abstinence over a period of 2–4 months. Compared to γ-GT, the sensitivity of MCV in screening as evidence of alcohol misuse, at least in men, is inferior. In interpreting MCV values, other causes such as vitamin B12 or folic deficiency, nonalcoholic liver diseases, reticulocytosis, and hematologic diseases should be considered.

The mechanism responsible for increasing MCV is hitherto unclear; direct hematotoxic damage or interaction of ethanol and its metabolites, especially acetaldehyde, with erythrocyte membrane has been suggested (Allen et al. 2009).

16.3.3 Carbohydrate-Deficient Transferrin (CDT)

Transferrin is the most important iron transport molecule in humans; its synthesis and glycolization occur in hepatocytes. Depending on the iron load as well as the number

and breakdown of carbohydrate chains, different isoforms can be detected. Differentiation occurs through measurements of isoelectric points (pl), whose values depend on the load of bound iron ions and number of sialin acid residuals in carbohydrate chains (Stibler 1991a; Arndt 2001). Stibler and Kjellin (1976) found abnormal isoforms with much increased pl-values over 5.65 in the liquor and serum of alcohol-dependent patients and traced this back to small levels of bound sailin acid residuals. In subsequent investigations, more precise differentiation in mono-, di-, and asialotransferrin was feasible, and all abnormal isoforms were subgrouped under CDT (Stibler et al. 1986; Helander 2003b). All abnormal transferrin molecules increase in chronic alcohol consumption (Martensson et al. 1997; Arndt 2003). Measurements with HPLC showed that, though, increased alcohol consumption lead to increased disialotransferrins, while increases in asialotransferrin occur in chronic increased alcohol consumption only (Helander et al. 2003). A variety of methods and respective reference levels for the detection of CDT is available. Hitherto, measurements of CDT using HPLC is the reference standard, with routine measurements of various enzyme immunoassays in use (Helander et al. 2003; Jeppsson et al. 1993; Helander et al. 2001). For confirmation analyses, immune electrophoresis is employed (Hackler et al. 2000), while direct CDT detection method using specific antibodies is still under development (Helander 2003b; Hackler et al. 2000).

The underlying pathomechanism for CDT development is not exactly known. Inhibition of intracellular transmission of carbohydrates to transferring by toxic effects from ethanol or acetaldehyde is presumed. Ethanol's influence on the activities of membrane-bound sialine transferases and plasma sialidases in hepatocytes has been discussed, in which an imbalance in favor of sialine acid reduction enzymes occurred (Arndt 2001, Xin et al. 1995).

There has been no agreement in previous studies concerning the correlation between CDT concentrations in serum and the absorbed alcohol amounts. Though Allen et al. (1994) showed an increase in CDT with daily consumption of 60–80 g alcohol over 7 days, other studies reported contradicting results (Lesch et al. 1996; Oslin et al. 1998; Salmela et al. 1994). Additionally, contradicting results on the effect of moderate drinking (<40 g alcohol) are found (Sillanaukee et al. 2003).

The clinical strengths of CDT as a biomarker vary depending on gender, BMI, age, nicotine abuse and anorexia (Fleming et al. 2004). Previous studies showed that CDT in men is a more sensitive indicator for alcohol-related diseases compared to women (Mundle et al. 2000; Anton et al. 2001; Huseby et al. 1997). Anton and Moak (1994) presumed that CDT values in women are increased under natural conditions but not much in increased alcohol use. Furthermore, hormonal factors appear to play a role – CDT values are definitely increased in pregnant women, but reduced in postmenopausal women (Stauber et al. 1996). Obviously in the female gender, differences in CDT serum activity depend on age as well (Whitfield et al. 1998),

Among the various conventional alcohol markers, CDT is currently considered the most useful and significant indicator (Bortolotti et al. 2006). Information on sensitivity and specificity varies, since no methodical standardization exists. Further, the heterogeneity of test populations concerning age, gender, alcohol consumption, duration of abstinence before serum extraction, as well as current

liver diseases makes the comparison with other traditional markers difficult. In selected, clinical patient groups, various test methods with specificity between 90 and 100 % with high sensitivity (50–90 %) were reported (Stibler 1991b; Kwoh-Gain et al. 1990; Stowell et al. 1997a, b).

In WHO/ISBRA Study, the sensitivity of CDT with 60 % in men was slightly less than that of γ-GT; in women the sensitivity reached only 29 % (Laposata 1999) (Conigrave et al., 2002b). False-positive increased CDT values can occur in biliary cirrhotic, autoimmune hepatitis, genetically determined transferrin variants, or the autosomal recessive inherited CDG syndrome (Stibler 1991b; Salaspuro 1999). Most patients with liver diseases have insignificantly increased CDT values so that the specificity, especially in comparison to other state markers, must be stated exceptionally high and usually reach at least 90 %. Thus, CDT could be used for detection of chronic alcohol consumption and changes in drinking patterns in these patients (Bortolotti et al. 2006; Helander and Tabakoff 1997). With a half-life of 14 days and normalization of CDT values in abstinence, evidence of drinking relapses in the post-acute phase after alcohol withdrawal treatment can be obtained (Stibler 1991b; Niemelä 2002).

16.3.4 Serum Transaminases (ASAT/ALAT)

Increases of aspartate aminotransferase (ASAT) and alanine aminotransferase (ALAT) in serum are nonspecific signs of hepatocellular damage. While ASAT is produced in the liver, skeleton, and cardiac muscle tissues, ALAT is a liver-specific enzyme. Thus, an increase in ALAT practically indicates liver diseases (fatty degeneration, tumors, metastases, cirrhosis, cholangitis). Regarding measurements of ASAT, it must be differentiated between alcohol sensitive, mitochondrial (m-ASAT), and cytoplasmic isoform (c-ASAT). Conclusions on an alcohol-induced liver damage can only be drawn from increased m-ASAT/c-ASAT quotients. Increased ASAT values would be found in alcohol-dependent patients from 39 % to 47 % (Rosman and Lieber 1994). In the WHO/ISBRA Study, sensitivity of ASAT between 23 % and 45 % (women vs. men) could be found (Savolainen et al. 1990). The toxic effects of ethanol on mitochondria lead to increased release of ASAT compared to ALAT. A ratio of ASAT/ALAT exceeding 1 (and even more so when it approaches 2) indicates a strong likelihood of an alcoholic etiology (Hannuksela et al. 2002; Savolainen et al. 1990).

In summary, the sensitivity and specificity of both enzymes as indicators for alcohol misuse are considered variable so that an interpretation of an increased serum activity is mainly meaningful in the context of other liver values (bilirubin, alkaline phosphatase, γ-GT).

16.3.5 HDL Cholesterol and Apolipoprotein

Increases in HDL cholesterol and apoprotein I/II are described in many studies as specific and sensitive indicators of chronic alcohol strain; by contrast triglycerides

and total cholesterol are nutritionally influenced. Alcohol leads to an increase in the concentrations of cholesterol and phospholipids within the HDL particles and causes a shift to bigger portions of phospholipids in richer and larger HDL_2 particles (Goldberg et al. 1995; Lucas et al. 2005).

Studies showed this phenomenon to be the basic principle for the observed cardioprotective character of moderate alcohol consumption (Clemens et al. 1986; Moore and Pearson 1986). Chronic alcohol load causes an increase in HDL over 50 mg/dl; after withdrawal and with continuing abstinence, the values normalize within 1–4 weeks (Goldberg et al. 1995; Gilg et al. 1995). The pathogenic cause for alcohol-related HDL and apoprotein increases is postulated to be an enzyme induction as well as increased lipoprotein lipase activity (Gilg et al. 1995; Hannuksela et al. 2004).

Increased HDL levels without alcohol can occur under the influence of medication (sedatives, lovastatin), pronounced underweight, and physical strain. Still, the specificity of this marker is highly esteemed; moreover, it proved itself to be practicable (Hannuksela et al. 1992a). Particularly in patients without liver damage, HDL and apoprotein I/II can be used for monitoring abstinence since changes in alcohol consumption would be accurately reflected.

16.3.6 Cholesteryl Ester Transfer Protein (CETP)

Cholesteryl ester transfer protein is a glycoprotein synthesized in the liver and catalyzed out of HDL particles through lipid diffusion into LDL particles (Hannuksela et al. 1992b). Through alcohol consumption, the plasma concentration and activity of CETP are reduced, thereby increasing HDL concentration. Moderate drinking, by contrast, hardly influence CETP activity (Lucas et al. 2005; Hultberg et al. 1991; Kärkkainen et al. 1990). According to the study from Hannuksela et al. (1992b), the sensitivity and specificity of CETP as an alcohol marker can be compared to those of MCV, γ-GT, ASAT, and ALAT. Nonetheless, the use of CETP as an indicator for alcohol misuse is limited by the complex measurement method and by the influence of drugs and various diseases.

16.3.7 β-Hexosaminidase

β-Hexosaminidase is a lysosomal liver enzyme detected in serum or urine using spectrometric methods. Stowell et al. (Stowell et al. 1997b) reported higher serum activity of this glycoprotein in alcohol-dependent patients compared to healthy controls. A daily consumption of 60 g alcohol leads to significant serum increases; even short-term alcohol load is reflected in alcohol patients by its low half-life and resulting limited normalization in values (<6.2 U/l) 2–4 days later (Hultberg et al. 1991; Kärkkainen et al. 1990). As described by Humaloja et al. (1997), the pathological mechanism in rats is the reduction in biliary elimination of the enzyme in chronic ethanol intake. The specificity of β-hexosaminidase in serum is stated to

be 91–98 %; the sensitivity is 69–94 % (Stowell et al. 1997b; Taracha et al. 2001). According to studies by Kärkkäinen and Salaspero (1991), β-hexosaminidase activity reflects recent alcohol consumption, while β-hexosaminidase in urine remains increased for longer periods after alcohol consumption.

16.3.8 Methanol (MeOH)

Methanol is a monovalent alcohol produced endogenously; under physiological conditions, the concentration in serum is between 0.5 and 1.0 mg/l. Methanol can be ingested exogenously through alcoholic drinks, fruit juice, and pectin-containing fruits (e.g., bananas or apples). The metabolism of methanol occurs in the liver through alcohol dehydrogenase (ADH), which shows a manifold increased affinity to ethanol compared to methanol even without alcohol ingestion (Rietbrock 1969). That being so, in the presence of ethanol in concentrations over 0.2–0.5 %, a competitive inhibition of methanol breakdown occurs which, in continuing ethanol availability, leads to the accumulation of endogenous methanol (Mani et al. 1970). Should the ingested alcohol also contains methanol (e.g., fruit-flavored gin, whisky), the blood levels would be potentiated even more by endogenous accumulation. The methanol levels normalize itself in alcohol abstinence within several hours to several days (Haffner et al. 1997). Early evidence of increased blood methanol levels after longer drinking periods was reported in the 1970s (Magrinat 1973), among others. In numerous studies, a coincidence between increased methanol levels and blood alcohol levels has been found. Consequently, methanol values >10 mg/l, which were not caused by normal and short term, even high alcohol load over 1.5–2.0 %, were estimated and considered as an indicator for recent alcohol misuse or longer-term alcohol consumption phase (Iffland 1993; Iffland et al. 1984). Despite its high specificity, methanol is only suitable as a short-term state marker because it is rapidly normalized. Its significance lies primarily in screening alcohol misuse in clinical as well as forensic cases.

16.3.9 Acetone and Isopropanol

Physiologic levels of isopropanol in blood are up to 0.1 mg/l acetone up to 7 mg/l (Gilg et al. 1989; Iffland and Staak 1990). Both substances are not found in alcoholic drinks. Isopropanol and acetone are in reciprocal biotransformation process, meaning isopropanol is reduced to acetone and formed, through oxidehydration, from acetone. Both processes occur via alcohol dehydrogenase. Alcohol load causes an increase in isopropanol in the blood; conversely in withdrawal acetone is increased (Gilg et al. 1995; Lewis et al. 1984). Fulop et al. (1986) found increased isopropanol and acetone levels mainly in alcohol-dependent patients with concurrent eating disorders or reduced nutritional intake. It is an established practice to pool both substances in serum concentration, and a level of 9 mg/l has been recommended (Iffland et al. 1994). Still, isopropanol and acetone

appear less convincing than methanol as alcohol markers because increased acetone levels also result from metabolic disorders like ketosis in hunger, diabetes, cooling, and heavy physical strain.

16.3.10 Combination of Individual State Markers

Since individual conventional alcohol markers were found to be insufficiently sensitive and/or specific for the recognition of alcohol misuse, several important parameters in varying combinations were investigated. The better known combinations comprised of CDT, γ-GT, MCV, and ASAT.

16.3.10.1 Gamma-Glutamyl Transferase and Carbohydrate-Deficient Transferrin

Some studies showed that the combined use of γ-GT and CDT resulted in higher sensitivity and specificity compared to the use of either one alone (Hietala et al. 2006; Chen et al. 2003). Sillanaukee et al. (2001) and Sillanaukee and Olsson (2001) reported a sensitivity of 75 % and specificity of 93 % for γ-CDT from 257 alcohol-dependent patients and 362 occasional drinkers. γ-CDT is estimated using the formula [γ-CDT = 0.8 ln(γ-GT) + 1.3 ln (CDT)]. Compared to CDT and γ-GT alone, ASAT, ALAT, or MCV showed the logarithmic transformation from γ-GT and CDT to have the best predictive value to differentiate between alcohol-dependent patients and occasional drinkers (Niemelä 2007). Values for γ-CDT correlate to current amounts of consumption, regardless of whether a heavy alcohol-dependent individual or an occasional drinker was tested (Brinkmann et al. 2000). γ-CDT can thus be used to monitor abstinence, though in continuing abstinence, the values normalize within 2–3 weeks. Considering the cost efficiency and simple application, γ-CDT appears to be a suitable indicator in clinical routine work (Figs. 16.1 and 16.2).

16.3.10.2 Alc-Index

By combining methanol, acetone/isopropanol, γ-GT, and CDT in a logistic regression formula, Brinkmann et al. (2000) developed the so-called Alc-index to differentiate between alcohol-dependent patients and nondrinkers. The basic principle for the investigations was the hypothesis that each of these alcohol markers shows overlap in values in the collective with none or low alcohol consumption and alcoholics. From the results, an Alc-index of 1.7 as cutoff was defined with a specificity of 100 % and a sensitivity of 90 % to differentiate between alcohol-dependent and non-alcohol-dependent individuals. The advantage of this index is the single cutoff point instead of four different cutoff points for individual markers.

16.3.10.3 Early Detection of Alcohol Consumption Test (EDAC)

EDAC uses results from a series of routine lab parameters to identify heavy drinkers and light drinkers in study groups. In the 1980s attempts were made using

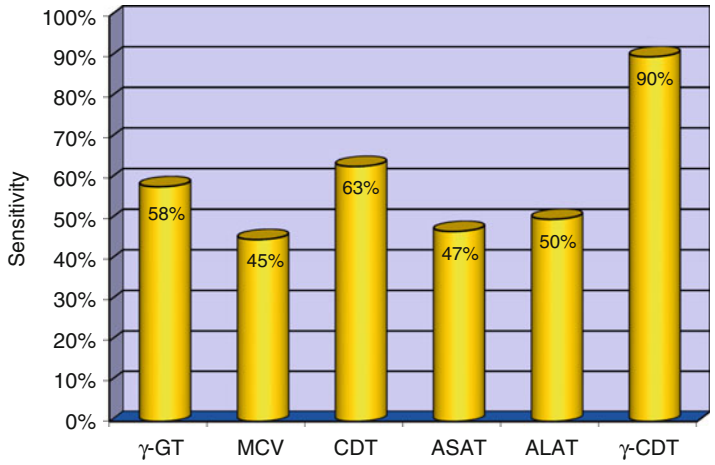

Fig. 16.1 Comparison of sensitivities of conventional markers with γ-CDT (Modified from Niemelä 2007)

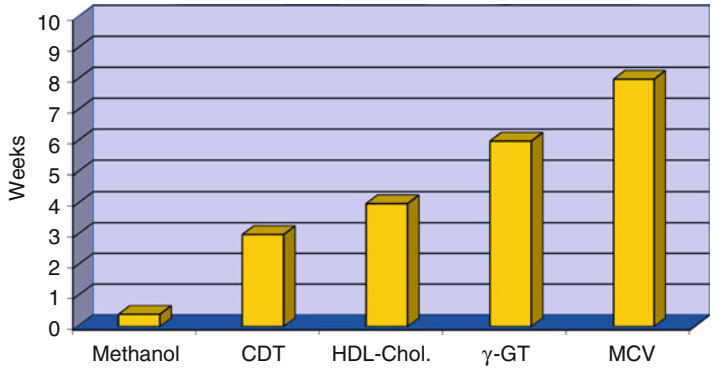

Fig. 16.2 Depiction of alcohol markers in appropriate timelines (Modified from Gilg et al. 1995)

multivariate statistical analysis to differentiate between hazardous alcohol misuse and alcohol dependence (Harasymiw et al. 2000, 2004). The use of multiple chemical and clinical parameters should reflect the physiological effects of alcohol on various organs and organ systems (Harasymiw and Bean 2007). These studies were subsequently abandoned because of the impracticability of undertaking the statistical analyses. Later, Harasymiw et al. (2000) developed the EDAC test to be an established procedure, in which a form of "mathematical fingerprint" for each tested patient could be created from 10 out of 30 routine lab values through a linear discrimination analysis. The fingerprint of an individual could possibly be that from a heavy alcoholic and presented as P-positive, representing the degree of concordance to the stereotyped alcoholic lab profile. In general, a P-positive value over

50 % showed current heavy alcohol consumption, whereas values below or equal to 50 % showed evidence of light alcohol misuse (Harasymiw and Bean 2007). The EDAC test was successfully used as screening for alcohol misuse and to identify heavy or risky alcohol consumption in various studies on different study populations (Harasymiw et al. 2000; Bean et al. 2001). Harasymiw und Bean (2007) reported higher sensitivity of 34–65 % (women/men) for EDAC test compared to 23–30 % for γ-GT in a population of 1605 heavy drinkers or probands with risky alcohol consumption. The specificity is 89 % (men) and 98 % (women). In a review from Montalto and Bean (2003), sensitivity and specificity over 80 % each was reported in the identification of alcohol misuse in heavy male and female drinkers. Given these results, the EDAC test may be a suitable way of combining routine laboratory tests for use in primary care settings. Its cost-effectiveness depends on the availability of multiple laboratory analyses, particularly using automated statistical analyses which are now available through certain providers.

16.4 Conclusion

Biomarkers are an important compliment to self-reported alcohol consumption in the diagnosis and management of alcohol use disorders. Traditional biomarkers have several limitations imposed by their sensitivity and specificity and practicability and cost-effectiveness. Combinations of these markers allow some insight into the individual's alcohol consumption over recent days and weeks. The diagnostic sensitivity of individual parameters, like ASAT or ALAT, is low; the specificity is moderately high, with the exception of CDT which shows moderate sensitivity and high specificity to differentiate between alcohol-dependent individuals and control persons. The strengths of these traditional markers lie in their practicability and, except for CDT, cost efficiency in clinical routine. Normalization of this marker occurs only after weeks or months of abstinence so that inference of current or short-term recent alcohol consumption can be made.

In contrast, direct ethanol metabolites are highly sensitive and specific, and they cover the recent time period between consumption and detection. They open new perspectives for the prevention, interdisciplinary cooperation, diagnosis, and therapy of alcohol-related disorders.

Brief Intervention for Illicit Drug Users

17

Jennifer Harland, Linda Gowing, and Robert Ali

Contents

Abstract

Screening and brief intervention is an effective public health measure for the early detection and management of substance use disorders. There is a range of validated screening tools designed for use in various settings and contexts. This chapter provides an overview of the process that is a fundamental next step following screening, namely, the provision of an effective and targeted brief intervention for illicit drug users.

It includes an overview of the evidence related to brief interventions for people using cannabis, amphetamines, cocaine, or opiates. Although research in this area is somewhat limited, the chapter will draw on the empirical evidence for effective brief intervention in a range of areas and suggest practical approaches to engage illicit drug users. There are many possible settings (primary care, emergency department, and mental health) and various ways of presenting brief interventions,

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment: International Perspectives*, DOI 10.1007/978-88-470-5322-9_11,

such as via a computer. As illicit drug use is rarely limited to one substance, implications for polydrug users are addressed. Practical steps and examples are provided, based on the principles of motivational interviewing, to demonstrate how effective brief interventions can be implemented.

Some of the common barriers to implementing brief interventions in practice will be explored. Practical solutions will be offered as a guide to overcoming both real and perceived barriers to conducting targeted and effective brief interventions in practice.

17.1 Introduction

The combination of physical, psychological, and social dimensions makes drug dependence a complex condition (Gowing et al. 2001). Addressing substance misuse is a high priority for health policy, and there are clear public health and economic benefits from the early detection of an emerging problem to prevent its escalation. Screening combined with brief intervention provides a comprehensive, integrated, public health approach across the full spectrum of substance misuse (Babor et al. 2007).

Most people with clinically significant (low-moderate severity) problems relating to their substance use will not seek help from specialist addiction treatment services (Humeniuk et al. 2012). General health-care professionals therefore play an important role in the early detection of substance misuse. Any health-care visit presents an opportunity for screening and brief intervention, and routine practice should include asking about and documenting substance use (Saitz 2010).

There is strong evidence for the effectiveness of brief interventions in primary care settings for alcohol (Kaner et al. 2008) and tobacco and growing evidence that brief interventions are effective for cannabis (Copeland et al. 2001; Copeland and Swift 2009), benzodiazepines (Bashir et al. 1994; Heather et al. 2004), amphetamines (Baker et al. 2001; 2003), opiates (Saunders et al. 1995), and cocaine use (Stotts et al. 2001). Research has shown that screening and brief intervention has led to a reduction in mortality (Cuijpers et al. 2004), health-care costs (Kaner et al. 2008), criminal justice involvement, and societal costs (Sullivan et al. 2011). The present chapter should be read in conjunction with the companion ▶ Chaps. 12, "Screening, Early Detection and Brief Intervention for Alcohol Use Disorders" and ▶ 13, "Screening for Nicotine and Drug Use Disorders."

17.2 Providing Effective Brief Interventions for Illicit Drug Users

17.2.1 Nature of Brief Interventions

The definition of brief intervention varies throughout the literature and is often used as an overarching term to include related, but slightly different, types of interventions such as brief motivation and brief motivational enhancement (Ager

et al. 2011). Overall, the goals of brief intervention are to assess and identify substance use behavior in clients, provide advice on these behaviors, facilitate behavior change with regard to substance use, and motivate the client to receive further treatment if necessary (Bien et al. 1993; Miller and Rollnick 2013). For the purpose of this chapter, brief intervention is defined as:

> A practice that aims to explore real or potential problems with substance use and help strengthen an individual's motivation to change. Brief cminterventions are generally of short duration (5–30 min) and may extend over one to four sessions (Gowing et al. 2001).

Brief intervention is time limited and structured and contains goal-oriented interventions (Babor et al. 2007). It includes clear directive advice with a focus on increasing the patient's insight and awareness regarding substance use and encouraging behavioral change through motivational interviewing and self-management approaches (Miller and Rollnick 2013). Brief interventions should be personalized and offered in a supportive, nonjudgmental manner.

The theoretical bases for brief interventions are grounded primarily in client-centered therapy, cognitive behavioral approaches, and the transtheoretical model of behavior change. As brief interventions are typically organized around a developmental theory of normative and nonnormative patterns of alcohol and other drug use, this is an appropriate theoretical framework for eliciting behavior change in brief interventions (Winters and Leitten 2007).

Generally, brief interventions are not intended to treat people with serious substance dependence; however, they are a valuable tool for intervening in problematic or risky substance use. Brief interventions can also be used to encourage those with more serious dependence to accept more intensive treatment within the primary care setting or referral to a specialized alcohol and drug treatment agency. The aim of the intervention is to help the patient understand that their substance use is putting them at risk and to encourage them to reduce or give up their substance use (Humeniuk et al. 2003).

17.2.2 Effectiveness of Brief Interventions for Alcohol and Smoking Cessation

There is a considerable range of literature on the effectiveness of screening and brief intervention. For alcohol, brief interventions shift drinking patterns in the hazardous and harmful range to a lower-risk range. A Cochrane review of screening and brief intervention for alcohol involving 29 primary care trials showed that brief interventions were associated with a significant reduction of four standard drinks per week (95 % CI 2.3–5.4) at 12-month follow-up compared with controls (Kaner et al. 2007). For smoking cessation, 17 studies of brief intervention provided by doctors found a significant increase in the odds of quitting attributable to advice (odds ratio 1.74, 95 % CI 1.48–2.05).

17.2.3 Effectiveness of Brief Interventions for Illicit Drug Users

Screening and brief intervention provided in acute care settings is associated with modest changes in self-reported recent illicit drug use (Woodruff et al. 2013). A review of randomized controlled trials of motivational interviewing among drug-abusing or drug-dependent individuals found that 14 of the 17 trials identified reported positive treatment effects (Miller et al. 2003). Among US college students, a brief intervention reduced alcohol, cannabis, and other drug use at 3 months, with greatest effects among heaviest users (McCambridge and Strang 2004); however, findings were not maintained at 12 months.

A randomized controlled trial conducted by Shetty (2011) found that a culturally competent, motivational intervention integrated into the care of vulnerable patients with facial injury reduced illicit drug use behaviors. Participants received an individualized behavioral intervention via two counseling sessions, the first shortly after their injury and the second 4–6 weeks later (Shetty 2011).

Although there is limited research on the effectiveness of brief interventions with specific illicit substances, an overview of the available evidence on cannabis, amphetamines, opiates, and prescription medications is presented below.

17.2.3.1 Cannabis

Brief interventions have shown promise among both adult and adolescent cannabis users with research to date finding brief interventions effective in reducing the quantity and frequency of use and a number of cannabis-associated problems (Carroll et al. 2006; Copeland et al. 2001; Dennis et al. 2004; Kamon et al. 2005; Stephens et al. 2000). These studies have typically compared a brief intervention (from one to six sessions) to a delayed treatment control (DTC) condition and are largely based on cognitive behavior therapy (CBT) and motivational enhancement therapy (MET).

An Australian study by Martin and Copeland (2008) found that individuals who received a single assessment session combined with a feedback session based on MET had greater reductions in cannabis use and the number of DSM-IV criteria endorsed for cannabis dependence in comparison to those in a delayed treatment control condition.

A meta-analysis of brief interventions for cannabis by the UK National Institute for Health and Clinical Excellence (NICE) found a significant increase in the likelihood of abstinence associated with brief intervention treatment (relative risk 3.33, 95 % CI 1.99–5.56) (National Collaborating Centre for Mental Health 2007). Among samples of adolescents attending emergency departments, a brief intervention with booster sessions, delivered by peers, was effective in preventing cannabis use and "days high" at 12 months (Beralnstein et al. 2009). McCambridge et al. (2008) found that there was no difference in outcome between motivational interviewing and drug information and advice at either the 3- or 6-month follow-up study interval. There was, however, substantial evidence of variability in outcomes by practitioner, regardless of the intervention being delivered, including in relation

to the primary outcome measure of reduced frequency of cannabis use at the 6-month follow-up interval (McCambridge et al. 2008).

Earlier age of initiation of cannabis use increases the severity of psychosocial and substance use problems (Walton et al. 2013). Treatment engagement among young people has been suggested to be quite low, despite reported increases in treatment uptake among adults (Copeland 2004). Time-limited brief interventions may be efficacious in engaging young people who are resistant to long-term treatment (Martin and Copeland 2008). Simply providing advice may be an effective brief intervention with young cannabis users (McCambride et al. 2008).

17.2.3.2 Amphetamines

In a randomized controlled trial of regular amphetamine users, Baker et al. (2001) reported that a brief intervention ($n = 32$) consisting of either a two-session intervention of motivational interviewing and cognitive behavioral therapy or a four-session intervention consisting of a motivational interview and skills training in avoidance of high-risk situations, coping with cravings, and relapse prevention was feasible among regular users of amphetamine when compared with the control group ($n = 32$) who received a self-help booklet. The main finding was that more people in the intervention condition abstained from amphetamines at 6-month follow-up compared to the controlled condition (Baker et al. 2001).

In a follow-up study, Baker and Dawe (2005) reported a significant increase in the likelihood of abstinence from amphetamines among those receiving two or more treatment sessions. Reduction in amphetamine use was accompanied by significant improvements in stage of change, benzodiazepine use, tobacco smoking, polydrug use, injecting risk-taking behavior, criminal activity level, and psychiatric distress and depression level.

From the findings, Baker and Dawe (2005) recommend a stepped-care approach. A basic intervention would consist of a structured assessment of amphetamine use and related problems, self-help material, and regular monitoring of amphetamine use and related harms. Baker and Dawe (2005) suggest offering two sessions of CBT at the outset for regular amphetamine users with further treatment offered depending on response.

17.2.3.3 Cocaine

Benefits have been shown after two sessions of motivational interviewing for cocaine users with low initial motivation to change (Rohsenow et al. 2004). Platt (1997), from a review of cocaine misuse, concluded that a nonconfrontational, empathic, and mutually respective therapeutic relationship is more likely to engage those more entrenched users who are unwilling to accept that they have a problem.

17.2.3.4 Heroin

Research into brief interventions with heroin users is limited; however, a study conducted by Saunders et al. (1995) concluded that brief motivational interventions were a useful adjunct to clients on methadone programs. They found that over

a 6-month period, clients receiving brief motivational interventions directed at illicit opiate use demonstrated a greater and more immediate commitment to abstinence than those who did not receive motivational interventions. Compared to the control group (who received an educational session), the intervention group also reported more positive outcomes for abstinence, had fewer opiate-related problems, were initially more contemplative of change, complied with the methadone program longer, and relapsed less quickly (Saunders et al. 1995).

17.2.3.5 Adapting Brief Interventions to the Client

It is important to recognize that illicit substances are not taken by sharply distinct population groups and two or more substances may be used concurrently or during the same use episode (Humeniuk et al. 2012). This has an impact on the focus and content of the brief intervention as the clinician works with the client to ascertain their goals and motivation to change.

Although the underlying principles of brief interventions remain the same, it is important to consider some of the characteristic traits of drug-using groups. For example, amphetamine users are generally younger than opiate users and more sexually active, and the pharmacological effects of amphetamines may result in high levels of unsafe sex behavior (Hall et al. 1993). The majority of amphetamine users are polydrug users. Benzodiazepine use is common and is often used to assist with amphetamine-related problems (Baker and Dawe 2005).

17.2.4 Settings for Brief Interventions

Most people with substance-related problems of low to moderate severity are unlikely to approach specialist addiction treatment services but do have regular contact with their general practitioner (Humeniuk et al. 2003). Primary care is the best place to screen and offer brief interventions for people with low-moderate severity problems that are nonetheless clinically significant. Any health-care visit provides an opportunity for substance use screening and brief intervention based on motivational interviewing principles (Miller and Rollnick 2013). Primary care clinicians can play a vital role in the early detection of the problem of substance use, but there is a pressing need for an empirically verified and efficient approach to screening and brief intervention.

17.2.4.1 Primary Health-Care Settings

In the developed world, 85 % of the population visit a primary health-care clinician at least once per year (Humeniuk et al. 2003). Patients whose tobacco, alcohol, and other substance use is hazardous or harmful have more frequent consultations. Many common health conditions seen in primary care may be related to substance use, and the primary care worker can use this link to introduce screening and brief interventions for substance use. The intervention then forms part of the management of the presenting complaint.

Primary care settings provide the best context and opportunity for change over time, since patients have an expectation of preventive care and often have a long-term and trusting relationship with a clinician (Saitz et al. 2010). There is research evidence supporting the effectiveness of brief interventions that target either alcohol use or smoking in primary health-care settings (Kaner et al. 2008). Brief interventions for substances other than alcohol have also been shown to be effective in primary care settings, if culturally appropriate intervention procedures are developed (Humeniuk et al. 2003).

An annual cross-sectional study of approximately 1,000 general practitioners throughout Australia has been provided since 1998 by the Bettering the Evaluation and Care of Health (BEACH) program. Frewen et al. (2008) analyzed the BEACH data between April 2000 and March 2007 and showed that general practitioners addressed illicit drug use approximately 55,000 times per year and of these, cannabis made up 3.2 % of all encounters which specified an illicit drug. The most common response was to offer counseling (approximately 52.7 % of cannabis encounters) and referral (approximately 22.5 % of cannabis encounters), while recommending a medication for a specific cannabis-related problem was less common (approximately 9.3 % of cannabis encounters) (Frewen et al. 2008).

Patients view primary care as a credible source of advice about health risks including substance use (Humeniuk et al. 2003). Nurses comprise the greatest proportion of health-care workers and serve in a variety of settings, often in roles that are focused on health promotion and patient education. This makes practice nurses ideal providers of screening and brief intervention (Puskar et al. 2013).

17.2.4.2 Emergency Departments

Emergency departments can provide brief interventions that are directly linked to harmful consequences of substance use. Combined with the "teachable moment" or post-injury period of heightened receptivity, this environment presents an opportunity to contextualize the substance misuse problem and potentially enhances the outcomes (Shetty 2011).

Currently, evidence of the benefits of brief interventions in emergency department settings in terms of reduced alcohol and other drug use and associated injuries or high-risk behaviors is inconclusive because of variability in studies in such settings (Newton 2013): however, one study of brief interventions in hospital emergency departments linked adolescents with treatment and found decreased substance-related visits to the emergency department in the following 12 months (Tait et al. 2005).

Although screening and brief intervention for hospital patients appears to be a simple, logical, and inexpensive approach, some concerns have been raised. Saitz (2010) suggests that performance measures should assess evidence-based practices, and screening and brief interventions in hospitals are not yet evidence based. Adding validated questionnaires to busy hospital routines is not simple. Hospitals need to establish procedures to address positive results and issues around confidentiality, stigma, and discrimination (Saitz 2010).

17.2.4.3 Mental Health Settings

Mental illness is estimated to co-occur in 37 % of individuals with an alcohol use disorder and in more than 50 % of individuals with a substance use disorder (Brooner et al. 1997; Degenhardt et al. 2001). Therefore, in any screening activity, it is likely that a significant subset of people receiving a brief intervention will have a mental illness. Existing literature provides an encouraging perspective regarding the benefits of brief intervention for individuals with a mental illness (Grothues et al. 2008; Baker et al. 2002; Hulse and Tait 2002). Krupski et al. (2012) found that brief intervention may not have a differing impact based on the presence of a mental illness diagnosis.

Substance misuse is common in early psychosis and impacts negatively on outcomes. Kavanagh et al. (2004) found that many people with early psychosis and substance misuse have the skills to moderate or stop consumption and may require little or no intervention to trigger an attempt to control their substance use after an early psychiatric admission. Enhancing motivation to alter drug use and refining skills may assist this process. A brief motivational approach may help to support engagement in treatment and may also be a viable first-line intervention for substance use in early psychosis. However, as commented by Kavanagh et al., further evidence is needed to support this conclusion (Kavanagh et al. 2004).

In relation to cannabis, research suggests that brief interventions may be efficacious for reducing cannabis use in those with comorbid externalizing disorders. Dennis et al. (2004) found a brief intervention to be effective in reducing frequency of cannabis use and symptoms of dependence and/or abuse in young people with self-reported psychiatric comorbidity. The majority of this comorbidity was confined to externalizing disorders, such as conduct disorder, attention-deficit/hyperactivity disorder, and alcohol use disorders.

17.2.4.4 Use in Information Technology

Advances in information technology have seen innovative approaches to providing information and support for people aiming to reduce or stop their substance use. Research has suggested that web-based brief intervention programs may be useful in reducing substance use in young adults (Bingham 2010). Web-based brief interventions have the advantage of greater reach and increased cost-effectiveness while minimizing potential barriers, such as staff time and training (Ondersma et al. 2011).

Computer-based brief intervention has been shown to decrease cannabis related problems and other drug use in adolescent cannabis users presenting to primary care (Walton et al. 2013). This approach is especially promising for financially limited primary care settings located in socioeconomically disadvantaged areas assuming such areas have access to computers and the internet (Walton et al. 2013).

Touch-screen tablet computers have been shown to be a confidential, acceptable, patient preferred, and cost-effective method of collecting health information (Hahn and Cella 2003). They have been used effectively for depression (Proudfoot et al. 2003) and smoking cessation (Free et al. 2011) interventions. Based on these

findings, opportunities and implications for screening and brief intervention for illicit substance use via computer tablets are currently being explored.

The use of a phone application or 'app' is seen to be less confrontational than face-to-face communication, particularly if the person is uncertain whether their substance use is a problem. In Australia, the 'Night Coach' phone app developed by the Australian National Council on Drugs, offers screening via the ASSIST and a brief intervention based on the persons responses and risk category. The person is able to track the amount of money they have spent on their substance use and links are provided to specialist support and treatment services.

17.2.5 Key Principles in Conducting a Brief Intervention with an Illicit Drug User

In order to deliver an effective brief intervention, it is essential to understand the underlying principles of behavior change in the context of motivational interviewing. Motivational interviewing is a collaborative conversational style for strengthening a person's own motivation and commitment to change (Miller and Rollnick 2013). The stages of change model is useful for conceptualizing a client's motivation to address their problems as the stages reflect the person's readiness to change and are important landmarks for deciding upon appropriate intervention strategies (Leamon et al. 2005). The stages of change divides the process into five distinct stages (pre-contemplation, contemplation, preparation, action, maintenance) with stage-specific goals to achieve before progression (Prochaska et al. 1992).

Brief intervention is especially useful when working with patients in the pre-contemplation and contemplation stages, but the principles and skills are important at all stages (Miller and Rollnick 2013). The brief intervention approach suggested here is based on the motivational interviewing principles developed by Miller and Rollnick (2002, 2013).

Motivational interviewing makes use of five specific skills. These skills are used together to encourage patients to talk, to explore their ambivalence about their substance use, and to clarify their reasons for reducing or stopping their substance use. The first four skills are often known by the acronym OARS – open-ended questions, affirmation, reflective listening, and summarizing. The fifth skill is "eliciting change talk" and involves using the OARS to guide the patient to present the arguments for changing their substance use behavior (Miller and Rollnick 2002, 2013).

The transtheoretical model offers an integrative framework for understanding the process of behavior change. The stages of change represent a key component of the transtheoretical model and describe a series of changes through which people pass as they change behavior (DiClemente and Velasquez 2002). The model proposes that individuals in a change process tend to negotiate a cyclical pathway that traverses a number of recognizable change stages (DiClemente and Hughes 1990).

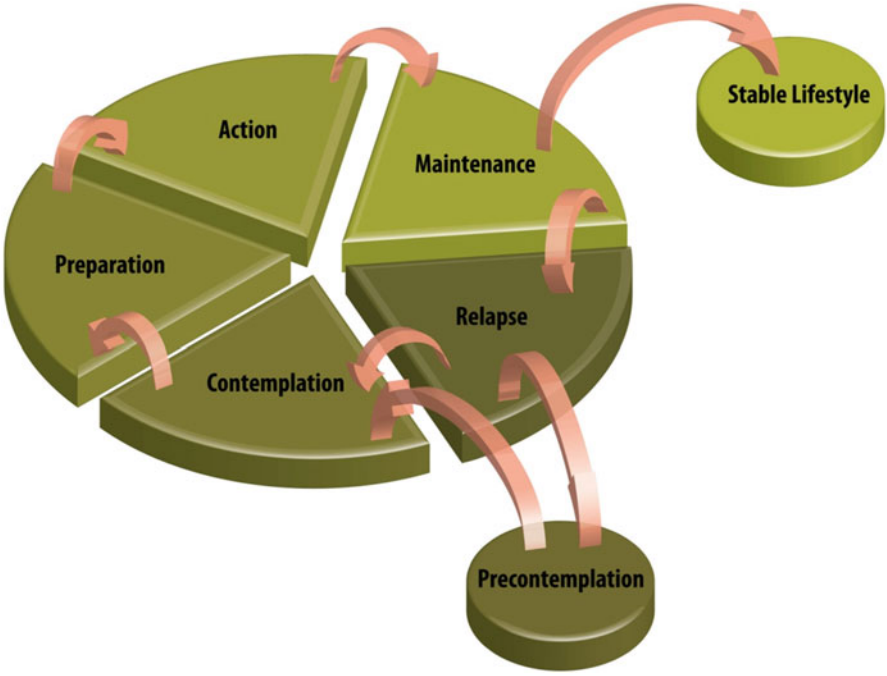

Fig. 17.1 Stages of change model (http://www.medicine.uottawa.ca/sim/data/Images/TTM_diagram.gif)

The stages of change model can be used to match interventions with a person's readiness to take in information and change their substance use (Fig. 17.1).

17.2.5.1 Linking an Appropriate Brief Intervention to the Client's Stage of Change

The multidimensional nature of drug use makes it important that drug users are assessed for motivation to change.

People in the **pre-contemplation** stage either are unaware of problem behavior or are unwilling to change. This is often expressed as "I like using" or "I do not want to stop using" (WHO 2004). People in pre-contemplation are not convinced that the negative aspects of the current behavior outweigh the positive and can be considered as "happy users" (Berridge and Robinson 2003). Individuals at this stage generally do not seek treatment unless they are coerced. They engage in little activity that could shift their view of the problem behavior and can become defensive if challenged about their behavior (Prochaska and Goldstein 1991).

The appropriate brief intervention for an illicit drug user in the pre-contemplation stage is to provide information about the effects of substance use, explore harm minimization options, and supply a list of contacts and services in case assistance is required in the future. The focus of the clinician at this stage is to

be nonjudgmental and respectful of the client's choice but at the same time raise awareness and provide relevant information (Naegle and D'Avanzo 2000). Raising doubt is an effective approach as it increases the client's perception of risks and problems with their current behavior. The overall strategy is to maintain a low intensity of interaction so the individual does not feel overwhelmed or pressured to change (Miller and Rollnick 2002).

Contemplation is a very paradoxical stage of change as, although the person is aware of a problem, they have not made a significant commitment to change (Miller and Rollnick 2002). Individuals at the contemplation stage are aware of the harms of use and the benefits of changing but are still ambivalent about changing. This can be expressed as "I don't believe how much I am spending on drugs, but I really like it" (DiClemente et al. 2004).

During a brief intervention, the clinician can be quite influential at this stage as they encourage the client to explore the risks of continued use versus the benefits of changing. The clinician can help the client "tip the balance" in favor of the most positive behavior. It is important to note that responsibility for change lies with the client and that the clinician reinforces the advantages of change and promotes self-efficacy of the client. For clinicians, it is important that they recognize ambivalence as a vital part of the contemplation stage of change. It must also be recognized that contemplation does not mean commitment (DiClemente and Velasquez 2002).

The individual has entered the **preparation stage** when they have decided to take action in the near future and are making plans and developing motivation to engage in change activities. This is often expressed as "I want to know how to give up" or "I am ready to try cutting down." The person may be confused about the best way forward and may seek advice of professional, friends, family, and people who have been through a similar experience to learn from their experience.

Individuals at the preparation stage have often sought treatment previously and may have tried and failed to change in the past. Yet, they have often learned valuable lessons from past change attempts (DiClemente and Velasquez 2002). It is important in the preparation stage to assist the client in finding the best course of action. This can be done by offering a menu of options, cocreating a plan, goal setting, demystifying the change process, and inspiring realistic hope (Prochaska et al. 1992). People at this stage may benefit from validation and reinforcement in respect to their reasons for change and assistance in planning strategies to bring about change. The overall strategy at this stage is to help the client determine the best course of action to take in seeking change.

The next stage is **action** and this is when people most overtly modify their behavior. During this stage, the person makes the move and actually implements the plan for which they have been preparing (DiClemente and Velasquez 2002). It is important that the clinician help the client to take steps toward change such as monitoring progress, reinforcing incremental success to increase self-efficacy, and helping to problem-solve as issues arise (Naegle and D'Avanzo 2000).

People at the action stage may benefit from problem-solving and goal-setting skills to assist with implementing and integrating change. They may require an introduction to the significant potential of relapse and mapping of change processes, including adjustment to the impact of change on self-identity (WHO 2004).

In the next stage, **maintenance**, the person works to consolidate the gains attained during the action stage and fights to prevent relapse. Without a strong commitment to maintenance, there will be a short lapse or relapse to the old behavior. Although traditional therapies view maintenance as a static stage, the stages of change model sees it as a critically important continuation that can last from as little as 6 months to as long as a lifetime (DiClemente and Velasquez 2002).

The maintenance stage is characterized by a substantial and sustained change of behavior and by attempts to prevent relapse or consolidate previous gains (Migneault et al. 2005). People at this stage may require assessment of the strategies that they have found useful in changing and assistance in dealing with any potential problems with sustaining the gains. They may also benefit from reinforcement of relapse prevention strategies, including returning to self-management strategies before a relapse occurs (Miller and Rollnick 2002).

The stages of change model recognizes that **relapse** is possible, and likely, when trying to change behavior. People often cycle through the stages many times before reaching their goal (Migneault et al. 2005). Therefore, a lapse should not be considered a failure but rather a minor setback. After a relapse, individuals often regress to an earlier stage and then begin progressing through the stages again. Often, people who relapse have a better chance of success the next time as they have learnt new ways to deal with old behaviors and they have history of partial success to build on (DiClemente and Velasquez 2002).

Therefore, a relapse should not be wasted as it is an opportunity for the client to refine self-management skills (DiClemente and Velasquez 2002). People who relapse need to analyze events leading up to the lapse and post-relapse impacts. Relapse is often typified by self-blame which only intensifies the impact and possible duration of the setback.

Brief Intervention in Action

Ben is a 22-year-old university student attending a large Australian university. Originally from the country, Ben has found assimilation into city living challenging. Ben lives in a share house with three older males who work as tradesmen and smoke cannabis daily. Although Ben was an occasional cannabis user in the past, his use has escalated over the past 2 years and he is now smoking daily. Ben failed two subjects in his final year and is finding it hard to stay motivated to complete his degree. Ben has not visited his family and friends “back home” for over 6 months; previously, he would make the effort and travel home fortnightly.

Ben visited the university medical center for a persistent cough. While waiting to see the doctor, Ben completed an Alcohol, Smoking and Substance

Involvement Screening Test (ASSIST) as standard procedure of the practice. Ben scored in the moderate-risk range for his cannabis use. The practice nurse engaged Ben in a brief intervention highlighting the associated risks of his current pattern of use. Although reluctant to discuss his cannabis use at first, the practice nurse was able to evoke Ben's ambivalence with his current pattern of use and offer a menu of options for him to consider. Ben's goal to complete his degree and return to his home town was the greatest motivator for change. Ben opted for online assistance and reduced his cannabis use during the following 3 months. Ben is making some positive changes by re-engaging with his family and attending lectures at university.

17.2.5.2 Conducting a Brief Intervention

As outlined in Fig. 17.2, the brief intervention is guided by the level of risk identified in the screen. Using the example of the Alcohol, Smoking and Substance Involvement Screening Test (ASSIST), individuals who are identified in the low-risk range are encouraged to remain at this level, may benefit from general health information, and are advised of the risks of increasing their use. For people in the moderate-risk range, advice is given on the possible adverse effects of continued use, and the client's current level of concern and motivation for change is explored. The focus of a brief intervention in the high-risk range is for the client to recognize and understand the risks associated with their current pattern of use and encourage them to engage in structured treatment for their substance use.

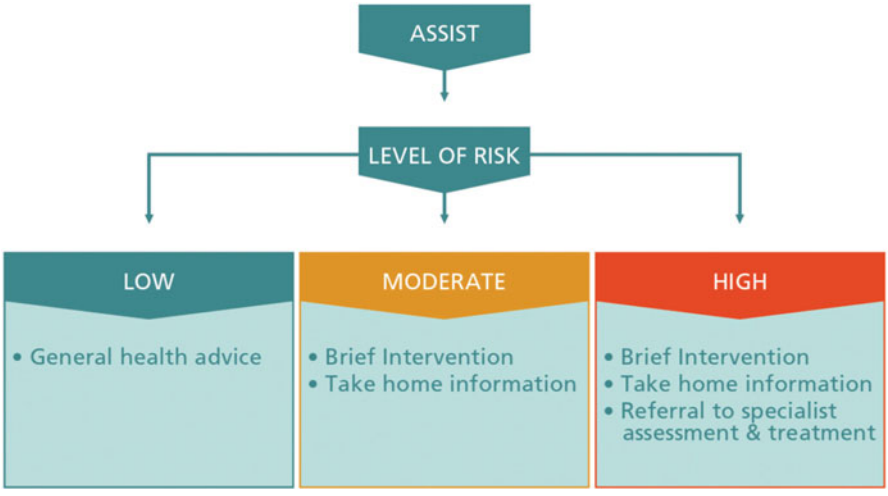

Fig. 17.2 ASSIST linked brief intervention

A useful framework to structure a brief intervention is provided by the FRAMES model. This highlights the six key components of a brief intervention: Feedback, Responsibility, Advice, Menu of options, Empathy, and Self-efficacy.

FRAMES

Feedback The provision of personally relevant feedback is a key component of brief intervention and generally follows a thorough assessment of drug use and related problems. Feedback can include information about the individual's drug use and problems from a screening instrument such as the ASSIST, information about personal risks associated with current drug use patterns, and general information about substance-related risks and harms. If the person's presenting complaint could be related to substance use, it is important to inform then about the link as part of the feedback. Feedback may also include a comparison between the person's substance use patterns and problems and the average patterns and problems experienced by other similar people in the population.

Responsibility A key principle of intervention with substance users is to acknowledge that they are responsible for their own behavior and that they can make choices about their substance use. The message that "ultimately the choice is yours" enables the person to retain personal control over their behavior and its consequences. This sense of control has been found to be an important element in motivation for change and to decrease resistance.

Advice The central component of effective brief interventions is the provision of clear advice regarding the harms associated with continued use. People are often unaware that their current pattern of substance use could lead to health or other problems or make existing problems worse. Providing clear advice that cutting down or stopping substance use will reduce their risk of future problems will increase their awareness of their personal risk and provide reasons to consider changing their behavior.

Menu of options Effective brief interventions provide the person with a range of alternative strategies to cut down or stop their substance use. This allows the person to choose the strategies which are most suitable for their situation and which they feel will be most helpful. Providing choices reinforces the sense of personal control and responsibility for making change and can help to strengthen the patient's motivation for change. Giving information or guides to cutting down or stopping is a good first start and can be used alone or in conjunction with several options.

Empathy A consistent component of effective brief interventions is a warm, reflective, empathic, and understanding approach by the person delivering the intervention. Use of a warm, empathic style is a significant factor in the person's response to the intervention.

Self-Efficacy The final component of effective brief interventions is to encourage the person to have confidence in their ability to make changes in

their substance use behavior. People who believe that they are likely to make changes are much more likely to do so than those who feel powerless or helpless to change their behavior. It is particularly helpful to elicit self-efficacy statements from patients as they are likely to believe what they hear themselves say.

17.2.6 International Perspectives and Concluding Remarks

Brief intervention following screening can make a difference by raising awareness of an individuals substance use issues and decrease risky behaviors. However, having a conversation with a person about substance use can be challenging, particularly in countries with heavy penalties for illicit drug use. This places the clinician in a perplexing situation. The clinician may be aware of the benefits of screening and brief intervention and may be keen to implement the process, but asking the screening questions may result in the mandatory reporting of the illicit drug use. How does a clinician operate within the non-maleficence principle of "*above all*, *do no harm*" when, in some countries, heavy fines, incarceration, and capital punishment are consequences of illicit drug use?

Rather than try and provide a solution to this complex dilemma, a couple of guiding principles are suggested. Above all, the clinician needs to be honest with the client about the potential consequences of their responses. Gaining trust is paramount in establishing any therapeutic relationship. Providing the client with all the necessary information related to their responses within their country's legal context is essential. Although the harmful effects of substance misuse are well known, information may not be readily available in some countries. Providing general information on the consequences of drug use may be a helpful start.

For clients who require a more complex intervention or referral into treatment, the focus of the brief intervention may be on what options are available. This may be very limited and will vary significantly between countries. When faced with mandatory reporting, the clinician may suggest reporting together and include the client in the process. This approach adheres to the client-centered principle of brief intervention and is within the legal framework of most countries. Including a treatment plan and highlighting the client's motivation to change in this process may also be helpful in the reporting process.

Barriers to effective brief interventions are not limited to countries with heavy penalties for illicit drug use. Research has found that many health-care professionals have negative or stigmatizing attitudes toward people who use substances. Some studies found that nurses had more negative attitudes than other health professionals (Howard and Chung 2000). Research has shown that nurses generally thought they had a role in screening for substance use, but not in intervention (Puskar et al. 2013).

17.2.6.1 Addressing the Barriers and Where to Go From Here

For brief interventions to become part of routine practice for health professionals, an approach at the health system level, based on the evidence, accompanied by training and promotion is needed. Continuing medical education is one way of addressing this. It is suggested that screening, brief intervention, and referral for treatment should be taught in medical school and residency (Brown et al. 2012). Similarly for nurses, the inclusion of screening and brief intervention training in undergraduate or graduate nursing curricula has been called a "next step" to improve uptake and implementation (Broyles and Gordon 2010). Attention should be paid to providing education and training about the fundamentals of brief intervention and to monitoring negative attitudes and practitioner's perceptions of their competence and confidence to deliver screening and brief intervention (Puskar et al. 2013).

The prospect of intervention early in drug use careers to curtail escalation in risk and divert away from harm is enduringly attractive (McCambridge et al. 2008). Further opportunities for brief intervention for illicit drug users need to be explored. There is a group of interventions that provide a first point of contact with drug users with the aim of providing information about drug use, particularly about approaches to reduce the risks to both the individual and the general community. In some countries, this includes peer education, clean needle and syringe distribution programs, immunization programs, and supervised injecting rooms. Outreach workers, police, and justice system personnel are also in regular contact with drug users. Although this contact may be unrelated to drug use, if drug use is identified or suspected, the contact can deliver a brief intervention or provide information about drug use and encourage engagement in treatment.

Although a strong theoretical base has been made for substance use screening and brief intervention, further randomized controlled trials are needed to determine its efficacy. Few randomized trials have addressed the question of whether brief intervention reduces illicit drug use and its consequences by identifying patients who need treatment before they seek it (Saitz et al. 2010).

Drugs of Abuse and Pharmacotherapies for Substance Disorders

Ivan D. Montoya and Julio Bobes

Drugs of Abuse and Pharmacotherapies for Substance Use Disorders: An Introduction

18

Ivan D. Montoya and Julio Bobes

Abstract

Drug abuse continues being a public health problem. Old drugs such as alcohol, tobacco, opioids, and cannabis; newer drugs such as cocaine, amphetamines, hallucinogens, sedatives, and anabolic steroids; and the newest drugs such as the synthetic cannabinoids are producing devastating medical and psychosocial consequences among people of all ages and in most countries of the world. This section provides an overview of the pharmacological and psychosocial effects of the most common drugs of abuse as well as the state-of-the-art treatments of the addictive disorders that may result from their compulsive use. The section also includes chapters that highlight some specific therapeutic approaches, special issues related to the implementation of some treatments in some countries, and topics related to the research of new pharmacotherapies for drug addictions. In addition, this section offers a unique international perspective to these topics, which is consistent with the global nature of the drug abuse problem and responds to the need of going beyond country boundaries to effectively tackle this worldwide epidemic.

It is our pleasure to introduce the Section III of the textbook, which is titled Drugs of Abuse and Pharmacotherapies for Substance Disorders. The field of Addiction Medicine is rapidly transforming. For the most part of the last century, people with addictions were considered morally flawed and lacking in willpower. Recently,

thanks to the great scientific advances in neurosciences, we have a better understanding of the neurophysiological basis of addiction. As a result, the concept of addiction has evolved. Addiction is now considered a medical condition associated with changes in the brain, manifested by compulsive drug use behaviors. This change in the concept of addiction has allowed scientists to explore new ways to prevent, diagnose, and treat this disorder.

Old drugs of abuse continue affecting large segments of the populations while at the same time new drugs with new challenges are constantly emerging. Old drugs such as alcohol, tobacco, opioids, and cannabis; newer drugs such as cocaine, amphetamines, hallucinogens, sedatives, and anabolic steroids; and the newest drugs such as the synthetic cannabinoids are producing devastating medical and psychosocial consequences among people of all ages and in most countries of the world. The use of old and new drugs rapidly crosses national boundaries and currently it is not possible to consider a drug use problem as specific or circumscribed to a country or a region. For that reason, it is imperative to ignore country boundaries and approach the drug use problems as global, clinical, and public health issue.

The main goal of this book is to provide a didactic and scientifically based overview of the different drugs of abuse and of their state-of-the-art treatment. It gives me a great pleasure to introduce this section because it is very comprehensive and multifaceted. The content of the chapters can be divided in three areas: (1) the specific drugs of abuse and their treatment, (2) highlights of some specific therapeutic approaches, and (3) an area that may be called "miscellaneous" because it includes a variety of topics related to the advancement of new treatments.

The first area covers the most relevant drugs of abuse and their current therapeutic approaches. It includes chapters with focus on alcohol, nicotine/tobacco, opioid, cocaine, amphetamine, cannabis, hallucinogen, inhalant, sedatives, anabolic steroid, xanthenes (including caffeine), and khat use. Unfortunately, there are no medications approved by regulatory agencies to treat the addiction to most of these drugs of abuse. For most of them, the only treatment provided is psychosocial support, which sometimes its efficacy has little or no scientific support.

Currently there are medications approved to treat alcohol, nicotine/tobacco, and opioid addiction; however, some of them are not approved in all countries. For alcohol addiction, the approved pharmacotherapies include disulfiram, acamprosate, naltrexone, and nalmefene. For nicotine/tobacco addiction, they include nicotine replacement therapies, bupropion, and varenicline. For opioid addiction, methadone, buprenorphine, buprenorphine/naloxone, naltrexone, and lofexidine are approved. Unfortunately, the number of patients who can benefit from the prescription of these medications is often limited due to multiple factors including national policies, economic constraints, and lack of clinician's expertise and confidence to prescribe them.

The second area of this section includes specific interventions that might be unique or offer new therapeutic opportunities for patients to assist them in their struggle against drug addiction. They include the pharmacological treatment of alcohol use disorders, addiction treatment with acupuncture, biologics (vaccines,

antibodies, enzymes) to treat drug addictions, buprenorphine implant in the treatment of opioid addiction, transcranial magnetic stimulation as drug addiction treatment, as well as nutrients, phytomedicines, and mind-body treatments for substance abuse. This area also covers some important experiences with specific treatments in different parts of the world such as the experience in France with buprenorphine in the treatment of opioid addiction, the experience in China and Iran with the implementation of methadone programs for the treatment of opioid addiction, and the experience in Russia with the use of naltrexone to treat opioid addiction.

The third area of this section covers aspects related to advancing the understanding of the mechanisms of action of drugs or abuse such as the enzymatic aspects of alcoholism and the risks of opioid agonist diversion. It also provides an overview of the recent advances in the research of medications to treat drug addictions as well as the regulatory aspects involved in the development and ultimate approval of anti-addiction medications by regulatory agencies, particularly the Food and Drug Administration (FDA) of the United States.

We envision that this section of the textbook will be useful to multiple readers. It is expected that clinicians at all levels of experience, from general counselors to addiction specialists, will find this section a reference to guide their clinical work and hopefully will result in improving the treatment of their patients. This section can also be useful to junior and senior investigators who may be interested in learning about the drugs of abuse and their treatment as well as the current research on pharmacotherapies for addiction and the research process required by the FDA to obtain approval. We think that students in the health-care disciplines that converge in the interdisciplinary treatment of drug addictions are an important group who will greatly benefit from this section because it provides the information in a didactic and comprehensive way. At the same time, the section gives them the opportunity to learn in more detail about some specific topics and gain an international perspective.

Finally, we want to thank all the authors who contributed to this section for their dedication and effort in writing their chapters and contributing to make this textbook an important contribution in the advancement and dissemination of the knowledge about drugs of abuse and their treatment throughout the world.

Pharmacological Long-Term Treatment of Alcohol Use Disorders

19

Karl Mann and Falk Kiefer

Contents

Abstract

The acute and long-term consequences of alcohol use disorders are very well known. Multiple treatments for these disorders have been investigated, and some of them have received approval by regulatory agencies. Disulfiram blocks the natural degradation of alcohol. It inhibits the acetaldehyde dehydrogenase, and the accumulation of acetaldehyde in the body results in unpleasant symptoms such as rush, nausea, headache, diarrhea, vomiting, and a drop in blood pressure. Disulfiram should only be prescribed once the patient has been detoxified and is free of alcohol and without withdrawal symptoms. Naltrexone is a competitive opiate antagonist with high affinity to the μ-receptor and lower affinity to the δ- and κ-receptors and is approved to treat alcohol dependence in individuals who are not opioid dependent. Acamprosate binds to NMDA receptors and thus dampens the glutamate-mediated excitability and is approved for the treatment of alcohol dependence in people who already established a state of alcohol

abstinence. Nalmefene is the most recent medication approved for use in alcohol dependence. It was approved by the European Medicines Agency in 2012 for a reduction of heavy drinking days and/or total alcohol consumption. Nalmefene is a selective opioid ligand with an equally high affinity to the μ- and κ-receptors and medium affinity to the δ-receptor. It acts as an antagonist at the μ- and δ-receptor, but different from naltrexone, it is a co-agonist at the κ-receptor. The official indication for nalmefene is to reduce alcohol consumption. The chapter will discuss these and other medications that are being investigated for the treatment of alcohol use disorders.

19.1 Introduction

Ever since mankind realized that alcohol consumption can be accompanied by serious consequences and by what later was called impaired control, ways out of this dilemma were searched. Myths and magic around the world deal with remedies to solve or at least reduce this problem. Greek mythology has it that an amethyst helps to cope with alcohol intoxication. In the Middle Ages in France, draconian measures were taken to deal with public drunkenness. King Francois I ordered that "anyone who appeared in public in a state of intoxication should on the first occasion be imprisoned on bread and water, on the second chastised with birch and whip, and on the third publicly flogged. Should further relapses occur the delinquent was to have an ear cut off and suffer banishment" (Lewin 1931). Obviously this approach failed as so many following later. During the nineteenth and much of the twentieth century, alcoholism was considered a moral weakness. Cure was awaited from secluding individuals into asylums with strong elements of education and strengthening religious beliefs. First pharmacological attempts such as Dr. Shilo's "lemon cure" seem peculiar in retrospect. He recommended the use of 231 lemons over a period of precisely 29 days. "All five subjects developed a complete indifference to alcohol, with the craving stamped out" (Edwards 2000, 2005). Obviously this attempt did not make it into widespread use either.

In the last century, the development and testing of psychotherapies was put on the agenda. Likewise, more sophisticated pharmacological ways of securing abstinence or of reducing alcohol consumption to less harmful levels began to be considered. Some advances were based on serendipity and good clinical observation and judgment. The best-known example is the observation that workers in the rubber industry reported to feel sick when they drank alcohol. It was found that disulfiram as a by-product of rubber fabrication was released into the air and that this explained the reduction in alcohol consumption in those workers who were exposed.

As first claims for successful treatments were made, a need for standardized ways of assessing patients' improvements became evident. At the end of this process, randomized, controlled double blind trials seem the mandatory standard, although good clinical judgment keeps its place in finding new treatment options. In this chapter, we shall give an overview on currently available medications for the

long-term treatment of alcohol dependence. We concentrate on the compounds for which sufficient evidence base is available, which are approved for alcohol dependence and which are currently being used in many parts of the world. Wherever possible we concentrate on meta-analyses without referring to all the individual studies. Should there be Cochrane reviews on specific medications, our recommendations shall rely on those. The presentation of medications roughly follows the order of their approval by national or international authorities. There are a few other medications which are not approved for alcoholism but for other medical indications and which are currently suggested for an off-label use in alcoholism. These will be mentioned on a shorter note.

19.2 Pharmacological Treatment Options

19.2.1 Disulfiram

19.2.1.1 Pharmacology

As mentioned above, the potential of disulfiram (tetraethylthiuram disulfide) to modify alcohol consumption was found by serendipity. After disulfiram had been identified as the substance which caused the change in drinking habits, further research revealed the mechanism of action (Martensen-Larsen 1948). Disulfiram blocks the natural degradation of alcohol. Specifically it irreversibly inhibits the acetaldehyde dehydrogenase for 2–5 days, a condition which is only terminated by de novo synthesis of the enzyme. The accumulation of acetaldehyde in the body results in unpleasant symptoms such as rush, nausea, headache, diarrhea, vomiting, and a drop in blood pressure. Similar symptoms can be seen in about 50 % of the Asian population with a genetically determined lack of an ISO-enzyme of the acetaldehyde dehydrogenase which again leads to an accumulation of acetaldehyde when alcohol is consumed.

19.2.1.2 Indications and Contraindications

The indication for severe alcohol dependence is clear. Disulfiram should only be prescribed once the patient has been detoxified and is free of alcohol and without withdrawal symptoms. Several contraindications need to be taken into account: cardiomyopathy, coronary heart disease, severe heart arrhythmia, esophageal varicosis, hypothyroidism, and advanced arteriosclerosis. Disulfiram should also not be prescribed when patients suffer from asthma bronchiale, decompensated liver cirrhosis, and severe hypotonia. Accumulation of acetaldehyde in the human body as mentioned above can lead to very aversive reactions including death in a number of cases where the administration of disulfiram was not sufficiently supervised. Therefore, disulfiram should only be prescribed by doctors who are well aware of its potential but also of its risks and who have ample experience with the drug. For this caveat many colleagues consider disulfiram only as a “second choice treatment”; others prescribe it quite regularly (Brewer 1993).

19.2.1.3 Dosage and Undesired Effects

The dosage of disulfiram has to be tapered up starting with 250 mg in the first day moving to 500 mg as of the third day of treatment for maintenance dosage. Higher doses up to 1,000–1,500 mg might be appropriate when patients take the pill every second day (Mon-Wed-Fri). The drug should be taken orally; attempts with subcutaneous implants were not really convincing in the long run (Marie 1955). Originally patients were asked to drink alcohol after having taken disulfiram. Under supervision they should thus experience the aversive effects of the drug when alcohol is consumed. Later studies indicated that this test is not mandatory. Disulfiram worked as well without it (Krampe et al. 2006). If no alcohol is consumed, the most important side effect is sedation and initial sleepiness. However, this is transient in most cases and therefore no real reason for concern.

19.2.1.4 Efficacy

An early meta-analysis showed the superiority of disulfiram over placebo (Agosti 1995). However, this result was questioned by a large randomized trial in the USA where no significant benefit was found (Fuller et al. 1986). While this trial was very influential in some parts of the world, it did not convince clinicians who had long worked with this drug especially after some of the earlier safety issues had been resolved (Chick 1999). In Germany, disulfiram witnessed a renaissance after a group at Göttingen University published a long-term study with extremely ill patients who had been coming into the clinic literally every day for supervised intake for more than a year (Krampe et al. 2006). So far we have only limited evidence on disulfiram from head-to-head comparisons with other anticraving medications. Some publications point to a superiority over other approved medications such as acamprosate and naltrexone (Besson et al. 1998; De Sousa 2004; Laaksonen et al. 2008). This was reflected in several meta-analyses as well (i.e., Berglund et al. 2003).

19.2.2 Naltrexone

Naltrexone is the second drug which was approved for the long-term treatment of alcoholism. Based on observations in monkeys (Altshuler et al. 1980), two clinical trials were undertaken in the USA which showed a benefit over placebo (Volpicelli et al. 1992; O'Malley et al. 1992) and convinced the FDA to grant a rapid approval.

19.2.2.1 Pharmacology

Naltrexone is a competitive opiate antagonist with high affinity to the μ-receptor and lower affinity to the δ- and κ-receptors. The consumption of alcohol increases the release of brain endorphin (Gianoulakis et al. 1996) and subsequently of dopamine which results in the positive reinforcing effects of alcohol. A specific blockade of the μ-receptors and thus of the positive reinforcement of alcohol is the most likely explanation of naltrexone's clinical efficacy (Sinclair et al. 2002; Heilig et al. 2011). Although the plasma half-life of naltrexone and its active metabolite

ß-naltrexol is only about 10–12 h, its μ-receptor occupancy shown with PET studies lasts for about 48–72 h (Lee et al. 1988). For the specific impact of a polymorphism of the μ opiate receptor gene, see below.

19.2.2.2 Indications and Contraindications

Naltrexone has been approved for the treatment of drug and alcohol dependence. When prescribing naltrexone, it is important to assure that there was no recent opioid consumption either as pain medication or consumed illegally.

19.2.2.3 Dosage and Undesired Effects

While dosages of 100 g and more have been tested, it is a broad consensus nowadays that a daily dosage of 50 mg which means one pill a day is sufficient in the treatment of alcoholism. Nausea, dizziness, headache, and insomnia are the most prevalent side effects of naltrexone. In the USA, naltrexone carries a box warning by the FDA due to its potentially aggravating effects of alcoholic liver dysfunction.

19.2.2.4 Efficacy

The two pivotal trials (Volpicelli et al. 1992; O'Malley et al. 1992) were followed by many more studies around the world (Mann 2004). More than half of them showed significant superiority over placebo. Those which did not were often not powered well enough, were done in difficult to treat patients (Krystal et al. 2001), or had a very high placebo response (Gastpar et al. 2002; Mann et al. 2013). Recent meta-analyses and a Cochrane analysis conclude that there is a clear benefit of naltrexone in the treatment of alcoholism (Rösner et al. 2010a, b). A genetic component in treatment response was first demonstrated in a post hoc analysis of three independent trials (Oslin et al. 2003). Patients were genotyped looking for carriers of the Asp40 allele (A/G, G/G) versus individuals carrying the Asn40 allele (A/A). The positive treatment effect was confined to patients who carried at least one G allele. This finding has been replicated several times (Anton 2008) but remains somewhat controversial due to negative studies (Gelernter et al. 2007).

19.2.3 Acamprosate

Acamprosate, a calcium-bis-acetylhomotaurinat, was first discovered and tested in France (Lhuintre et al. 1985; Mann 2004). The results of several clinical studies led to an approval in most European countries in the mid-1990s. The approval in the USA followed about a decade later.

19.2.3.1 Pharmacology

Acamprosate is the calcium salt of N-acetyl homotaurine, a small, highly flexible molecule with similarities to many amino acids, most notably glutamate, gamma-aminobutyric acid, aspartate, glycine, and taurine (Spanagel and Zieglgänsberger 1997; Spanagel and Kiefer 2008). Its mechanism of action seems to be linked to

a high activity of the glutamatergic system in alcoholics. Acamprosate binds to NMDA-receptors and thus dampens the glutamate mediated excitability (Spanagel and Mann 2005). There are some reports about a binding of acamprosate to the polyamine site of the NMDA receptor as well as binding to the mGluR5 receptor (Harris et al. 2002). It could be shown that a blockade of the mGluR5-receptor reduced the self-administration of alcohol in free-choice paradigms in animal models (Spanagel and Mann 2005). Although most recent work has focused on the glutamatergic system, homotaurine is a known GABA(A) receptor agonist, and studies on neuronal networks in vivo suggest that acamprosate may have differential effects on glutamate/NMDA receptors at low concentrations, with effects on GABA(A) receptors at higher concentrations (Pierrefiche et al. 2004). Some data suggest that acamprosate dampens alcohol-induced dopamine release (Cowen et al. 2005). The same could be true in conditioned withdrawal situations. This would mean that acamprosate also acts via a blockade of the reinforcing effect of alcohol (for a more exhaustive discussion of acamprosate's potential mechanisms of action including its neuroprotective effects, see de Witte et al. (2005) and Mann et al. (2008).

19.2.3.2 Indications and Contraindications

Acamprosate is approved for the treatment of alcohol dependence. It is supposed to be prescribed for the maintenance of an already established state of abstinence. Contraindications are pregnancy and lactation as well as renal insufficiency with serum creatinine levels of more than 120 µmol/l.

19.2.3.3 Dosage and Undesired Effects

The daily dosage of acamprosate is 1996 mg (three times two tablets). Since it takes several days until clinically meaningful brain concentrations are established, the treatment should begin as soon as possible. Acamprosate does not interact with other medications and does not influence alcohol toxicity. Its main side effects are diarrhea and other gastrointestinal symptoms as well as headache and pruritus.

19.2.3.4 Efficacy

There have been a large number of randomized controlled trials worldwide testing acamprosate against placebo (Kiefer and Mann 2010). The majority showed a significant benefit of acamprosate. This is corroborated by Cochrane analyses, the latest of which was published in 2012 (Rösner et al. 2010a, b). However, there were several negative studies as well such as the large COMBINE study in the USA (Anton et al. 2006) and more recently by Mann et al. (2013). Based on its potential mechanism of action described above (dampening of a hyper-glutamatergic state) it was speculated that acamprosate could be more beneficial in severely affected patients who are more likely to suffer from an upregulated glutamate system (Spanagel and Kiefer 2008). Our own study with a head-to-head comparison of two cohorts of patients who differed in severity measures did not support this assumption (Mann et al. 2013). Another idea according to which acamprosate

would be more beneficial to individuals who relapse for the negative reinforcing effect of alcohol (Verheul et al. 1999; Mann et al. 2009; Heilig et al. 2011) still awaits empirical support. The first studies aiming to associate acamprosate's efficacy with genetic markers suggest an involvement of a single-nucleotide polymorphism located in the *GATA binding protein 4* (*GATA4*) gene (Kiefer et al. 2011). *GATA4* represents a factor regulating the transcription of ANP and showed an association with alcohol dependence in two independent genome-wide association studies on alcohol dependence (Treutlein et al. 2009; Edenberg et al. 2010).

19.2.4 Nalmefene

Nalmefene is the most recent medication approved for use in alcohol dependence. It was approved by the European Medicines Agency in 2012 for a reduction of heavy drinking days and/or total alcohol consumption.

19.2.4.1 Pharmacology

Nalmefene is a selective opioid ligand with an equally high affinity to the μ- and κ-receptors and medium affinity to the δ-receptor. It acts as an antagonist at the μ- and δ-receptors, but different from naltrexone, it is a co-agonist at the κ-receptor (Bart et al. 2005). Studies in rodents seem to show that the difference compared with naltrexone concerning the action at the κ-receptor might be of relevance lending the drug higher potency in animals with more severe dependence (Walker et al. 2011). However, this finding needs to be replicated in humans.

Nalmefene has several metabolites which have much less affinity to the μ-receptors than the parent substance. Only nalmefene 3-O-sulfate contributes to the pharmacological effect, but this metabolite is only present in low concentrations. Nalmefene has a plasma half-life of 10–12 h. Blockade of brain receptors with nalmefene lasts between 48 and 72 h.

The mechanism of action is mainly based on its antagonistic properties at the μ-receptor. This counteracts the reinforcement driven by an alcohol-triggered mesolimbic dopamine release which is facilitated by the release of ß-endorphins. In studies with animal models, an additional effect based on nalmefene's role as a partial κ-receptor agonist (Walker et al. 2011) was observed. This is currently being investigated in humans.

19.2.4.2 Indications and Contraindications

The official indication for nalmefene is to reduce alcohol consumption (number of heavy drinking days, total alcohol consumption) in alcohol-dependent patients who have a high drinking level according to the World Health Organization (WHO 2000: men >60 g/day and women >40 g/day) and continue to have this level 2 weeks after the initial assessment. It is important to ensure that patients have not recently consumed opioids either as pain medication or illegally.

19.2.4.3 Dosage and Undesired Effects

The dosage per day is 20 mg, but nalmefene can be taken as needed. Dizziness, nausea, and insomnia are the most prevalent side effects. In the recent clinical trials, these were mild to moderate and mostly transient.

19.2.4.4 Efficacy

Several earlier studies indicated its efficacy in reducing consumption in alcohol-dependent patients (Mason et al. 1999; Karhuvaara et al. 2007). One study did not show a significant effect (Anton et al. 2004). Recently three large-scale phase III studies were conducted in Europe which showed efficacy over placebo in reducing heavy drinking days and total alcohol consumption; all three studies are published (Mann et al. 2013; Gual et al. 2013; van den Brink et al. 2013).

19.2.5 Topiramate

This medication is approved for the treatment of epilepsy. Its use in alcoholism has been tested because of indications that it reduces the reinforcing effects of alcohol and inhibits glutamatergic pathways in the corticomesolimbic system (Johnson 2005; White et al. 2004). A first positive single-site trial (Johnson et al. 2003) was followed by a larger multisite trial (Johnson et al. 2007). This latter showed a significant effect over placebo in reducing alcohol consumption. Patients did not have to be abstinent to participate which was different from many other studies referred to in this chapter (with the exception of the nalmefene trials, see above). The effect size was considerable, but undesired effects were as important as expected. Therefore, the medication had to be carefully titrated from week 0 to week 5. Undesired effects were paresthesia, headache, taste perversion, fatigue, and difficulty with concentration and memory. A smaller and more recent study did not show a significant effect (Likhitsathian et al. 2013). However, as expected the first meta-analysis comes to a positive overall effect of the drug (Arbaizar et al. 2010). In conclusion, off-label use may be worth trying but only with a titration of the dose and under very careful consideration and monitoring of these side effects (Aubin and Daeppen 2013).

19.2.6 Baclofen

Baclofen acts as an agonist at the B subunit of GABA receptor (GABA-B). Since GABA neurotransmission is known to be involved in the regulation of anxiety as a common symptom in patients being treated for alcohol withdrawal and alcohol dependence, baclofen was repeatedly tested in alcohol-dependent subjects (Addolorato and Leggio 2010). Recently, Brennan et al. (2013) assessed the benefit of baclofen for alcohol dependence in a review of the literature based on randomized controlled trials and case series. Although primary outcomes

differed between trials, patients treated with baclofen (30 mg) experienced higher rates of abstinence from alcohol than those taking placebo in the majority of case series and two of the randomized controlled trials (Addolorato et al. 2002, 2007). Data suggest that baclofen was safe in patients with alcohol dependence, including those with moderate to severe liver cirrhosis and may provide beneficial anxiolytic effects. However, the largest available randomized controlled trial by Garbutt et al. (2010) failed to show a benefit for 30 mg baclofen in assessing the efficacy and safety in terms of weekly heavy drinking days and percentage of abstinent days or for the secondary outcomes of craving, for example, depression. Again, baclofen was well tolerated with no significant reported adverse events.

Taken together, positive effects from using baclofen for the treatment of alcohol dependence can be surmised; however, the small number of studies currently does not allow a final conclusion. Larger trials that include higher dosages of baclofen (up to 270 mg daily) are currently ongoing.

19.2.7 Combining Anticraving Medications

There were a number of attempts to combine anticraving medications. The most important maybe were testing acamprosate plus naltrexone versus placebo or versus each single medication. While a first combination study (Kiefer et al. 2003) showed a benefit of the combination over placebo, an Australian study (Morley et al. 2006) and the COMBINE study (Anton et al. 2006) were not able replicate this finding. However, treatment groups differed markedly, and the role of detoxification and abstinence when starting medication as well as the role of the interaction with concomitant psychotherapy remain to be determined. At least two comparisons of acamprosate and/or naltrexone with disulfiram point to a higher efficacy of disulfiram (Besson et al. 1998; Laaksonen et al. 2008), but these studies had to be done single blind with all the limitations involved here. In conclusion, to date a combination of anticraving medications in uncomplicated alcoholics (no depression, etc.) does not seem overly convincing.

19.2.8 Additional Psychosocial Treatment

Some kind of counseling to ensure motivation and compliance was mandatory in almost all of the trials referred to in this chapter. In most cases this additional psychosocial treatment was manualized, and staff had to be trained to deliver it (Starosta et al. 2006; Pettinati et al. 2004; Johnson et al. 2007; Brüeck and Mann 2006). It varied in intensity with no hint that more is better (see COMBINE study, Anton et al. 2006). For clinical practice this means that some kind of counseling including advice and maybe motivational elements is recommended when these medications are prescribed to alcohol-dependent patients.

Contents

Abstract

Most ethanol taken into the body is converted to acetaldehyde by alcohol dehydrogenase (ADH), and then from acetaldehyde to acetic acid by aldehyde dehydrogenase (ALDH). However, polymorphisms exist in the genes of these enzymes. A super-active form of ADH1B and an inactive form of ALDH2 have preventive effects against alcoholism. In addition, several reports have suggested an association between polymorphisms in ADH1C, ADH4, and ALDH1A1 and alcoholism. Moderate to heavy drinkers with inactive ALDH2 and less-active ADH1B have a much higher risk of gastrointestinal tract cancer compared with those with active ALDH2 and super-active ADH1B. The ADH1B and ALDH2 polymorphisms are associated with various physical diseases such as liver disease, pancreatitis, and diabetes mellitus. Alcoholics with inactive ALDH2 have unique clinical characteristics; for example, they

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment: International Perspectives*, DOI 10.1007/978-88-470-5322-9_13,

develop alcoholism more slowly. Inactive ALDH2 is thought to cause high blood acetaldehyde concentrations and a painful flushing response, which suppresses alcohol consumption. However, the mechanism by which super-active ADH1B decreases alcohol consumption and the risk of alcoholism remains unclear. Identifying ADH1B and ALDH2 genotypes might be useful in the prevention and treatment of alcoholism.

20.1 Introduction

Most alcohol taken into the body is eliminated in the liver; first, ethanol is converted to acetaldehyde by alcohol dehydrogenase (ADH), and then acetaldehyde is converted to acetic acid by aldehyde dehydrogenase (ALDH). These enzymes have genetic polymorphisms that can alter the activity of alcohol and acetaldehyde metabolism. These polymorphisms are known to have a great effect on drinking behavior in healthy people as well as on the risk of alcohol dependence. Moreover, variations in metabolic enzymes are associated with the risk of physical diseases, including gastrointestinal tract cancer and liver cirrhosis, in moderate to heavy drinkers. Several studies have suggested that the clinical characteristics and disease course of alcohol dependence differ between the ADH and ALDH genotypes. In this chapter we review variations in alcohol-metabolizing enzymes and alcoholism.

20.2 Polymorphisms of Alcohol Metabolizing Enzymes and Alcoholism

20.2.1 Alcohol Dehydrogenase (ADH) and Alcoholism

More than 90 % of alcohol taken into the body is eliminated via the liver. Three mechanisms mediate the oxidation from ethanol to acetaldehyde: ADH, the microsomal ethanol oxidizing system (MEOS), and catalase. ADH works at low to high concentrations of alcohol and plays a major role in alcohol metabolism. MEOS works only at high concentrations of alcohol. Catalase is considered to have a minor effect on alcohol metabolism.

There are five classes of ADH (class I–V), encoded by seven genes (ADH1A, ADH1B, ADH1C, and ADH4–7). Class I ADH consists of homo- or heterodimers of α-, β-, and γ-subunits encoded by ADH1A, ADH1B, and ADH1C, respectively. Class I ADH enzymes have high affinity for ethanol and contribute the most to ethanol metabolism in the liver. Class II ADH, which is a homodimer of two π subunits encoded by the ADH4 gene, has a higher K_m (the Michaelis constant) for ethanol than class I ADH, but is still believed to play some role in ethanol elimination, although the effect seems weaker than that of class I ADH enzymes. Class III (ADH5) and class IV ADH (ADH6) seem to have little involvement in ethanol oxidation. Class V ADH (ADH7) is abundant in the stomach and considered to contribute during the early stage of alcohol metabolism in the stomach

mucosa. ADH genes cluster on chromosome 4q, and some whole-genome studies suggest a link between the chromosomal region containing the ADH genes and the risk of alcoholism (Long et al. 1998; Reich et al. 1998).

There are functional polymorphic loci in the ADH1B gene: ADH1B*1, ADH1B*2, and ADH1B*3. The ADH1B*2 allele has an arginine to histidine substitution at the 48th position (rs1229984), and the ADH1B*3 allele has an arginine to cysteine substitution at the 370th position (rs2066702). The ADH1B*1 allele is common in Caucasians but occurs in only a small portion of Asians; the allele frequency of ADH1*1 is more than 90 % in Caucasians and only 30 % in Asians. In contrast, the ADH1B*2 allele is more common in the Asian population, with an allele frequency of about 70 % in Asians and about 10 % in Caucasians (Goedde et al. 1992). ADH1B*3 is comparatively common (about 15 %) in populations of African ancestry.

In vitro studies have shown that ADH homodimers that consist of beta subunits encoded by the ADH1B*2 allele are "super-active" in ethanol oxidization, much more so than those encoded by the ADH1B*1 allele (Yoshida 1994). Similarly, homodimers composed of the subunit encoded by the ADH1B*3 allele are more active in ethanol oxidization than the ADH1B*1. The impact of ADH polymorphism on alcohol metabolism in humans is not clear. A few studies that measured blood alcohol and acetaldehyde concentrations after oral administration of ethanol in Japanese subjects showed that there was little difference in the alcohol elimination rate and peak blood acetaldehyde concentrations among the three ADH genotypes, that is, ADH1B*1/1, ADH1B*1/2, and ADH1B*2/2 (Mizoi et al. 1994). In contrast, a few studies with African-American subjects reported that individuals with the ADH1B*3 allele have a higher alcohol elimination rate than those without the ADH1B*3 allele (Thomasson et al. 1995). However, the oral administration challenge has methodological limitations in that it is difficult to evaluate the diffusion of ethanol into various organs. A study using the alcohol clamping method, in which ethanol was administered to Jewish subjects by intravenous infusion, showed a higher alcohol elimination rate in individuals with the ADH1B*2 allele than in those with the homozygous ADH1B*1 allele (Neumark et al. 2004). Birley et al. studied the association between alcohol elimination rate and single nucleotide polymorphisms (SNPs) in ADH genes clustering in chromosome 4 and reported that a number of SNPs revealed allelic associations with alcohol metabolism, but the effect of Arg48His polymorphism in the ADH1B gene was minimal (Birley et al. 2009).

The super-active form of ADH1B is known to have preventive effects against alcoholism. Genetic studies have shown the allele frequencies of ADH1B*2 are lower in alcoholics than in controls (Table 20.1). The frequencies of ADH alleles differ among ethnic groups, but differences in ADH allele frequency between alcoholics and controls have been confirmed in several ethnic groups (Higuchi et al. 2004). The frequency of the ADH1B*3 allele has also been reported to be significantly lower in alcoholic subjects than in controls, as was shown with the ADH1B*2 allele (Edenberg et al. 2006).

The mechanism by which the super-active form of ADH1B decreases the risk of alcoholism is unclear. One possible explanation is that higher activity of ADH1B*2

causes higher acetaldehyde production, which in turn leads to adverse effects that suppress drinking behavior. However, there is no evidence of an accumulation of acetaldehyde after alcohol intake in humans who have the ADH1B*2 allele.

The γ-subunit encoded by ADH1C has a polymorphisc loci at the 272 (rs1693482) and 350 (rs698) amino acid position in high linkage equilibrium: ADH1C*1 with 272Arg-350Ile and ADH1C*2 with 272Gln-350Val. The subunit encoded by ADH1C*2 allele has less activity during ethanol elimination. Several studies reported that the ADH1C*2 allele is associated with a higher risk of alcohol dependence than the ADH1C*1 allele (Zintzaras et al. 2006). It is suggested that this association might be due to the linkage equilibrium between ADH1C*1 and ADH1B*2; however, the association is detected even in a population that rarely has the ADH1B*2 variant (Montane-Jaime et al. 2006).

Some studies have also suggested that the variation of class II ADH encoded by the ADH4 gene is associated with alcohol dependence. An analysis of SNP markers at the ADH gene cluster on chromosome 4q22 found that the strongest association with alcohol dependence was detected at the ADH4 gene region (Edenberg et al. 2006), but the particular locus responsible for this association and its function are still unclear.

20.2.2 Aldehyde Dehydrogenase (ALDH) and Alcoholism

Most acetaldehyde produced from ethanol by ADH and other oxidizing enzymes is oxidized to acetic acid by ALDH in the liver. There are several ALDH family genes in humans, but ALDH1 and ALDH2 are the most important for acetaldehyde metabolism. It is considered that mitochondrial ALDH2 plays a major role in the

elimination of acetaldehyde, while cytosolic ALDH1A1 and mitochondrial ALDH1B1 are also involved in acetaldehyde metabolism. Both ALDH2 and ALDH1 are tetrameric enzymes composed by the subunits encoded by each allele.

The ALDH2 gene has polymorphic loci that alter the function of acetaldehyde metabolism. The ALDH2 gene is located at chromosome 12q24 and consists of 13 exons and 12 introns. This gene has a single-point mutation in the exon 12 coding region corresponding to a Glu to Lys amino acid substitution (rs671). This polymorphic site encodes active (Glu487, ALDH2*1) and inactive (Lys487, ALDH2*2) subunits of ALDH2. The isozyme containing the Lys487 subunit has no role in the elimination of acetaldehyde; therefore, it is supposed that the homozygote of the ALDH2*2 allele is not active in the elimination of acetaldehyde, and even the heterozygote is only minimally active. In fact, oral ethanol administration studies have shown that individuals with the ALDH2*2 allele have higher peak blood acetaldehyde concentrations after ethanol intake than those who have only the ALDH2*2 allele (Luu et al. 1995). This polymorphism is found only in East Asian populations.

Individuals whose genotype contains the ALDH2*2 allele suffer a "flushing" response upon drinking. The flushing response is an adverse effect of alcohol due to its high acetaldehyde concentration. The response includes unpleasant symptoms such as facial flushing, nausea, headache, palpitations, and rapid heartbeat. Individuals with homozygotes of the ALDH2*2 allele have a severe flushing response after a small amount of ethanol intake and even those with heterozygotes experience these symptoms when they drink large amounts of alcohol.

The ALDH2 polymorphism is associated with drinking behavior and furthers the risk of alcoholism. It is reported that the ALDH2*2 genotype has a strong influence on drinking patterns and alcohol consumption levels in healthy people (Higuchi et al. 1996). Moreover, genetic association studies have shown that the ALDH2*2 allele has a preventive effect on the risk of alcoholism (Higuchi et al. 2004). The allele frequencies in an East Asian population range from 0.24 to 0.34, whereas the allele frequencies in East Asian alcoholics range from 0.02 to 0.10 (Table 20.1). The mechanism of this effect is considered to be that the discomfort associated with the flushing response after alcohol consumption prevents individuals from drinking heavily.

Several genetic association studies between ALDH1A1 polymorphism and alcohol dependence have been conducted. The ALDH1A1 gene has two polymorphic loci in the promoter region – ALDH1A1*2, a 17-bp deletion, and ALDH1A1*3, a 3-bp insertion – and transfection assays suggest that these polymorphisms might be functional (Spence et al. 2003). Polymorphisms in the ALDH1A1 gene are reported to be associated with the risk of alcohol dependence and drinking behavior (Ehlers et al. 2004). A possible explanation for this association may be that the deficiency of ALDH1A1 activity causes flushing similar to that seen with inactive ALDH2.

20.2.3 ALDH2 and ADH1B Polymorphism and Cancer

Alcohol consumption is known to increase the risk of several types of cancer, including esophageal, pharyngeal, colorectal, and breast cancer. Many studies have

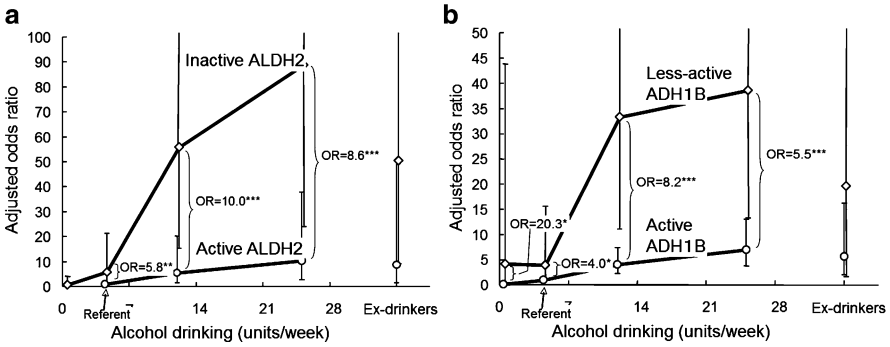

Fig. 20.1 Alcohol consumption and the risk for esophageal squamous cell carcinoma according to (**a**) ALDH2 genotype and (**b**) ADH1B genotype. The subjects were classified as never/rare drinkers; current drinkers who consumed 1–8.9 units/week (light drinkers; 1 unit = 22 g ethanol), 9–17.9 units/week (moderate drinkers), or 18+ units/week (heavy drinkers); or ex-drinkers. Odds ratios were adjusted for age, frequency of drinking strong alcoholic beverages straight, pack-years of smoking, frequency of intake of green and yellow vegetables, and frequency of fruit intake. The *vertical lines* indicate the 95% confidence interval. *$p<0.05$, **$p<0.01$, and ***$p<0.001$ (Reprinted from Yokoyama et al. 2010)

shown that ALDH2 deficiency increases the carcinogenic effect of alcohol in moderate to heavy drinkers (Yokoyama et al. 2010). Figure 20.1a shows the relation between the risk of esophageal squamous cell carcinoma and the amount of alcohol consumption in the individuals with active ALDH2 (ALDH2*1/*1) and inactive ALDH2 (ALDH2*1/*2). A case-control study of Japanese esophageal squamous cell carcinoma patients and controls demonstrated that moderate drinkers (198–365 g ethanol/week) with inactive ALDH2 had a 55.8-fold greater risk of this cancer than never/rare drinkers (<22 g ethanol/week) and that risk far exceeded the odds ratio of 10.4 of heavy drinkers (≥396 g ethanol/week) seen in the active ALDH2 group (Yokoyama et al. 2002). Similarly, a meta-analysis reported a higher risk of head and neck cancer, including oral, pharyngeal, and larynx cancer, in the inactive ALDH2 group than the active ALDH2 group among moderate (odds ratio: 1.68) and heavy drinkers (odds ratio: 3.57) (Boccia et al. 2009). The association between ALDH2 and esophageal cancer is considered to be due to the carcinogenicity of acetaldehyde. The high acetaldehyde concentration in the esophagus of individuals due to the lack of ALDH2 activity causes DNA damage and further carcinogenesis.

The ADH1B polymorphism is also associated with the risk of esophageal cancer. Individuals with the less-active form of ADH1B have a higher risk of esophageal and oropharyngeal cancer compared with those who with super-active ADH1B (Fig. 20.1b). Unlike ALDH2, the association between ADH1B and esophageal cancer seems unclear, because there is little evidence that the ADH1B polymorphism affects acetaldehyde concentration. One possible explanation might be that ethanol and acetaldehyde remain at higher levels in the blood and saliva for longer periods in individuals with less-active ADH1B than in those with super-active ADH1B.

20.2.4 ADH1B and ALDH2 Polymorphism and Physical Diseases

The ADH1B and ALDH2 polymorphism are associated with various physical diseases such as liver disease, pancreatitis, and diabetes mellitus. A recent large survey of Japanese alcoholic men demonstrated that the age-adjusted odds ratio for liver cirrhosis, chronic calcific pancreatitis, and diabetes mellitus was higher in alcoholics with super-active ADH1B or active ALDH2 than in those with less-active ADH1B or inactive ALDH2 (Yokoyama et al. 2013). Moreover, the active form of ALDH2 was associated with hypertension. A meta-analysis of East Asian case-control studies showed the same results; that is, less-active ADH1B and active ALDH2 are associated with a high incidence of liver disease, cirrhosis, and pancreatitis (Li et al. 2011, 2012). This association might be due to differences in alcohol consumption in subjects due to variations in ADH1B and ALDH2.

20.2.5 Clinical Characteristics of Alcoholics with Inactive ALDH2 and Super-Active ADH1B

The variations of ADH1B and ALDH2 have been reported to affect clinical characteristics and the disease course of alcohol dependence. A survey conducted in Japan reported that alcoholic men with inactive ALDH2 developed incidents and symptoms related to alcohol dependence more slowly than alcoholics with active ALDH2 (Murayama et al. 1998). The onset of every symptom was delayed 1–5 years in the inactive ALDH2 group compared with the active ALDH2 group. Interestingly, the onset of alcoholism was earlier in alcoholic women with inactive ALDH2 than those with active ALDH2, which contrasts with the findings seen in male alcoholics (Kimura et al. 2011). One of the reasons for these gender differences might be that the inactive ALDH2 group had psychiatric comorbid diseases more frequently than the active ALDH2 group. In the same way as with ALDH2, the development of alcohol dependence in alcoholic men with super-active ADH1B was delayed compared with those with less-active ADH1B (Eriksson et al. 2001).

There is a difference in personality profile between alcoholics with active and inactive ALDH2. A survey that assessed personality traits using Cloninger's Tridimensional Personality Questionnaire found that alcoholics with inactive ALDH2 revealed higher novelty-seeking and lower harm-avoidance scores compared with those with active ALDH2 (Kimura et al. 2009).

ADH1B polymorphism affects the severity of alcohol withdrawal syndrome. A study using Japanese subjects suggested the prevalence of alcohol withdrawal syndrome was higher in alcoholics with less-active ADH1B than in those with super-active ADH1B (Suwaki et al. 2001). Although there was no difference in alcohol consumption between the super-active and less-active ADH1B groups, the less-active ADH1B group had significantly higher blood alcohol concentrations; therefore, variation in alcohol metabolism may alter the severity of withdrawal symptoms. There is also a report that demonstrates the association between ADH4

polymorphism and the severity of delirium tremens (Gizer et al. 2011). In contrast, there is little evidence of the relation between ALDH2 polymorphism and the severity of alcohol withdrawal syndrome.

20.3 Conclusion

The variations of alcohol-metabolizing enzymes like ADH1B and ALDH2 are strong genetic determinants of drinking behavior and alcohol dependence. Because the polymorphisms of ADH1B and ALDH2 are associated with gastrointestinal tract carcinogenesis, other physical diseases, and clinical alcoholism, a better understanding of these polymorphisms may be useful in the prevention and treatment of alcohol-related problems as well as in the study of the genotypes of alcohol-metabolizing enzymes. One of the mechanisms underlying the effect of the variations of alcohol-metabolizing enzymes is considered to be elevated concentrations of acetaldehyde after drinking. However, many of the mechanisms remain unclear, especially in terms of ADH polymorphisms. Further study is necessary to understand the pathogenesis of alcohol dependence and related disorders.

Abstract

Chlordiazepoxide's sedative activity was serendipitously discovered by Sternbach in 1955 in Basel, Switzerland, and this first benzodiazepine (BZD) was introduced in 1960 for the treatment of anxiety and insomnia, followed shortly by diazepam in 1963. Given their lower toxicity, BZDs soon replaced barbiturates and other hypnotic drugs, and they became widely prescribed. Although generally considered effective and safe for short-term use for a wide range of conditions, the long-term use of BZDs is much more controversial as they lose efficacy and have been associated with adverse reactions. Problems associated with long-term use include rebound of the symptoms for which they were prescribed, alteration of sleep architecture with loss of sleep efficiency, nightmares, agitation, anterograde amnesia leading to cognitive impairment, confusion, depression, psychomotor compromise with increased risk of falls and motor vehicle accidents, withdrawal symptoms upon discontinuation, and risk of dependence and abuse in special populations. In the late 1980s and early 1990s, a new group of $GABA_A$ receptor agonists at the benzodiazepine receptor site, the Z-drugs, was introduced for the treatment of insomnia, the most common being zaleplon, zolpidem, zopiclone, and its s-enantiomer eszopiclone. Chemically distinct from the benzodiazepine group, they have been promoted to be safer than traditional BZDs and gained wide acceptance with the public and practitioners. However, given their site of action at the benzodiazepine site of the $GABA_AR$, complications are expected to be similar. In fact, the FDA, on May 14, 2013, released a safety announcement recommending a dose reduction for zolpidem extended release as well as a warning not to operate a vehicle or machinery requiring complete mental alertness on the day following the use of zolpidem due to residual psychomotor impairment. Next day sedation, physical dependence and withdrawal, cognitive and psychomotor problems are found in patients receiving Z-drugs. Abuse of the Z-drugs is on the increase and studies suggest that Z-drugs may also increase the risk of depression.

Clinicians prescribing sedatives should ensure short-term use to maximize benefit while minimizing misuse and diversion. They can play a critical role in identifying patients at risk to misuse or divert prescription drugs. Several studies demonstrate that BZD discontinuation in patients with long-term use and dependence is associated with improved quality of life. The management of the patients with BDZ abuse and/or dependence and interventions for BZD detoxification will be described.

21.1 Introduction

Benzodiazepine (BZD) and other BZD receptor agonists (so-called Z-drugs) remain among the most widely prescribed drugs, in spite of recommendations to prescribe SSRIs for long-term treatment of anxiety disorders and melatonin agonists for insomnia. Alprazolam, zolpidem, diazepam, clonazepam, and lorazepam are listed among the 200 most commonly prescribed medications in the United States (Tan et al. 2011). Alprazolam is the tenth most often prescribed medication in the United States, and the number of prescriptions increased from 41.4 million in 2007 to 49.1 million in 2011. Zolpidem follows as the 12th most prescribed drug with 34.5 million prescriptions in 2007 and increasing to 44.6 million prescriptions in 2011. The prevalence of regular BZD use is estimated between 2.2 % and 17.6 % in the general population (Donoghue and Lader 2010; Lader 2011), and 5.4 % of the population receive BZD agonist prescriptions for insomnia.

Public health problems associated with BZDs are mainly due to chronic prescriptions for legitimate symptoms, diversion to other persons than the patients for whom the prescription was initially ordered, and broader illegal trade for nonmedical use. The nonmedical use of prescription drugs has soared in the last 20 years and become a major public health threat. Due to the heterogeneity in individuals classified as "misusers" or "abusers" of prescription medications, it is difficult to determine the true magnitude and clinical significance of problems associated with any particular form of inappropriate medication use (Barrett et al. 2008). However, sedatives are among the medications most frequently used without prescription in the United States (Manchikanti 2006). In one study, 84 % of 3,234 benzodiazepine users identified in a study of 15 general practices were still using them 8 months later, and in the 1996 Australian National Health Survey, 58 % of the 359,300 benzodiazepine users had been taking them for at least 6 months (Parr et al. 2009).

Although misuse and abuse of BZDs can be found at any age, they disproportionately impact vulnerable populations, including the elderly, adolescents and young adults, pregnant women, individuals subject to sexual victimization or dating violence, those with a history of mental illness, and those with a history of substance abuse disorders. BZD misuse is among the most widespread forms of adolescent prescription drug misuse. In population-based national surveys, 9.3 % and 9.5 % of 12th grade students report lifetime sedative and anxiolytic use for recreational purpose (Johnston et al. 2009). In European countries, an average of 5.6 % of adolescents had used tranquilizers/sedatives with prevalences ranging from 1.5 % in Ukraine and the United Kingdom to about 13 % in Lithuania and France. In Brazil, adolescents have a 5 % lifetime use of sedatives or tranquilizers; females and students attending private schools are at increased risks of BZD use (Opaleye et al. 2013).

Long-term use of BZDs is prevalent among seniors in North America, Australia, and Europe (Curran et al. 2003). Approximately 9–54 % of elderly adults have used benzodiazepines in a given year (Llorente et al. 2000), and two thirds of the prescriptions were inappropriate.

People who are mentally or physically vulnerable are more likely to misuse these drugs. In 2009, at least 33 % of drug-related emergency department (ED) visits in

the United States were related to CNS depressants. ED visits involving benzodiazepines more than doubled between 2004 and 2009. This demonstrates an alarming increase in the abuse of BZDs and other non-BZD hypnotics. In addition, there is a significant increase in the involvement of alprazolam, clonazepam, and zolpidem in drug-related suicide cases since 2004, with a 148 % increase for zolpidem and a 105 % increase for alprazolam.

Substance abuse treatment programs and emergency departments' data indicate that the combination of benzodiazepines and narcotic pain reliever abuse is common as 80 % of people who abused benzodiazepines also misused other drugs, most commonly opioids. An estimated 3–41 % of alcoholics abused benzodiazepines. The rehabilitation of patients who also abuse BZDs in combination to other drugs is very challenging as they represent a treatment-resistant population.

The number of admissions to addiction treatment for abuse of BZDs nearly tripled in the United States between 1998 and 2008, compared to an 11 % increase in overall substance abuse admissions. The number of annual admissions for combined abuse of benzodiazepine and narcotic pain reliever increased by 570 % from 5,032 admissions in 2000 to 33,701 admissions in 2010. The majority of these admissions were non-Hispanic white males between 18 and 34 years of age. Most BZD abusers (95 %) reported abuse of another substance besides the BZD, with 82.1 % reporting primary abuse of another substance and 12.9 % reporting primary abuse of BZD (SAHMSA Treatment Episode Data Set 2011).

21.2 Pharmacology of Benzodiazepine and Other BZD-Site Agonists

BZDs and the Z-drugs are allosteric modulators on the gamma-aminobutyric A receptor ($GABA_AR$). Gamma-aminobutyric acid (GABA) is the most important inhibitory-type neurotransmitter and its actions are mediated by ionotropic ($GABA_A$)- and metabotropic ($GABA_B$)-type receptors, which are widely distributed throughout the central nervous system. The $GABA_AR$ are ligand-gated ion channels allowing influx of chloride (Cl-), causing hyperpolarization of the neuronal membrane, and inhibiting the firing of new action potentials. The $GABA_AR$ is a transmembrane receptor made of five subunits (2 α, 2 β, and 1 γ) binding GABA on the extracellular side of the receptor. It takes two GABA molecules to activate $GABA_AR$. Barbiturates bind between the γ and β_2 subunit, while BZD and the Z-drugs bind between α_1 and $\gamma 2$ interface. Barbiturates, benzodiazepines, and ethanol are $GABA_A$-positive allosteric modulators (i.e., their binding induces a neuronal response only in the presence of the actual agonist GABA), with two GABA molecules needed to open the chloride channel. BZDs and Z-drugs act as GABA potentiators by increasing the frequency with which the chlorine channel opens when two GABA molecules bind to $GABA_AR$. The increase in intracellular chloride concentration hyperpolarizes the neuron which becomes less excitable (Heikkinen et al. 2009; Tan et al. 2010).

It is through their ability to increase the potency of $GABA_AR$ that BZDs and Z-drugs produce a transient relaxation for patients with anxiety or insomnia disorders.

The shorter the onset of action after drug taking, the more efficient is the learning of the subjective effect associated to the drug. With BZDs of short onset of action (30 min), the individual learns that relaxation, stress relief, or sleep is obtained by taking a pill rather than by learning more effective practices of stress reduction and a more structured lifestyle with regular sleep hygiene. Moreover, attempts to discontinue medications after several weeks of regular intake are met with resurgence or rebound of the primary symptom of anxiety or insomnia, frustrating the attempts, triggering further drug seeking, and leading to automatic and compulsive drug-taking behaviors or the cycle of addiction. With chronic intake, tolerance sets in to the effect and duration of the desired effect of the drug, requiring increases in doses and frequency of doses. Tolerance to chronic benzodiazepine use appears to result from neuroadaptive processes involving both desensitization of inhibitory gamma-aminobutyric acid (GABA) receptors and sensitization of excitatory glutaminergic receptors (Ashton 2005).

When high-dose benzodiazepines or ethanol is abruptly discontinued, this "downregulated" state of inhibitory transmission is unmasked, leading to characteristic withdrawal symptoms of anxiety, insomnia, irritability, autonomic hyperactivity, sweats, and, possibly, seizures.

Benzodiazepine drugs form a homogenous class of medications made of a benzene ring and a diazepine ring. The differences between the different benzodiazepine drugs are in their side chains. On the other hand, the non-benzodiazepine drugs (Z-drugs) bind specifically to and activate the benzodiazepine site of $GABA_A$ receptors but they are not chemically related to benzodiazepines. They are principally classified into three groups of chemicals: (1) imidazopyridines (zolpidem, alpidem, necopidem, saripidem), (2) pyrazolopyrimidines (zaleplon, divaplon, fasplon, indiplon, loredipIon, ociplon, panadiplon, taniplon), and (3) cyclopyrrolones (eszopiclone, zopiclone, pagoclone, pazinaclone, suproclone, suriclone). Given their specific binding and allosteric modulation of $GABA_A$, these drugs have similar long-term negative effects to benzodiazepines including adverse cognitive (amnesia) and psychomotor effects, compromise in balance, standing steadiness, night falls, and motor incoordination leading to driving impairments. Due to their heterogeneous chemical classes, routine toxicology screens for drugs of abuse do not include the Z-drugs sedatives, so that the extent of their impact on emergency room visits and other societal costs remain underreported. In clinical trials, these sedative hypnotics were found to more than double the risk of depression compared to the groups taking placebo. Consequently, the long-term use of sedative hypnotic drugs increase the suicide risk as well as overall mortality risk (partially due to increase in risks of cancer and infections). The Z-drugs have similar risks of rebound and withdrawal effects as benzodiazepine drugs.

21.3 Clinical Uses of BZDs and Z-Drugs

In this section, we are first reviewing accepted indications for BZDs. BZDs and other BZD-site agonists are indicated for short-term use and at the lowest effective dose for these indications.

Indications include panic disorders and phobias preventing specific functions or procedures (such as flying in an airplane, undergoing an MRI for patients with claustrophobia). They are also indicated for short-term management of anxiety disorders, such as caused by a sudden stressor such as grief, and the short-term management of insomnia associated with alcohol withdrawal, withdrawal from sedatives with short half-lives, emergency intervention for grand mal seizures, and muscle relaxant of severe muscle spasms. They are used in the treatment of acute paranoia or other psychotic state induced by cocaine or other drug toxicity, in short-term intervention of psychiatric emergencies accompanied by psychosis or mania, and to induce sedation before the onset of action of lithium or other antipsychotic medications (neuroleptics). They are also used for premedication to relieve anxiety of an upcoming surgical procedure or dental intervention, in anesthesia induction, sedation for procedural medical interventions, and sedation in intensive care (to facilitate mechanical ventilation and/or sedate patients in distress).

21.4 Pharmacokinetic

BZDs are well absorbed by the gastrointestinal tract after oral administration. After intravenous administration, BZDs quickly distribute to the brain and central nervous system. Only midazolam has reliable absorption after intramuscular administration. The main difference between BZDs relates to the time to peak effect (onset of action) and duration of action, depending on the metabolic half-life and the presence or not of psychoactive metabolites. BZD characteristics predicting the severity of the benzodiazepine withdrawal syndrome are higher dose, longer duration of treatment, shorter half-life, and more rapid taper. Clinical variables of BZD withdrawal severity include severity of preexisting anxiety and/or depression, personality disorder, panic disorder, and history of or concurrent substance use disorder. Withdrawal from rapidly absorbed, short-acting drugs with no active metabolites (e.g., alprazolam, triazolam) can start within hours of the last dose; withdrawal from substances with long-acting metabolites (e.g., diazepam) may have gradual onset with a peak within 1–10 days after the last dose.

21.5 Problems Related to the Long-Term Use of BZDs

The long-term clinical use of BZDs is much more controversial. Advocates of long-term management with BZDs quote patients' acceptability and widespread belief of safety and efficacy. However, several academic and public health policies strongly advise against long-term use of BZDs for PTSD, generalized anxiety, insomnia, depression, and panic attacks due to the lack of evidence of demonstrated long-term efficacy in the treatment of these conditions and their problematic effects (Table 21.1).

Sedatives adversely affect cognitive (memory, attention) and psychomotor functioning impacting daily activities. BZD-associated impairments in reaction time,

Table 21.1 Potential problems related with the use of BZDS

Potential side-effects of BZDs
Sedation, residual effects during day-time
Cognitive effects, especially in mild cognitive impairment
Amnesia, not remembering activities
Impulsivity associated with poor working memory
Impairment – implications while driving, operating machinery
Potentiation of respiratory depression from other medications (opioids)
Paradoxical reaction due to desinhibition
Reinforcement of avoidance, inflexibility: prevents coping/learning of adaptive response
Problems associated with long-term use of BZDs or Z-drugs
Impairment, psychomotor deficits (cerebellar: unsteadiness, nystagmus, propensity to falls, poor coordination, slurred speech, disorientation). Increase risk of falls with injuries in elderly (falls at night with head injuries, hip fractures, etc.)
Decrease in self-regulation and awareness (metacognition): decrease in ability to perform simple repetitive tasks (decrease in skills, including driving skills), increase in reaction time, decrease in accuracy of performance, decrease in performance in tasks of attention
Decrease in cognition: decrease in memory consolidation and learning (anterograde amnesia). The memory impairment increases with tasks of increased complexity
Acceleration of cognitive decline in elderly or potential for pseudodementia in elderly or other vulnerable patients. Cognitive failures
Increase in the risk of motor vehicle accidents (60–80 % more accidents in drivers on BZDs or Z-drugs)
Behavioral problems with forensic implications. Problems of disinhibition in persons with borderline personality disorders or impulse disorders. This can lead to paradoxical increase in anxiety, hyperactivity, and aggressive impulses. The person may not have any recollection of the incident (fugue states)

attention, and visuospatial skills increase vulnerability for motor vehicle accidents. There is also a clear association between the use of BZDs in aged people and increased risk of falls and fractures and of traffic accidents (Thomas 1998; Gunja 2013). Psychomotor impairment, falls, and hip fractures are more likely to occur with Z-drugs that have longer half-lives.

Among war veterans, potential adverse consequences are BZD misuse and/or addiction, especially among those patients with an already established substance use disorder. Disinhibition has been described in patients with traumatic brain injury; these two conditions are common and often underdiagnosed among veterans with PTSD returning from Iraq and Afghanistan. In addition, it is becoming apparent that BZDs have the potential to reduce the effectiveness of exposure-based psychotherapy, which is considered a pillar in the treatment of veterans with PTSD and requires effective short-term memory, as the mechanism underlying effectiveness is a change in memory (Lund et al. 2013).

Evidence-based guidelines insist on BZD's liability for physical dependence which may occur even with appropriate therapeutic dose but for longer period of time. The risk for negative effects such as abuse and dependence is minimized when they are prescribed for short term (e.g., 2–4 weeks for intense grief reaction).

As stated earlier, because of rebound, i.e., exacerbation of symptoms for which the medications were taken initially, a large proportion of BZD recipients become chronic users, with ensuing development of tolerance and the potential for physical and psychological dependence. The dilemma is the difficulty to prevent what is anticipated for short-term therapy to become long-term misuse with no established evidence of long-term benefit and the liability of dependence and negative psychomotor and cognitive side effects (Lader 2011).

21.6 BZDs Misuse, Abuse, and Dependence

Three different populations of patients with BZD dependence can be described (Lader 2011), and this classification is useful to guide the type of intervention:

- Those who are prescribed benzodiazepine at constant dose for more than 3 months, i.e., they are at risk of negative cognitive consequences from BZDs. These may include patients on multiple psychoactive prescription medications for chronic pains (iatrogenic dependence).
- Those who are prescribed BZDs for more than 3 months and are progressively increasing their doses.
- Those who use BZDs both from legal and illegal sources in a pattern reminiscent of polysubstance abuse.

Many people who take prescription sedatives take them responsibly and benefit from their use, especially if they are taken for short term (less than 6 weeks). Longer duration or high dose of benzodiazepine use, however, increases the odds for developing benzodiazepine dependence (Kan et al. 2004). Also, women and those who have preexisting cognitive impairment (elderly), panic disorders, or suicidal ideations have elevated odds of developing dependence on benzodiazepines (Voyer et al. 2009). If BZD doses are voluntarily or involuntarily reduced or stopped, withdrawal symptoms or resurgence of the initial symptom is likely to occur. This type of physiological dependence is the most common and it is believed that several millions worldwide have this type of BZD dependence.

21.7 Recreational BZD Abuse

Intentional abusers actively seek the sedatives because of their rewarding psychoactive properties. Sedatives can be abused due to their ability to relax anxious feelings and remove inhibitions (such as during social encounters), similar to the euphoric feelings induced by alcohol or illegal drugs (Yu 2012).

The drugs are purchased from legal or illegal sources for recreational use or obtained from friends or family members who have prescriptions. Other sources include illicit sales of diverted supplies or the Internet. The modern everywhere technology, such as the easy access to Internet, plays a significant role in this regard by opening up a new source for access to drugs, explaining a portion of the increase in their abuse. Illegal online pharmacies sell controlled substances, including

sedatives, over the Internet without regard for local laws, without a valid prescription, and without medical guidance and supervision (Forman et al. 2006). Direct marketing of medications to patients through media (especially television) may be related to changed attitudes toward ingestion of psychotherapeutic agents.

Misuse of psychoactive medications, particularly in the case of individuals with prescribed BZDs, may not only stem from the individual factors but from a lack of quality health-care service. The fact that these drugs are considered "medication" and are endorsed by physicians may give a false sense of safety. Health-care providers may inadvertently play a role in misuse behaviors by failing to recognize a patient's potential for developing a substance abuse/dependence disorder, misdiagnosing the patient, overprescribing the medication, or just due to time pressure on the physician: it takes more time to refuse a patient's request and teach alternative behavioral strategies for anxiety or insomnia than to agree and write the requested prescription.

Increased "medicalization" and pharmacotherapeutic management of common symptoms such as insomnia and subsequent increase in prescription of BZDs or Z-drugs have also led to more addiction and abuse problems. More worrisome, and by no means rare, are those who are on chronic prescription of opiates and sedatives for chronic pain, given the increased potential for respiratory depression and cardiac arrest especially with comorbid diagnoses of COPD or obstructive sleep apnea.

Finally, while doctor shoppers, physicians, and the Internet receive much of the attention regarding diversion, data suggest that there are numerous active street markets involving patients, Medicaid recipients, and pharmacies as well. Diversion can occur in many ways, including the illegal sale of prescriptions by physicians and those who are referred to on the street as "loose" pharmacists; "doctor shopping" by individuals who visit numerous physicians to obtain multiple prescriptions; theft, forgery, or alteration of prescriptions by health-care workers and patients; robberies and thefts from manufacturers, distributors, and pharmacies; and thefts of institutional drug supplies. Many of these individuals have conditions that have been appropriately diagnosed and addressed with a proper course of treatment but are selling their prescription drugs for profit or exchanging them for illicit drugs. In addition, there are many individuals posing as legitimate patients for the purposes of scamming physicians and pharmacists or otherwise defrauding the system (Inciardi et al. 2007).

21.8 BZD Withdrawal Syndrome

Withdrawal symptoms can sometimes occur after as little as 4 weeks of daily use of BZDs but occur in about half of the patients treated daily for more than 4 months (el-Guebaly et al. 2010), and may last for 6–8 weeks. In some protracted cases, it can last for months. However, many patients will report more restorative sleep and improved quality of life after a few weeks off the medications, due to improved cognitive and psychomotor functioning (Salzman et al. 1992).

The onset of withdrawal symptoms produces subjective "need" for BZDs (or craving) prolonging their use, often for years after the initial indication for the drug has passed. Many long-term users, aware that the drugs are no longer effective and are causing adverse effects, try to stop but are unsuccessful because of the emergence of withdrawal symptoms (Ashton 2005).

The symptoms after discontinuation of BZDs have been described in different ways:

Recurrence or relapse refers to reemergence of symptoms that existed prior to the treatment but at the same intensity.

Rebound refers to symptoms similar to the symptoms the patient had before using BZDs but experienced with increased intensity.

Withdrawal refers to a cluster of symptomatology due to autonomic hyperactivity. This is believed to be a hyperexcitability in the same physiological system that was initially modified by the drug, which meant to counteract the effects of the drug in an attempt to maintain homeostasis.

As stated before, the symptoms of BZD withdrawal are a function of their pharmacokinetics, duration of use, the underlying diagnoses, or individual personality. Withdrawal symptoms include anxiety; irritability; agitation; tremulousness; increased sensory perception such as photophobia, hyperosmia, or altered taste; hyperacusis; paresthesia; and hypersensitivity to touch. Patients also can have allodynia, pain, sore eyes, myalgia, insomnia, fatigue, lethargy, lightheadedness, dizziness, tinnitus, depersonalization, derealization, poor concentration, poor memory, headaches, depressed mood, palpitations, nightmares, diaphoresis, muscle twitching, muscle ache, memory and concentration impairments, dizziness, feeling faint, and gastrointestinal symptoms such as anorexia and nausea (Peturson 1994). Occasionally, more severe symptoms such as seizures, psychotic reactions, or delirium and rarely death from complication of seizure can occur. Kindling is a neurologic sensitization phenomenon resulting from repeated sedative withdrawal episodes and leading to more severe withdrawal intensity upon successive episodes, including an increased propensity to seizures.

21.9 BZD Abuse in Specific Populations

While in the past sedative medications traditionally have been prescribed to women and older age groups, the growing problem of prescription drug abuse in the beginning of the twenty-first century affects individuals of both genders and of all ages, including middle school-aged children (ages 12–16) worldwide. For example, in Canada, a national health survey showed the use of sedatives doubled between 1994 and 2003 with particular increase among men, individuals under 60 years of age, and among obese men and underweight women (Vozoris and Leung 2011). Usually, high prevalences among specific populations reflect the presence of underlying conditions that can explain in part the known relationship between sedatives and morbidity/mortality. This is the case of the greater odds of sedative medication use found among morbidly obese men complicating obesity-related

sleep disruption (obstructive sleep apnea) and the associated cardiac mortality risk that has been found to be increased in the presence of BZDs. The same is true with chronic obstructive pulmonary disease, when the anxiety triggered by shortness of breath is treated with BZDs.

21.10 Adolescents and Young Adults

The lifetime prevalence of anxiety ranges between 15 % and 20 % and the median age of onset is 11 years of age, constituting one of the most common and earliest type of psychopathology among children and adolescents (Mohr and Schneider 2013). Anxiety disorders are found in 5–19 % of all children and adolescents, and in children younger than 12, prevalence ranges between 2.6 % and 5.2 %, with separation anxiety as the most common disorder (Costello et al. 2004; Ford et al. 2003). Children with an anxiety disorder are more likely to be engaged in drug abuse activities as young adults at follow-up (Beesdo et al. 2009).

Sleep disorders are also very common in pediatric populations, with as many as 17 % of adolescents having unrestorative sleep (Roberts et al. 2002). However, sleep problems among children often go unrecognized in general practice, in part because of parents underreporting of sleep problems in their children or adolescents. Awareness of the importance and potential consequences of sleep problems on academic performance, neurocognitive function, and daytime behavioral problems has to be emphasized (Blunden et al. 2004). Children and adolescents are frequently sleeping less than 9 hours at night, the recognized minimum amount of sleep required in this age group. Intrinsic contributors to inadequate sleep patterns in children and adolescents include developmental changes causing a shift in circadian rhythm during puberty, delayed sleep phase syndrome (7 % of adolescents), sleep-disordered breathing, and insomnia-type symptoms found in up to 34 % of adolescents. Extrinsic factors include early school start time and poor sleep habits (also called sleep hygiene) such as use of electronic devices near or during bedtime and caffeine consumption, especially problematic when undisclosed in soda or other foods (Tan et al. 2012). Anxiety, poor academic performance, behavioral problems, and sleep problems have been recognized as risk factors for substance use, abuse, and dependence.

The nonprescribed use of sedatives among adolescents and young adults is a cause of concern in many countries. Fast brain development during this life stage, especially the development of executive function and learning acquisition, implies that exposure to amnesia-inducing drugs may stunt development and result in devastating neurobiological changes and behavioral consequences such as missed educational milestones, increased impulsivity (inversely correlated with short-term memory), and school dropouts. Young people report using sedatives to relieve anxiety symptoms and to sleep, with high percentage of teenagers and many of their parents believing that prescription drugs, even taken nonmedically, are more safe than illegal drugs.

Uncharted societal changes exposing children and adolescents are increased exposure to direct-to-consumer advertisement of medications since 1992, rushed medical visits promoting fixing of problems via prescription while decreasing

patient–clinician interaction, increased media distractions, and increased time competition for numerous activities all potentially resulting in increased anxiety.

21.11 Elderly

Published guidelines advise against the use of benzodiazepines or Z-hypnotics (BZD-Z) in the elder. However, inappropriate use of BZDs and non-BZDs among this age group is widespread although the risk–benefit ratio is clearly greater than 1. Estimated prevalence rates of insomnia in older people is over 30 %, and studies report that a third to half of seniors in North America and the United Kingdom are prescribed either a Z-drug or benzodiazepine for sleep disturbance (Glass et al. 2005; Nubukpo and Clement 2013). These are concerning statistics given the risks of sedatives in this age group for adverse health consequences. Older adults experience high rates of illnesses and are exposed to numerous pharmacologic agents, decreased drug metabolism, and increased susceptibility to toxic effects and cognitive and motor impairment, including falls and injuries. These medications can interact with over-the-counter medicines and dietary supplements, consumed in significant quantities by seniors. Cognitive adverse events (memory loss, confusion, disorientation, pesudodementia), psychomotor-type adverse events (reports of dizziness, loss of balance, or falls), and morning impairment (residual morning sedation) can lead to accidents, including when operating vehicles. Patients over 65 are significantly less likely to stop BZDs than younger patients (Holden et al. 1994); however, drug dependence is often unrecognized among older adults.

21.12 Women

Women are a vulnerable population for BZD drug abuse. First, women are more likely than men to suffer from depression, anxiety, trauma, and victimization, all of which are also associated with substance abuse. Second, women at different ages report using drugs to cope with stressful situations in their lives. Third, studies suggest that women are significantly more likely than men to be prescribed medications with high abuse liability such as narcotics and anxiolytics and not rarely in combination and for long periods of time.

BZDs cross the placenta and have the potential to accumulate in the embryo/fetus and may consequently cause adverse problems (Iqbal et al. 2002). The general consensus is that BZDs have low teratogenic potential but may be associated with an increased risk of cleft palate. Current recommendations are that in order to minimize risk if BZDs are absolutely needed, they should be prescribed at the lowest effective dose for the shortest possible duration, avoiding use in the first trimester and avoiding poly-pharmacotherapy use (Dell'osso and Lader 2013). Pregnant women on BZDs are often tapered off their BZD treatment. However, there is a portion of BZD-dependent pregnant women who are unable to discontinue their BZDs in spite of knowing the associated risk of cleft palate and the potential harm of BZD on the developing brain.

Pregnant women substance users with BZD dependence are in general very impaired, emotionally challenged with frequent relapses and issues of noncompliance with treatment recommendations possibly due to underlying trust issues. BZDs should never be used for pregnant women with other addictive disorders as they increase impulsivity and prevent learning more adaptive coping skills. Moreover, when BZDs are continued into the late pregnancy, neonatal abstinence syndrome may occur in the baby and can be prolonged. This additional stressor at the start of life is not only detrimental to the baby, as her irritability may jeopardize bonding between the mother and child dyad, which may be very significant given the preexisting vulnerabilities of the mother. Alternative approaches to treating anxiety and stress during pregnancy are "desperately" needed, and more should be done to validate the usefulness of integrative approaches to improve self-regulation during pregnancy.

21.13 Polysubstance Users

The prevalence of benzodiazepine abuse reaches up to 50 % among opiate-dependent individuals, including those on agonist maintenance treatment. BZD use in opioid-dependent populations is a predictor of overdose, lethality, and poor treatment outcome including cocaine and other drug use, self-harm behaviors, and poor psychosocial functioning. Methadone fatalities include benzodiazepines in 75 % of cases as do almost all buprenorphine fatalities.

Benzodiazepines are frequently abused in combination with alcohol or other drugs (mainly opiates) to enhance the subjective reward of the primary substance, to offset their adverse effects (e.g., irritability induced by stimulants), or to alleviate withdrawal symptoms including insomnia due to a relative lack of access to the primary substance such as alcohol or opiates. The abuse of benzodiazepines in combination with other central nervous system depressants is particularly dangerous due to potentially fatal respiratory depression.

The rehabilitation literature demonstrates that among illegal drug users, those who also abuse benzodiazepine have worse outcome. This phenomenon could have several explanations: the concurrent dependence on BZDs and opioid pain relievers could lead to more severe withdrawal symptoms than opioid withdrawal alone, resulting in higher treatment attrition rates. More anxious patients are more averse or avoidant of discomfort and resistant to alternative treatment modalities (BZDs decrease flexibility). The negative impact of BZDs on memory and cognition prevents learning coping strategies indispensible to achieve abstinence.

21.14 Drug-Facilitated Rape

Ingestion of intoxicant during parties puts participants at risk for sexual assaults. Studies on the prevalence of drug-facilitated sexual assaults have been conducted in the United States. Of 1,179 urine samples from victims of sexual assault analyzed

over a 29-month period, alcohol was found in 41 %, followed by cannabinoids in 18.5 %, benzodiazepines in 8 %, and benzoylecgonine (cocaine metabolite) in 8 % (ElSohly and Salamone 1999).

A special case of BZD abuse is the surreptitious BZD administration to an unsuspecting victim by sexual predators. In addition to alcohol, the so-called date rape drugs most frequently used by rapists to sedate their victims are flunitrazepam (Rohypnol®), a fast-acting benzodiazepine, ketamine, and gamma hydroxybutyrate (GHB) and its congeners. Perpetrators choose these drugs because they act rapidly, produce disinhibition and relaxation of voluntary muscles, and cause the victim to have lasting anterograde amnesia for events that occurred under the influence of the drug. Many drugs associated with rape are given via alcohol, and alcoholic beverages potentiate the drug effects.

21.15 Treatment of BZD Dependence

The management of patients with BZD dependence includes three concurrent aspects: management of the acute withdrawal phase (Voshaar et al. 2006), developing strategies for addressing the underlying condition, as well as crisis management. Clinicians need to work closely with patients showing empathy in helping manage distress while providing menus of integrative or supportive therapies from which patients can choose from. Educational materials and tips regarding insomnia (sleep hygiene, sleep diary) and anxiety (cognitive behavioral programs, self-help materials, referrals to mindfulness resources, bibliographies) should be provided.

21.16 BZD Detoxification

For some long-term BZD user patients, minimal interventions such as brief consultation or a letter with information about risks of long-term use of BZDs and the recommendation for their discontinuation can be effective and do not produce adverse effects (Cormack et al. 1994; Heather et al. 2004).

The management of BZD withdrawal syndrome includes, either independently or in combination, (1) gradual tapering of the BZD, (2) switching to an equivalent dose of a long half-life BZD before gradual tapering of the latter (Lader et al. 2009), (3) the use of adjuvant medications, (4) treatment of the underlying conditions (i.e., SSRIs for anxiety) prior to detoxification and continuing these medications after BZD discontinuation (Rickels et al. 1990), and (5) non-pharmacologic treatments of underlying conditions (Table 21.4).

21.16.1 Gradual Tapering of the BZDs

The rate of BZD taper is different for each patient and needs to be individualized, but there are some common recommendations depending on the type of BZD

Table 21.2 Benzodiazepines in equivalent doses of diazepam* and half-life elimination

Benzodiazepine	Equivalent dosage (mg) of *diazepam 10 mg is approximately equivalent to	Half-life elimination (h)
Alprazolam	0.5 mg	6–12
Chlordiazepoxide	25 mg	5–30
Clonazepam	0.5 mg	18–50
Diazepam	10 mg	20–100
Flunitrazepam	1 mg	18–26
Flurazepam	15–30	25–100
Loprazolam	1 mg	6–12
Lorazepam	1 mg	10–20
Lormetazepam	1 mg	10–12
Nitrazepam	10 mg	15–38
Oxazepam	20 mg	4–15
Temazepam	20 mg	8–22

Table 21.3 Z-drugs in equivalent doses of diazepam* and half-life elimination

Z-drugs	Equivalent dosage (mg) of *diazepam 5 mg is approximately equivalent to	Half-life elimination (h)
Zaleplon	10 mg	1–2
Zolpidem	10 mg	2–4
Zopiclone	7.5 mg	4–8
Eszopiclone		4–8

pattern of use/misuse/dependence. A common recommendation is a reduction by 10–15 % every 1–2 weeks, leaving some empowerment to the patient for decision-making. Individualizing treatment seems to result in better treatment retention. There is evidence that most patients will be able to complete taper in 6–8 weeks, although some patients may need more time, including up to a year (Ashton 2005).

21.16.2 Switching to an Equivalent Dose of a Long Half-Life BZD Before Tapering Withdrawal

For patients dependent on the more potent BZDs (lorazepam, clonazepam) or on those with short duration of action (alprazolam, triazolam, zaleplon, zolpidem), it is recommended to switch to a diazepam equivalent for a few days and then rapidly taper off diazepam. This ensures a smoother detoxification as the drug will continue to taper itself for another 3–4 weeks after it is discontinued (Tables 21.2 and 21.3). Dose equivalence to diazepam can also be found at http://www.benzo.org.uk/bzequiv.htm.

For heavy BZD-dependent polysubstance abusers, outpatient detoxification may have less chance of success due to the availability of BZD from illegal sources, and residential treatment may be necessary to complete the detoxification after

diazepam substitution and taper over 2–3 weeks. Especially in this group, the use of adjuvant antiepileptic medications is indicated (see below).

21.16.3 Adjuvant Medication Treatment to Decrease BZD Withdrawal Symptoms

Antiepileptic medications such as carbamazepine, its safer metabolite oxcarbazepine (Croissant et al. 2008), and valproic acid are useful adjunct medications for attenuating BZD withdrawal symptoms especially for those coming off higher BZD doses, such as more than 20 mg diazepam equivalent daily. The newer antiepileptic zonisamide, which acts as both GABA enhancer and glutamate inhibitor, should also be investigated as it was found superior to diazepam on symptoms of craving, withdrawal, and depression for alcohol withdrawal (Rubio et al. 2010). Other GABA medications have been evaluated for BZD detoxification such as pregabalin (Bobes et al. 2012) and gabapentin. However, all these antiepileptic medications should not be considered for long-term substitution to BZD because of their negative effects on cognition.

Propranolol, captodiamine, and buspirone were not found to be effective in facilitating BZD withdrawal. Inpatient detoxification with the BZD antagonist flumazenil has been described, although patients in this study were then switched to and discharged on the long-acting BZD clonazepam at high doses (2–6 mg), so that the procedure cannot be considered a detoxification from BZD although the authors report that 53 % of their patients were BZD-free at 6 months (Quaglio et al. 2012). A double-blind evaluation of the procedure without substitution with a BZD, possibly under the protective effect of a non-BZD antiepileptic medication, has to be undertaken before the procedure can be recommended. The use of flumazenil in the setting of BZD dependence should be advocated with caution due to the high risk of seizures and aspiration.

21.16.4 Pharmacologic Treatment of Underlying Conditions

It is important to treat any underlying condition before, during, and after BZD withdrawal treatment. SSRIs and other antidepressant with low stimulating potential (sertraline, paroxetine, citalopram, escitalopram, mirtazapine, trazodone) are recommended for anxiety disorders, especially with concurrent depressive symptoms. Melatonin is recommended for insomnia.

21.16.5 Non-pharmacologic Treatment of BZD Addiction

Maximizing the use of non-pharmacologic interventions is critically important, and different types of health-care providers can play a significant role in providing these psychosocial interventions. We are briefly reviewing non-pharmacologic

Table 21.4 Steps recommended for BDZ discontinuation after long-term use

1. Send a letter or have a conversation with the patient explaining the negative consequences of long-term use of BDZs. Explain the process of taper and the non-pharmacologic options to deal with the symptoms related to BDZ discontinuation and/or underlying problems
2. Change to longer-acting medication and taper over a period of 6–12 weeks
3. If step 2 fails or the patient has a severe dependence with risk of seizures, use a medication to suppress the withdrawal symptoms for several weeks before and after BDZ reduction
4. If step 3 fails or the patient is at risk for complications, use inpatient dose reduction of BDZ over a period of 1–3 weeks
5. Consider the need for psychiatric or hypnotic medication different than BDZ to treat underlying anxiety and/or insomnia
6. Refer for therapy (CBT, mindfulness-based therapy, support groups)

approaches to the treatment of anxiety and sleep disorders. Although the review of these strategies is beyond the scope of this chapter, clinicians will benefit their patients in developing familiarity with self-empowering strategies aimed at improving quality of life and health by reducing stress while minimizing risks associated with pharmacologic management.

Historically, psychotherapy for anxiety disorders (panic, generalized anxiety, social anxiety, phobias) was the first available treatment to provide relief for anxiety symptoms. The initial long-term dynamic therapy has been replaced by short-term intensive dynamic psychotherapy, cognitive behavioral therapy, and other interventions such as exposure therapy and mindfulness-based therapies.

There are several promising therapies that have been used recently to treat anxiety. Some of them are COPE (Creating Opportunities for Personal Empowerment) that is a brief-focused cognitive behavioral therapy-based intervention that can be delivered to teens in school settings using a group format. Adolescents who received this therapy reported significant decreases in depression and anxiety on the Beck Youth Inventory as well as increases in personal beliefs about managing negative emotions. Evaluations indicated that the group COPE intervention was a positive experience for the teens (Mazurek Melnyk et al. 2013) (Table 21.4).

A 12-session program of mindfulness-based stress reduction (MBSR) in seventh and eighth graders at a small school for low-income urban boys resulted in less anxiety, improved coping, and a possible attenuation of cortisol response to academic stress, when compared with Health Education participants (Sibinga et al. 2013).

Pathological worry is considered a central symptom of generalized anxiety disorder but can be seen in other types of anxiety (e.g., excessive worry over future panic attacks). For that reason, studies of interventions that reduce pathological worry are considered very important. Results from a meta-analysis performed by Covin et al. (2008) found that cognitive behavioral therapy (CBT) for GAD can be a highly effective treatment for reducing pathological worry, especially for younger adults. CBT was also effective for geriatric patients and the improvement was both for the short term and over time.

Avoidance is another cardinal feature in patients with anxiety disorders and is a maladaptive learned behavior that may temporarily relieve anxiety symptoms but actually perpetuates the anxiety often causing significant impairments in functioning. Avoidance of the uncomfortable symptoms of the withdrawal or rebound reactions during BZD tapering is a major difficulty in interrupting the vicious cycle of using BZDs to combat painful subjective states during the recovery from BZD misuse and dependence. To break this cycle, it is essential for individuals with co-occurring disorders to learn strategies to self-regulate anxiety symptoms as well as alternative coping strategies. The psychological support is required during and after the withdrawal because patients remain extremely vulnerable for several months after discontinuation. Cognitive behavioral therapies (CBTs) are among the most efficacious psychosocial treatments that can be used to treat individuals with anxiety disorders and SUDs. Action commitment therapy (ACT, Blackledge and Hayes 2001) has also found wide acceptance as effective treatment for avoidance and anxiety disorders.

CBT demonstrated efficacy in SUD across diverse populations (Carroll and Schottenfeld 1997). The CB model of relapse is based on linear progression of responses in high-risk situations. It believes that increase in self-efficacy leads to increased coping with anxiety and stress and less substance use. Combination of CBT with contingency management and relapse prevention combined with pharmacotherapy are among the most successful treatments (Epstein et al. 2003). Acceptance commitment therapy (Blackledge and Hayes 2001) is a third-wave cognitive behavioral therapy intervention focusing on methods such as acceptance, mindfulness, cognitive defusion, decentering, and metaphors meant to reduce the impact of negative thoughts and feelings.

Although prolonged exposure therapy (Foa et al. 2007) has been deemed one of the treatments of choice for PTSD, there is limited research exploring its efficacy in substance-abusing populations because of the fear that exposure to trauma cues would precipitate relapse. Physical exercise may enhance sleep and contribute to an increased quality of life in older adults (Montgomery and Dennis 2002), and increased physical activity is favorably associated with restoring sleep (Lang et al. 2013). Cognitive behavioral therapy for insomnia is as effective for improving sleep quality while decreasing depression and improving mental health.

21.17 Prevention of BZD Abuse

21.17.1 Awareness of Professional Guidelines

Countries have created guidelines aiming at reducing the chronic use of BZD and consequently the risks of misuse and abuse. Several academic (American Psychiatric Association (APA), the National Institute for Health and Care Excellence (NICE), Royal Australian and New Zealand College of Psychiatrists (RANZCP), the UK Committee on Safety of Medicines (1988)) and governmental agencies (U.S. Department of Veterans Affairs (VA) and the U.S. Department of Defense (DoD),

the UK Department of Health via the Chief Medical Officer (2004)) have created evidence-based guidelines describing indications and recommended length of time for BZD use. Most of these guidelines emphasize selective serotonin reuptake inhibitors (SSRI) as first-line treatment for generalized anxiety, panic attacks, and post-traumatic stress disorder and generally discourage the use of BZDs. However, primary and mental health-care providers frequently continue prescribing BZDs in situations not included in the guidelines (Abrams et al. 2013).

21.17.2 Screening

Due to the strong association between anxiety disorders and substance use, as well as the strong association between drug abuse and prescription drug misuse, it is imperative to include screening questions regarding alcohol, smoking, and substance use histories when pharmacologic options for treatment of anxiety or insomnia are considered. Identifying at-risk individuals, considering alternative treatments where appropriate, and education on the safe and effective use of BZDs or Z-drugs may all decrease BZD diversion and misuse (McLarnon 2011). Obtaining patient signature for a treatment contract and monitoring the duration of therapy to limit at 2–6 weeks maximum are another way of preventing BZD-related problems. In addition, a history of respiratory insufficiency such as chronic obstructive lung disease or obstructive sleep apnea should be a relative contraindication to BZDs due to increased lethality in this group.

21.17.3 Patient Education

Education should highlight the side effects of BZDs, including their potential for physical dependence; rebound symptoms upon discontinuation; adverse effect on memory, cognition, and mood; the increased risk of falls; and accidents when operating vehicles or machinery within 24 h of taking the medication.

Prescribers should educate patients and their guardians that a prescription is only for the person who received the prescription, and inform about the risks of diversion including making medications available to other persons living in the household. Education should be provided regarding safe storage of medications in locked cabinets or boxes. Leftover medications should be disposed appropriately and returned to the pharmacist for environmentally safe disposal.

There is a need for widespread education regarding the importance of sleep in children and adolescents and the timely recognition of poor sleep habits and/or sleep problems (Blunden et al. 2004). Sleep hygiene interventions are beneficial in improving sleep quality in children, adolescents, and adults. Combination of sleep hygiene intervention, cognitive behavioral therapy (CBT), and stress reduction has been used to improve sleep and decrease the risk of relapse among adolescents with substance abuse problems (Bootzin and Stevens 2005).

21.17.4 Monitoring of Patients Receiving Prescriptions of BZDs

An office policy should be in place to prevent BZD or Z-drug medications refill beyond 4–6 weeks. Depression should be addressed with specific medications indicated for mood disorders or patients should be referred for mental health treatment.

Pharmacies should be engaged in patient monitoring, especially when filling prescriptions from different practitioners, feeding back this information with the respective practitioners in writing.

Inform patients in writing of the risks of benzodiazepine if prescriptions for benzodiazepine exceed 3 months, obtaining patient signature acknowledging reception of the information or via certified letter.

Programs that offer opiate detoxification may need to screen for concurrent benzodiazepine dependence and modify the detoxification protocol accordingly and address underlying psychiatric issues given their high prevalence in this population.

Clinicians should avoid prescribing sedatives to children, as studies have documented that adolescents who received a medical prescription for sedatives are more likely to use nonprescribed medications of this type. Receiving a prescription reinforces the belief among adolescents that sedatives are "low risk" and that medications are the answers to life's challenges or unpleasant emotions.

21.18 Conclusion

While the true extent of benzodiazepines abuse and diversion is unknown, it is well known that they are among the top most frequently prescribed medications in Western countries and they are used and misused regularly or continuously for insomnia and anxiety and as muscle relaxants. In addition, due to the adverse effects on memory and cognition, BZDs may affect daily activities such as driving or taking care of children. Benzodiazepine abuse leading to dependence is a common and costly comorbidity among substance abuse patients and one for which safe and effective treatments are greatly needed. BZD-related problems are also found among adolescents, seniors, war veterans, and women. Health-care providers and the society in general need to be aware not only of the large abuse liability of these substances but also of the importance of individual differences in risk for misuse and diversion. Detoxification from BDZs is usually a challenging process and needs to be closely monitored by experienced and compassionate providers due to the severe discomfort and the underlying problems that required the medications. Non-pharmacologic therapies such as sleep hygiene, exercise, outdoor activities, cognitive behavioral therapy, mindfulness skills training, or other relaxation interventions have been shown to be as efficacious as pharmacotherapy for insomnia and anxiety. These interventions have the benefits of long-term stress reduction, improvement of cognition and life satisfaction, and decrease in disease burden.

adjunct to reduce withdrawal symptoms, enhance treatment retention, and reduce relapse. The strategies tested in developing potential treatment medications include agonist substitution, antagonists, or modulators of non-cannabinoid neurotransmitter systems. Preliminary data from human laboratory and clinical studies suggest that the cannabinoid agonist nabilone, the opioid antagonist naltrexone, and the GABAergic drug gabapentin show promise and warrant further clinical investigation. Overall, results from clinical studies highlight the challenges in treating cannabis use disorders and the need to develop more efficacious therapeutic interventions.

22.1 Introduction

Cannabis is being used by approximately 5 % of the world's population, and a subset of regular users develop a cannabis use disorder characterized by tolerance, craving, and a withdrawal syndrome. Correspondingly, there is a demand for cannabis treatment that has risen dramatically in recent years. Yet, similar to other drug treatments, the vast majority of patients seeking treatment for their cannabis use fail to achieve abstinence.

The objective of this chapter is to inform clinicians about characteristic features of cannabis use disorders and update them on the current state of treatment research. Psychosocial treatment remains the primary approach utilized, but relatively poor response rates suggest that medications may be a useful adjunct to reduce withdrawal symptoms, enhance treatment retention, and reduce relapse. The strategies tested in developing potential treatment medications include agonist substitution, antagonists, or modulators of non-cannabinoid neurotransmitter systems. Preliminary data from human laboratory and clinical studies suggest that the cannabinoid agonist nabilone, the opioid antagonist naltrexone, and the GABAergic drug gabapentin show promise and warrant further clinical investigation. Overall, results from clinical studies highlight the challenges in treating cannabis use disorders and the need to develop more efficacious therapeutic interventions.

22.1.1 Cannabis Epidemiology and Pharmacology

Cannabis, obtained from the hemp plant *cannabis sativa*, is the most-used illicit drug worldwide, accounting for 75 % of all illicit drug use. Over the last decade, 2.5–5.0 % of the world's population reported using cannabis, with an estimated 119–224 million users worldwide (UNODC 2012). The highest prevalence of cannabis use is currently in Oceania (Australia and New Zealand) at 9.1–14.6 %, followed by North America (10.8 %), Western and Central Europe (7.0 %), and West and Central Africa (5.2–13.5 %). While the prevalence of cannabis use in Asia (1.0–3.4 %) remains lower than the global average, Asia's large population results in the highest absolute number of users worldwide (approximately 26–92 million).

In terms of production, Afghanistan and Morocco remain the largest global cannabis producers, where direct distribution is targeted to neighboring African, east European, and Asian countries. Most developed nations obtain cannabis from indigenously grown (mostly indoor) crops. In fact, the boom in indoor cannabis production in recent years has resulted in highly potent "exotic" strains of cannabis, popular in North America, Europe, Japan, and Oceania (UNODC 2012). Correspondingly, the average potency of confiscated cannabis in the United States tripled from 1992 to 2008. Laboratory studies show that high-potency cannabis is more reinforcing than low-potency cannabis (Chait and Burke 1994), supporting the idea that increased potency may impact the likelihood of developing problematic patterns of use.

Although epidemiological data suggest that only about 5–9 % of individuals who have tried cannabis develop dependence (compared with 15–25 % for cocaine), the widespread prevalence of cannabis use results in a significant number of dependent individuals (Anthony et al. 1994). Δ^9-tetrahydrocannabinol (THC) is the constituent of cannabis critical to the development of dependence. *Cannabis sativa* contains over 60 cannabinoid compounds, but THC is the primary psychoactive component of the plant and defines cannabis potency. THC binds to cannabinoid type-1 (CB_1) receptors, which are widely expressed throughout the body and densely populated in neural areas related to cognition, learning and memory, motor coordination, attention, and reward (for a review of neurobiology, see Cooper and Haney 2008).

22.1.2 Cannabis Use Disorders in Humans

Cannabis use disorders are defined as a problematic pattern of cannabis use leading to clinically relevant impairment or distress occurring within a 12-month period as manifested by cannabinoid tolerance and withdrawal; increasing amounts of cannabis use over time; inability to control consumption; craving; and recurrent cannabis use having negative implications on social, professional, and educational life (APA 2013).

Symptoms of cannabis withdrawal commonly appear after 24 h of abstinence, reach their peak around 2–6 days, and remit within 2 weeks, although impaired sleep patterns may persist for longer periods (Budney et al. 2004). According to DSM-V, withdrawal is diagnosed if at least three of the following symptoms develop within a week of abstinence: irritability, anger, or aggression; nervousness or anxiety; sleep difficulty (insomnia, disturbing dreams); decreased appetite or weight loss; restlessness; depressed mood; and at least one of the following physical discomforts – abdominal pain, shakiness/tremors, fever, chills, or headache. Additionally, the following symptoms may be observed a week post abstinence: fatigue, yawning, difficulty in concentration, and rebound periods of increased appetite and hypersomnia following initial bouts of appetite loss and insomnia (APA 2013). Cannabis withdrawal symptoms may cause significant distress and most likely contribute to relapse among those seeking treatment for their cannabis use (Haney et al. 2013a).

22.2 Treatment for Cannabis Use Disorders

In recent years, the proportion of people seeking treating for their cannabis use has been steadily increasing. Treatment admissions for cannabis have doubled in the USA in the last decade and tripled in Europe and Australia. Worldwide, it is currently estimated that 25 % of patients presenting for substance use treatment are those with cannabis use disorders (UNODC 2012). The primary approach for treatment is psychosocial, and to date, there is no approved pharmacological treatment to facilitate psychosocial treatment approaches.

22.2.1 Psychosocial Treatment

Research on psychosocial treatments for cannabis use disorders has been ongoing for the last 25 years, and results from these studies have demonstrated that outpatient treatment models can reduce cannabis use and promote abstinence compared to control conditions. In both adults and adolescents, modest success rates have been seen with cognitive behavioral therapy (CBT), motivational enhancement therapy (MET), contingency management (CM), and family-based therapies.

CBT focuses on providing skills necessary to achieve abstinence and cope with stressors and high-risk situations (Marlatt and George 1984; Monti et al. 2002). MET is a non-confrontational approach that aims to build motivation to reduce drug use, by addressing ambivalent feelings towards drug use, which may produce a motivation to change behavior (Miller and Rollnick 2002). Evidence from a series of controlled clinical trials for cannabis use disorders in adults suggests that the combination of CBT and MET achieves greater rates of abstinence than delayed treatment (Budney et al. 2007a). MET-CBT was associated with significantly greater long-term abstinence and reduction in frequency of cannabis use than control treatment, and typically achieved 19–29 % abstinence rates in the 12-month follow-up.

In an effort to improve outcome, several studies have examined the efficacy of CM for treating cannabis use disorders. CM, a process of systematically using positive reinforcement to reinforce abstinent behavior, has been shown to significantly enhance treatment retention and increase periods of abstinence for other drugs of abuse (Petry and Simcic 2002). The results from trials examining the efficacy of CM alone or in combination with MET-CBT for adult cannabis use disorders have shown that inclusion of CM significantly increased rates of abstinence. Specifically, inclusion of CM yielded enhanced abstinence rates to 35–37 % at the 12-month follow-up, whereas MET alone had abstinence rates of 5–10 % (Budney et al. 2007a; Litt et al. 2013).

By contrast, CM was not quite as efficacious for adolescent or young adults mandated to drug treatment. A study by Carroll and colleagues (2012) showed that the combination of CM and CBT was ineffective in improving treatment outcome for cannabis use disorders in young adults involved with the criminal justice system compared to CBT alone. In adolescents (12–18 years) presenting for publically funded treatment programs, a variety of treatment approaches,

alone and in combination (e.g., CBT, MET, CM, family therapy), yielded about 25 % abstinence rates 1 year later regardless of treatment condition (Dennis et al. 2004). These data suggest that maintaining cannabis abstinence may be more difficult in this population relative to adults.

Taken together, psychosocial approaches improve outcomes for people with cannabis use disorders relative to no treatment; however, relapse rates remain high (about 70 %), consistent with abstinence rates for other drugs of abuse. There is clearly a need to increase treatment outcomes by improving the efficacy of currently available treatment options. The development of medications to supplement psychosocial approaches may result in better treatment retention, alleviation of withdrawal symptoms, and a reduction in cannabis use.

22.2.2 Pharmacotherapy

A variety of medications have been investigated for their potential to improve marijuana treatment outcome. Most of the current research is limited to human laboratory models and small open-label or placebo-controlled clinical trials. A variety of human laboratory studies have been conducted to directly assess the effect of medications on different aspects of cannabis abuse (e.g., intoxication, withdrawal, self-administration) in a controlled, medically supervised environment. These studies provide useful information regarding safety and tolerability of medications combined with cannabis as well as provide clinically relevant outcomes to guide the selection of medications to test in expensive and time-consuming clinical trials. In terms of clinical studies, there are a handful of published case reports, open-label treatment studies, and randomized controlled trials assessing the effects of medications for cannabis use disorders. Medications investigated in the these models include cannabinoid substitutes such as dronabinol and nabilone and non-cannabinoid agents, which were selected to treat specific aspects of cannabis withdrawal symptoms or to blunt positive effects of cannabis.

22.2.2.1 Blocking Cannabinoid Intoxication: The Antagonist Approach

One strategy for developing pharmacological treatments for cannabis addiction is to reduce the positive subjective and reinforcing effects of the drug. The CB_1 receptor antagonist, rimonabant, was found to block many behavioral effects of cannabinoids in animals (Compton et al. 1996). In humans, an initial laboratory study found that acute doses of rimonabant dose-dependently blocked the effects of smoked cannabis. Compared to placebo, the highest rimonabant dose tested (90 mg) reduced positive subjective effects and cardiovascular effects of cannabis by around 40 % and 60 %, respectively (Huestis et al. 2001). A follow-up study assessed the effects of daily rimonabant (40 mg) administration over 15 days on responses to smoked cannabis (Huestis et al. 2007). Rimonabant (40 mg) significantly reduced the cardiovascular effects of cannabis on both days 8 and 15 of daily administration relative to placebo. Rimonabant maintenance also reduced cannabis' positive subjective effects on day 8 but not 15. Further, a single dose of

90-mg rimonabant reduced cannabis-induced heart rate increases but did not blunt the positive subjective effects of cannabis, thereby failing to replicate the earlier study. Unfortunately, rimonabant was found to increase the risk of adverse psychiatric reactions (depression, suicidality) in a clinical trial for obesity, so the medication has been removed from the market and further testing is not possible.

An alternative approach to medications directly blocking the cannabinoid receptor is to target neurotransmitter systems that have been implicated in the effects of cannabis. For example, preclinical studies have demonstrated a functional interaction between endogenous opioids and cannabinoids. Opioid antagonists such as naloxone and naltrexone have been shown to attenuate the reinforcing and rewarding effects of cannabinoid agonists in rodents and nonhuman primates. Conversely, in daily cannabis smokers, acute administration of a range of acute naltrexone doses (12–100 mg) enhanced the subjective and cardiovascular effects of cannabis (3.27 % THC) compared to placebo capsules (Cooper and Haney 2010). Yet, repeated naltrexone administration (50 mg), for 2 weeks or longer, appears to blunt positive subjective and reinforcing effects of smoked cannabis (Haney et al. in preparation). Taken together, these results suggest that clinical studies testing maintenance on naltrexone as an adjunct therapy in the management of cannabis use disorders may be warranted.

22.2.2.2 Alleviating Cannabinoid Withdrawal and Preventing Relapse

A variety of potential medications have been investigated for their ability to ameliorate cannabis abstinence symptoms and prevent relapse. Most promising findings are from studies employing a cannabinoid receptor agonist, such as dronabinol or nabilone. The first study using this approach reported that dronabinol (10 mg, five times/day for 6 days) significantly decreased symptoms of cannabinoid withdrawal, such as craving, anxiety, chills, misery, troubled sleep, and decreased food intake, while producing no evidence of abuse liability (Haney et al. 2004); this pattern of effects was subsequently replicated (Budney et al. 2007b). In a follow-up study, dronabinol was administered at a higher dose (20 mg, three times/day for 8 days). The study also incorporated a laboratory measure of relapse, which is operationally defined as cannabis self-administration, at a cost, after a period of abstinence. Dronabinol at this dose decreased symptoms of cannabis withdrawal, such as restlessness, anorexia, and chills, and produced mild intoxication, but did not decrease relapse to cannabis (Haney et al. 2008). In the same study, a combination of oral dronabinol (60 mg/day) and lofexidine (2.4 mg/day), an α_2-adrenergic receptor agonist shown to improve opioid withdrawal symptoms, was evaluated. Lofexidine was tested because preclinical studies showed that clonidine, another adrenergic receptor agonist, reduced cannabinoid withdrawal symptoms in rodents, presumably by reversing enhanced noradrenergic signaling during withdrawal. Lofexidine alone did not robustly attenuate mood symptoms of withdrawal but improved sleep and decreased cannabis relapse. Yet the combination of lofexidine and dronabinol produced the most robust improvements in sleep, withdrawal, craving, and relapse relative to placebo (Haney et al. 2008).

In terms of clinical data, there are two case reports testing long-term cannabis smokers with dronabinol in concert with other medications (Levin and Kleber 2008). One patient was medicated for 6 months with dronabinol (40 mg/day) and divalproex (250 mg/day), a mood stabilizer that reduces irritability and mood swings in bipolar disorder and during alcohol withdrawal. A second patient was maintained on dronabinol (10–15 mg/day) while also receiving venlafaxine (25 mg/day) for depression and modafinil (100 mg PRN) to counter the energy decreases experienced with dronabinol. In both cases, patients achieved and maintained abstinence.

A randomized, placebo-controlled, double-blind, 12-week trial was then conducted (Levin et al. 2011). Participants ($n = 156$) were randomized to either dronabinol (40 mg/day) or placebo following a 1-week placebo lead-in phase; both groups received weekly MET and CBT therapy. All participants reduced cannabis use over time irrespective of treatment, and there was no significant difference between treatment groups in the proportion of participants who achieved 2 weeks of abstinence at the end of the medication phase. However, the dronabinol group had higher treatment retention (77 %) compared to placebo (61 %), and consistent with laboratory studies, withdrawal symptoms were significantly lower in the dronabinol group than placebo.

Given that both the human laboratory and the clinic found that dronabinol decreased withdrawal but did not alter cannabis use, the next study tested nabilone: a cannabinoid agonist with better bioavailability, less individual variability in drug response, and a more predictable dose–response function than dronabinol (Bedi et al. 2012). Nabilone (6, 8 mg/day, for 8 days) significantly reversed withdrawal-induced irritability and disruptions in sleep and food intake (Haney et al. 2013b). Importantly, nabilone maintenance also decreased a laboratory measure of cannabis relapse. These findings are the most promising human laboratory evidence to date, where a single medication improved both cannabis withdrawal symptoms and prevented relapse and suggest that nabilone is a promising candidate for investigation in a clinical trial for cannabis treatment.

In terms of other cannabinoids, a case report presented the effects of cannabidiol, a non-psychoactive cannabinoid constituent of cannabis, on withdrawal symptoms following abrupt cessation of cannabis use in a chronic, heavy cannabis smoker (Crippa et al. 2013). Following maintenance on cannabidiol (300–600 mg/day) for 11 days, the patient demonstrated no self-reported abstinence symptoms. Controlled testing of cannabidiol is needed.

Various non-cannabinoid medications have also been evaluated in controlled inpatient studies for the treatment of cannabis withdrawal, largely with negative results. For example, bupropion, an indirect noradrenergic and dopaminergic agent used for tobacco cessation (150–300 mg/day for 28 days) was found to worsen ratings of irritability, restlessness, depression, and troubled sleep during cannabis withdrawal compared to placebo (Haney et al. 2001).

Since bupropion has stimulant properties that may have exacerbated abstinence-associated agitation and insomnia, subsequent human laboratory studies assessed the effects of medications with sedative properties on cannabis withdrawal and

relapse. Nefazodone and mirtazapine are both antidepressants that enhance noradrenergic and serotonergic activity. During cannabis withdrawal, nefazodone maintenance (450 mg/day for 26 days) decreased certain cannabis withdrawal symptoms (anxiety, muscle pain) but did not alleviate irritability, misery, or troubled sleep (Haney et al. 2003). Mirtazapine (30 mg/day for 14 days), on the other hand, robustly reversed sleep disruption and appetite loss during cannabis withdrawal, but did not improve participants' mood and did not decrease relapse (Haney et al. 2010).

Consistent with the laboratory data, clinical trials with bupropion and nefazodone were also negative. Bupropion (300 mg/day) and nefazodone (600 mg/day) were each compared to placebo in treatment-seeking, cannabis-dependent individuals (Carpenter et al. 2009). Patients ($n = 106$) were randomized to one of the study medications or placebo in this 13-week trial, with 1 week of placebo lead-in, 10 weeks of study medication, and 2 weeks of lead-out. All patients completed weekly sessions with a psychosocial intervention, and around half of the patients completed the 10-week medication phase. Both cannabis use and withdrawal symptoms decreased over time, and there was no effect of bupropion or nefazodone relative to placebo. Results of this clinical trial are, therefore, consistent with the conclusions of laboratory studies.

Venlafaxine and fluoxetine, both antidepressants, have been investigated for their utility in treating cannabis use disorders in those with comorbid depression. A randomized double-blind placebo-controlled trial with depressed cannabis-dependent adolescents ($n = 70$) found no advantage for fluoxetine (10–20 mg/day for 12 weeks) over placebo on either depression or cannabis use outcomes (Cornelius et al. 2010). A subsequent trial in adult patients ($n = 103$) found that extended-release venlafaxine ($\leq$375 mg/day for 12 weeks) was not effective relative to placebo in reducing depression and could potentially increase cannabis use in this population (Levin et al. 2013). Overall, neither laboratory nor clinical studies provide compelling evidence for the utility of antidepressants to treat cannabis use disorders.

Given that anxiety can be a symptom of cannabis withdrawal, the non-benzodiazepine, antianxiety medication, buspirone, was tested in a randomized, controlled clinical trial for cannabis use disorders (McRae-Clark et al. 2009). Cannabis-dependent patients were randomized to buspirone (60 mg/day) or placebo for 12 weeks in conjunction with a psychological intervention (two or three sessions of motivational interviewing during the first 4 weeks). The study reported a high dropout rate (50 %) and no direct effect of buspirone on self-reported anxiety, withdrawal symptoms, or craving. However, exploratory analyses suggested that decreased anxiety over the study predicted cannabis abstinence, indicating that anxiety symptoms may be a useful treatment target.

Divalproex has been investigated in the laboratory and the clinic for its mood-stabilizing properties. Although divalproex (1,500 mg/day for 29 days) decreased cannabis craving during abstinence, the medication worsened ratings of anxiety, irritability, fatigue, and cognitive performance relative to placebo (Haney et al. 2004). Similarly, a double-blind, placebo-controlled pilot study tested

divalproex (250–2,000 mg/day; adjusted to individual response) in combination with CBT for adults ($n = 25$) (Levin et al. 2004). Patients were randomized to either divalproex or placebo for an initial 6-week period after 2 weeks of placebo lead-in. In the 19 patients who completed at least the initial 8 weeks, self-reported irritability, cannabis craving, and cannabis use decreased over time. There was, however, an increased incidence of divalproex-related adverse reactions (fatigue, headaches, drowsiness, and nausea) and poor patient compliance during the trial. These negative results are consistent with the laboratory findings and do not support the clinical utility of divalproex.

Lithium, another mood stabilizer, has also been tested for the treatment of cannabis withdrawal. A small ($n = 9$), open-label, inpatient laboratory study administering lithium (600–900 mg/day for 6 days) reported a reduction in withdrawal signs in 50 % of the participants (Bowen et al. 2005). A second open-label trial maintained cannabis-dependent patients on lithium (1,000 mg/day) in an inpatient setting for 7 days (Winstock et al. 2009). Lithium was generally well tolerated in this short-term inpatient protocol. Although rates of reported withdrawal symptoms were lower and follow-up reports of abstinence higher than in some previous studies, the safety of outpatient lithium administration is a potential concern.

The hormone, oxytocin, is another potential treatment approach, as it has been shown in several preclinical models to reduce drug reinforcement and anxiety-like behavior. A trial is currently under way examining the effects of intranasal oxytocin following preliminary laboratory findings that acute administration of oxytocin (40 IU) alleviated stress-induced reactivity and craving in eight cannabis users (McRae-Clark et al. 2013). This data is supported by findings that oxytocin mediates lithium's effects on cannabis withdrawal.

A case study with the atypical antipsychotic, quetiapine, given to cannabis users with schizophrenia or bipolar disorder reported reduced cannabis use over the course of treatment (Potvin et al. 2004). Quetiapine is a 5-HT_{2A} and D_2 antagonist, a partial agonist at the 5-HT_{1A} receptor, and inhibits the norepinephrine transporter. An inpatient laboratory study evaluating the effects of quetiapine reported that although maintenance (200 mg/day for 15 days) improved sleep quality, increased caloric intake and decreased weight loss during cannabis withdrawal compared with placebo, quetiapine increased cannabis craving and self-administration. These data do not support quetiapine's potential for the treatment for cannabis use disorders (Cooper et al. 2012).

The clinical utility of atomoxetine (a norepinephrine reuptake inhibitor indicated for attention deficit hyperactivity disorder, ADHD) to treat cannabis withdrawal has been investigated in a small open-label study. Atomoxetine (20–80 mg daily for 11 weeks) demonstrated a trend to reduce cannabis use in cannabis-dependent individuals (Tirado et al. 2008). However, the medication produced adverse effects in the majority of patients (nausea, vomiting, dyspepsia, loose stools). A subsequent placebo-controlled trial evaluated the effects of atomoxetine on symptoms of ADHD and cannabis use in cannabis-dependent adults (McRae-Clark et al. 2010). In conjunction with MET, participants received

either atomoxetine ($n = 19$) or placebo ($n = 19$) for 12 weeks. Participants randomized to atomoxetine had greater improvement in ADHD on the Clinical Global Impression-Improvement scale than those treated with placebo, yet there were no significant effects of atomoxetine on self-rated ADHD symptoms or cannabis use outcomes. These results suggest that atomoxetine may improve some ADHD symptoms but does not reduce cannabis use in this population.

A small open-label, 12-week pilot study investigated the effects of the entacapone, an inhibitor of catecholaminergic catabolism, in patients meeting criteria for a cannabis use disorder ($n = 36$). Entacapone (up to 2,000 mg/day, daily and PRN), as acute or maintenance treatment, significantly decreased craving for cannabis in over half of the patients; controlled studies are needed to confirm these findings (Shafa et al. 2009).

A recent open-label treatment study in adolescents tested the antioxidant N-acetylcysteine (NAC), shown in animal studies to reverse alterations to the glutamate system associated with repeated self-administration of a range of addictive drugs. Patients ($n = 24$) received NAC daily (2,400 mg/day) over a 4-week period with no other intervention (Gray et al. 2010). The medication produced some mild-to-moderate side effects but was generally well tolerated. Self-reported cannabis use as well as cannabis craving decreased during treatment with NAC. In a subsequent 8-week double-blind, randomized, placebo-controlled trial, treatment-seeking cannabis-dependent adolescents (ages 15–21 years; $n = 116$) received NAC (1,200 mg) or placebo twice daily as well as CM and brief cessation counseling weekly (Gray et al. 2012). Participants receiving NAC had more than twice the odds of having negative urine cannabinoid results during treatment, compared with those receiving placebo. Exploratory secondary abstinence outcomes (assessing time to first negative urine cannabinoid test and end-of-treatment abstinence) favored NAC but were not statistically significant.

A recent inpatient laboratory study assessing the effects of baclofen, an antispasmodic agent that increases gamma-aminobutyric acid (GABA) signaling, failed to engender any clinical benefits for cannabis withdrawal (Haney et al. 2010). Baclofen (60, 90 mg/day) had few positive effects on mood or behavior, reduced cognitive performance across conditions, and did not reduce cannabis relapse. A case series assessed the effects of baclofen (40 mg/day) in six patients with both cannabis and nicotine dependence (Nanjayya et al. 2010). Common side effects were sedation and lethargy, consistent with the cognitive impairment demonstrated in the laboratory trial. The authors report that the medication was well tolerated and that withdrawal symptoms decreased in patients who maintained abstinence for between 1 and 13 months. However, the negative results of the controlled laboratory study do not support baclofen's potential to treat cannabis use disorders, despite this case findings.

Finally, a recent pilot clinical trial investigated the effects of the GABAergic agonist, gabapentin, for cannabis use disorders (Mason et al. 2012). Patients ($n = 50$) received either gabapentin (up to 1,200 mg/day) or placebo for 12 weeks in addition to manual-guided, abstinence-oriented individual counseling. Relative to placebo, gabapentin significantly reduced cannabis use and decreased

withdrawal symptoms. Gabapentin was also associated with significantly greater improvement in overall performance on tests of executive function.

In summary, a variety of cannabinoid and non-cannabinoid agents have been tested in the laboratory and clinic for their potential to reduce cannabis intoxication, withdrawal, and cannabis use. Most of these medications did not significantly reduce the wide spectrum of cannabis withdrawal symptoms, and some actually worsened them, but several medications showed promise in the human laboratory and in the clinic.

22.3 Conclusion

Prolonged cannabis use can lead to a clinically significant substance use disorder. Over the past 20 years, there has been a steady increase in studies focusing on both psychosocial approaches and medications development for cannabis use disorders. Most psychosocial treatment studies are better than control conditions but nonetheless produce low rates of long-term abstinence. Thus, as with drugs such as nicotine, alcohol, and opioids, adjunct pharmacotherapy is worth exploring to maximize treatment outcome. Among the cannabinoid and non-cannabinoid agents investigated, several appear to have therapeutic potential.

Cannabinoid agonists like dronabinol reduced withdrawal symptoms and improved treatment retention but failed to alter cannabis use in either the laboratory or the clinic. Yet another cannabinoid agonist, nabilone, reduced both laboratory measures of withdrawal and relapse. The advantages of nabilone over dronabinol include higher bioavailability as well as a longer duration of action, both of which are essential features of a potential treatment medication. Thus, its efficacy needs to be further explored in the clinic. Two medications shown to improve alcohol treatment outcome, gabapentin and naltrexone, also show promise. Further clinical studies confirming these promising findings are needed.

In terms of future directions, the inhibition of endocannabinoid catabolic enzymes, fatty acid amide hydrolase (FAAH), and monoacylglycerol lipase reduces cannabinoid withdrawal in animal models of cannabinoid dependence. Unlike cannabinoid substitutes, FAAH inhibitors do not appear to possess abuse liability (for a full review, see Panlilio et al. 2013). There is currently a study under way at Yale University measuring the efficacy of FAAH inhibitors for reducing withdrawal in cannabis-dependent individuals.

The impact of risk factors (both environmental and genetic) that lead to heavy drug use and the factors that make achieving abstinence challenging need to be better understood in order to optimize treatment approaches. Additionally, over 50 % of patients with cannabis use disorders also abuse other drugs such as nicotine and alcohol and have comorbid psychiatric disorders, but most treatment trials select for psychiatrically healthy cannabis users without dependence on other substances. Indeed, a recent laboratory study has shown that cigarette smoking is an important predictor of cannabis relapse in the laboratory and can influence the efficacy of medications used for treating cannabis use disorders (Haney et al. 2013a). In summary, with the growing treatment demand and increasing awareness about the risks of

cannabis abuse, research into treatment of cannabis use disorders is rapidly expanding. Existing evidence suggests that combining psychosocial treatment with a complementary medication is likely to reduce aversive cannabis withdrawal symptoms, prevent relapse, and improve treatment outcome.

Treatment of Cocaine Addiction

23

David A. Gorelick

Contents

Abstract

Cocaine use disorders represent a substantial clinical and public health burden in many countries, yet there are no well-proven and broadly effective treatments available, and no medication approved for this indication by any national regulatory authority. Psychosocial treatments are the mainstay of care, guided by the general principles of prompt engagement in treatment; minimum duration of 3 months; strict monitoring of cocaine use with consistent consequences for lapses; and engagement of the patient's social network. Contingency management (i.e., reinforcement for abstinence [cocaine-free urine samples] with vouchers or prizes) and cognitive behavior therapy (CBT) have the strongest evidence for efficacy in controlled clinical trials, often doubling the abstinence rate over standard drug counseling. Other interventions with mixed evidence include community reinforcement, motivational enhancement or interviewing, and participation in Cocaine Anonymous. Medications with efficacy in more

than one controlled clinical trial include disulfiram, oral stimulants in sustained-release formulation, and the anticonvulsant tiagabine. New treatments currently undergoing clinical study include anti-cocaine vaccines and repetitive transcranial magnetic stimulation (rTMS).

23.1 Introduction

Cocaine is a plant alkaloid found in leaves of the coca bush, *Erythroxylon coca*, which grows in the Andes Mountains region of South America. Its psychoactive properties make cocaine one of the most widely used and abused illicit drugs in the world. There were an estimated 17 million cocaine users worldwide in 2011, representing 0.4 % of the 15- to 64-year-old population (United Nations Office on Drugs and Crime 2013). About one-quarter (27 %) were in North America (4.6 million users, 1.5 % prevalence). While use in North America declined by about one-third over the past 5 years, it is increasing in West and Central Europe (4.0 million, 1.2 %); South America (3.3 million users, 1.3 %); Central America and the Caribbean (0.36 million users, 0.7 %); West, Central, and Southern Africa (2.2 million users, 0.7 %); and Oceania (0.37 million users, 1.5 %). Cocaine use remains relatively low in East and Southeast Europe (0.56 million, 0.2 %), North and Eastern Africa (0.03 million, 0.02 %), and Asia (1.3 million, 0.05 %).

Cocaine use is associated with a variety of psychological and physical health problems, resulting in a substantial clinical and public health burden in countries where use is prevalent. About one in six (16 %) cocaine users (via the intravenous or smoked routes of administration) develop addiction (psychological dependence) to the drug, with subsequent psychological (e.g., depression, psychosis) and socio-economic problems (Degenhardt and Hall 2012; Gorelick and Baumann 2014). Physical health problems associated with cocaine use include infectious diseases such as HIV and viral hepatitis (especially with injection use), trauma, cardiovascular disease, and stroke (Degenhardt et al. 2011; Degenhardt and Hall 2012; Gorelick and Baumann 2014). In 2010, cocaine use disorders were associated globally with an estimated 1.09 million years lived with disability (rate of 16 per 100,000 persons) (Vos et al. 2012), 1.1 million disability-adjusted life years (16 per 100,000 persons) (Murray et al. 2012), and 500 deaths (<0.05 per 100,000 persons) (Lozano et al. 2012). Data from longitudinal studies in five different countries (Brazil, Canada, Denmark, France, Italy) suggest that addicted cocaine users have death rates four- to eightfold higher than those of the same age and sex in the general population (Degenhardt et al. 2011), with even higher death rates in the presence of psychiatric comorbidity (Arendt et al. 2011).

Notwithstanding this substantial health burden, there are no widely used, broadly effective treatments for cocaine addiction. No medication is approved for this indication by any national regulatory authority because no medication has met the scientifically rigorous standard of consistent, statistically significant efficacy in adequately powered, replicated, controlled clinical trials. There are little or no

scientific data to guide decisions on many clinically important questions, such as optimal patient-treatment matching, the combination of psychosocial and pharmacological treatment, and the duration of treatment. Little is known about the treatment of special populations, such as pregnant women, the elderly, and those with medical or serious psychiatric comorbidity. The mainstay of treatment is psychosocial, with a variety of approaches being used. This chapter reviews the current state of cocaine addiction treatment.

23.2 Treatment Approaches

23.2.1 Psychosocial Treatment

A variety of psychotherapy approaches and other psychosocial interventions have been evaluated for the treatment of cocaine addiction, almost exclusively in specialized outpatient psychiatric or addiction treatment programs. These include motivational interviewing and motivational enhancement; psychodynamic, interpersonal, and supportive psychotherapy; and cognitive and behavioral therapies such as relapse prevention and contingency management. Some controlled clinical trials show modest, short-term (typically up to 3 months) improvement; longer-term outcomes are rarely evaluated (Dutra et al. 2008; Knapp et al. 2011; Penberthy et al. 2010). A meta-analysis of nine trials (five involving contingency management; three involving comorbid opiate dependence treated with methadone) enrolling 619 outpatients found that active treatment produced a 31.7 % abstinence rate versus 13 % in the comparison groups, for an effect size $d = 0.62$ (95 % CI = 0.16–1.08) (Dutra et al. 2008). A systematic Cochrane review of 27 randomized controlled trials enrolling 3,663 participants found contingency management, especially when combined with cognitive behavior therapy, more effective than other interventions in terms of better treatment retention and reduced cocaine use (Knapp et al. 2011). However, the substantial heterogeneity across studies precluded calculation of effect sizes, specific comparisons between treatments, or evaluation of moderating factors.

Regardless of treatment modality, several nonspecific factors are considered to significantly influence treatment outcome, although there is little direct evidence in support of many factors in the context of cocaine addiction treatment. Perhaps most important, more intensive treatment (e.g., more frequent visits or longer visits [e.g., day hospital]) and longer duration of treatment (minimum of three months) are associated with better outcomes, especially during early abstinence (Simpson et al. 2002; Zhang et al. 2003). However, there may be a ceiling to the long-term benefits of increasing treatment intensity. After 4–6 months, inpatient treatment was no better than day hospital (Schneider et al. 1996), and day hospital no better than 6 h per week of counseling (Coviello et al. 2001).

Other factors associated with better treatment outcome include prompt engagement with the treatment program (ideally, within 24 h of the decision to enter

treatment), nonjudgmental empathy with the patient (Darker et al. 2012), clear and realistic orientation to treatment goals and behavioral expectations, strict monitoring of cocaine (and other psychoactive substance) use (e.g., frequent urine drug testing) with prompt feedback to the patient and consistent consequences for cocaine use, involvement of the patient's social network (to the extent possible), and attention to any concurrent medical, psychiatric, vocational, legal, or social problems (Friedmann et al. 2004). Involvement with peer self-help groups such as Cocaine Anonymous (modeled after Alcoholics Anonymous) is also associated with improved treatment outcome (Weiss et al. 2005).

23.2.1.1 Contingency Management

Contingency management (CM) is a behavioral intervention that provides the patient something of value (i.e., reinforcement) when they perform a specific and measurable desired behavior. CM is used to reinforce either treatment adherence (e.g., clinic attendance, taking of medication, providing a urine sample for drug testing) or treatment outcome (e.g., providing a drug-negative ["clean"] urine sample). The reinforcement is commonly a cash equivalent such as a gift card or voucher exchangeable for an item that will not hinder recovery, e.g., food or small appliance. The cost of implementing CM has been a major barrier to its wide use. To reduce costs, some programs use as reinforcement the chance to win a prize, rather than a prize itself (the so-called "lottery" or "fish bowl" approach). This approach can be as effective as standard reinforcement (Olmstead and Petry 2009).

One of the earliest uses of CM was in the treatment of cocaine addiction (Higgins et al. 2008). A recent systematic review of 19 studies involving 1,664 patients found that CM, when combined with other psychological interventions, significantly improved treatment retention, reduced cocaine use, and had an additive benefit when combined with pharmacological treatment (Schierenberg et al. 2012). Two meta-analyses including 12 studies (820 patients) (Lussier et al. 2006) and seven studies (four included in the other meta-analysis) (370 patients) (Prendergast et al. 2006) found weighted effect sizes for abstinence during treatment of 0.35 (95 % CI 0.27–0.43) and 0.66 (0.44–0.87), respectively, indicating moderate to large effects. CM may be especially useful in promoting medication adherence and bridging the treatment gap until therapeutic medication effects appear (Carroll and Rounsaville 2007). CM is effective in treating cocaine addiction in a broad range of patients, including those with serious psychiatric comorbidity (Petry et al. 2013) or other substance use disorder (Alessi et al. 2011), older patients (Weiss and Petry 2013), and those at a variety of socioeconomic levels (Secades-Villa et al. 2013). CM is also effective when delivered by therapists in the community (Petry et al. 2012) outside a research setting.

23.2.1.2 Cognitive Behavioral Therapy

Cognitive behavioral therapy (CBT) aims to have the patient think differently about their drug use and unlearn ineffective behaviors and to employ cognitive and behavioral techniques to avoid drug use. The focus on high-risk contexts for drug

use, whether emotional states (e.g., depression, anxiety, stress), cognitive states (e.g., low self-efficacy), exposure to drug-associated cues, or acute withdrawal, is sometimes termed relapse prevention or coping skills training (Hendershot et al. 2011). A lapse (initial drug reuse) is not considered a treatment failure, but an opportunity to implement the skills learned to prevent a lapse from becoming a relapse.

CBT is more effective than drug counseling or psychotherapy in most, but not all, comparative studies (Knapp et al. 2011; Penberthy et al. 2010). Focused relapse prevention was no more effective than standard drug counseling in two of three early controlled trials involving a total of 205 patients – the overall meta-analytic effect size was −0.03 (95 % CI −0.17 to 0.11) (Irvin et al. 1999). The addition of CBT to CM does not generally enhance the efficacy of the latter.

23.2.1.3 Community Reinforcement Approach

The community reinforcement approach (CRA) broadens the behavioral approach to treatment beyond drug use to include the patient's total environment and activities, including skills training to enhance drug refusal and problem solving, family relations, social network, employment, and recreation (Knapp et al. 2011). CRA is often combined with CM and CBT as an integrated treatment package, making it impossible in many studies to evaluate the contribution of CRA itself. CRA plus CM is more effective than CRA alone or drug counseling (Knapp et al. 2011; Penberthy et al. 2010).

23.2.1.4 Drug Counseling

Drug counseling is a nonspecific, supportive form of psychotherapy which generally focuses on recovery issues as conceptualized by self-help recovery groups (e.g., Cocaine Anonymous) (Knapp et al. 2008). Some form of drug counseling is often the standard treatment or treatment as usual against which other treatments are compared in clinical trials. In the absence of convincing studies directly comparing the efficacy of individual with group counseling, most community treatment programs and many clinical trials provide group counseling for cost reasons. Drug counseling is not as effective as CM or CBT (Knapp et al. 2011). A large (487 patients), 6-month, multisite clinical trial found weekly individual plus group drug counseling more effective in reducing cocaine use than group counseling alone or combined with cognitive therapy or with supportive-expressive psychodynamically oriented psychotherapy (Crits-Christoph et al. 1999).

23.2.1.5 Motivational Enhancement

Motivational enhancement (ME) and motivational interviewing (MI) are brief (often one or two sessions) interventions that use a supportive, directive approach to enhance motivation for change (Penberthy et al. 2010). These interventions are used in primary care and other nonspecialized settings to initiate engagement in treatment, but the few published clinical trials provide mixed evidence for efficacy, either alone or combined with other psychosocial interventions (Penberthy et al. 2010).

23.2.1.6 Other Psychosocial Treatments

Several other treatment approaches are described in the literature but not well studied, including 12-Step facilitation (Knapp et al. 2011), web-based self-help (Schaub et al. 2011), and Cocaine Anonymous. The latter is a 12-Step, self-help organization modeled on Alcoholics Anonymous (Weiss et al. 2005).

23.2.2 Pharmacological Treatment

The goal of pharmacological treatment is to reduce or eliminate the positive reinforcement (euphoria, "high") from cocaine, reduce or eliminate the desire (craving) to take cocaine, and/or reduce or eliminate the negative reinforcement from cocaine withdrawal. The achievement of these goals does not guarantee treatment success, as the patient must also learn new beneficial ways of living to replace the cocaine-seeking and cocaine-taking behaviors that are being extinguished. Therefore, in clinical practice, medication almost never is used without some psychosocial treatment component. However, there are few data to guide decisions on the type, intensity, and duration of psychosocial treatment accompanying medication. Few controlled clinical trials explicitly compare the efficacy of medication combined with varying (or no) psychosocial treatments (Carroll et al. 2004). A 12-week controlled clinical trial of L-DOPA/carbidopa found better outcome with medication than placebo in patients also receiving contingency management combined with cognitive behavioral therapy (CBT) plus standard clinical management from a nurse, but not in two other groups receiving CBT plus standard clinical care without contingency management or only standard clinical care (Schmitz et al. 2008).

Four pharmacological approaches are potentially useful to achieve these treatment goals (Gorelick et al. 2004): (1) substitution treatment with a cross-tolerant stimulant (analogous to methadone maintenance treatment of opioid dependence), (2) treatment with an antagonist medication that blocks the binding of cocaine at its site of action (true pharmacological antagonism, analogous to naltrexone treatment of opioid dependence), (3) treatment with a medication that functionally antagonizes the effects of cocaine (such as by reducing the reinforcing effects of or craving for cocaine), and (4) alteration of cocaine pharmacokinetics so that less drug reaches or remains at its site(s) of action in the brain.

Most current clinical and research attention focuses on the second and third approaches, i.e., reducing or blocking cocaine's actions, either directly at its neuronal binding site (true pharmacological antagonism) or indirectly by otherwise reducing its reinforcing effects. The first approach has been evaluated in a small number of clinical trials, with mixed results. The fourth approach has shown promise in animal studies and early phase II clinical trials (Gorelick 2012).

Cocaine has two major neuropharmacological actions: blockade of synaptic neurotransmitter transporters (reuptake pumps), thereby inhibiting the uptake of previously released monoamine neurotransmitters and resulting in psychomotor stimulant effects, and blockade of sodium ion channels in nerve membranes, resulting in local anesthetic effects (Gorelick and Baumann 2014).

Cocaine's positively reinforcing effects derive from its blockade of the dopamine reuptake pump, causing presynaptically released dopamine to remain in the synapse and enhancing dopaminergic neurotransmission (Howell and Kimmel 2008). Cocaine's local anesthetic effects are believed to contribute to cocaine-induced kindling, the phenomenon by which previous exposure to cocaine sensitizes the individual so that later exposure to low doses produces an enhanced response.

23.2.2.1 Antidepressants

Tricyclic and other heterocyclic antidepressants are the most studied class of medications for cocaine dependence treatment. Their efficacy is presumed based on both their pharmacological mechanism of increasing biogenic amine neurotransmitter activity in synapses and their amelioration of the depressive symptoms frequently observed among cocaine-dependent individuals seeking treatment (see below for treatment of patients with comorbid depression).

Desipramine is the first and best studied medication for cocaine addiction treatment and is typically dosed at 150–300 mg/day (about 2.5 mg/kg), similar to doses used to treat depression. Meta-analysis suggests no significant efficacy compared with placebo, but with substantial heterogeneity across studies (Pani et al. 2011). Differences in patient characteristics, concomitant treatment, and desipramine plasma concentrations may account for some of the variability in desipramine efficacy. Patients dually dependent on cocaine and opiates may do better on desipramine if their opioid dependence is treated with buprenorphine rather than methadone (Kosten et al. 2005) or if they receive contingency management treatment along with medication (Kosten et al. 2003). There is limited evidence that patients with steady-state desipramine plasma concentrations above 200 ng/mL have poorer outcomes (Khalsa et al. 1993), with better outcomes at concentrations around 125 ng/mL (Kosten et al. 2003).

Experience with other heterocyclic antidepressants provides only limited evidence for efficacy (Pani et al. 2011). Reboxetine and maprotiline, which inhibit norepinephrine reuptake, and mirtazapine, which increases brain serotonin and norepinephrine activity by blocking the autoregulatory α_2-adrenergic and 5-HT_2 receptors, were effective in small open-label trials. Heterocyclic antidepressants not showing efficacy include atomoxetine, which inhibits norepinephrine reuptake; imipramine, the precursor of desipramine; and nefazodone and venlafaxine, which block both serotonin and norepinephrine reuptake.

Heterocyclic antidepressants have not been associated with unexpected or medically serious side effects. While theoretically possible, there is no evidence that patients who relapse to cocaine use while still on medication are at increased risk of cardiovascular side effects (Nelson et al. 1996).

Selective serotonin reuptake inhibitors (SSRIs), such as fluoxetine, paroxetine, and sertraline, have not been effective in controlled clinical trials, with one exception (Pani et al. 2011; Winstanley et al. 2011). One clinical trial found citalopram (20 mg/day) significantly better than placebo (Moeller et al. 2007). That study, unlike previous studies, used contingency management in addition to cognitive

behavioral therapy, suggesting the important influence of psychosocial treatment on medication efficacy.

Other types of antidepressants have not been found effective in controlled clinical trials (Pani et al. 2011), including monoamine oxidase (MAO) inhibitors such as transdermal selegiline (a selective MAO type B inhibitor which does not require a strict dietary regimen), bupropion (a weak inhibitor of monoamine reuptake that has stimulant-like behavioral effects in animals), and ritanserin, a 5-HT_2 receptor antagonist.

23.2.2.2 Dopamine Agonists (Antiparkinson Agents)

A variety of direct and indirect dopamine agonist medications have been evaluated (Amato et al. 2011), based on the dopamine depletion hypothesis of cocaine dependence (Dackis and Gold 1985), although the data supporting the hypothesis in humans are equivocal (Gorelick 1999). Findings with direct dopamine receptor agonists (primarily at the D_2 subtype) are inconsistent. Bromocriptine, pergolide (a mixed D_1/D_2 agonist), and pramipexole were not effective in one or more controlled clinical trials, while cabergoline and ropinirole were effective in a controlled clinical trial and open-label trial, respectively.

Amantadine is an indirect dopamine agonist that releases dopamine presynaptically and a weak antagonist at the *N*-methyl-D-aspartate glutamate receptor. Only one of more than half-a-dozen controlled clinical trials found amantadine (200–400 mg/day) better than placebo.

The amino acids L-DOPA, a precursor for catecholamine synthesis approved for the treatment of parkinsonism, and L-tyrosine, the precursor of L-DOPA, were not effective in several controlled clinical trials.

23.2.2.3 Disulfiram

Disulfiram increases dopamine concentrations by blocking the conversion of dopamine to norepinephrine by the enzyme dopamine-β-hydroxylase, so it can be considered a functional dopamine agonist (Gaval-Cruz and Weinshenker 2009). Five small controlled clinical trials in cocaine-dependent patients without alcohol dependence (but with concurrent opioid dependence treated with methadone or buprenorphine in four studies) found disulfiram (250 mg/day) significantly better than placebo in promoting cocaine abstinence (Kosten et al. 2013; Pani et al. 2010). However, two recent, larger controlled clinical trials (both in methadone-maintained patients) found no efficacy for disulfiram (Carroll et al. 2012; Oliveto et al. 2011). Some of the heterogeneity in treatment response may be due to genetic factors. One of the recent positive clinical trials found no significant efficacy for disulfiram in the subgroup of patients with the dopamine-β-hydroxylase gene allele that results in low enzyme activity (Kosten et al. 2013). Two other recent small controlled clinical trials in methadone-maintained patients that found no disulfiram efficacy overall did find significant efficacy in subgroups with functional variants in the ankyrin repeat and kinase domain containing 1 (*ANKK1*) and dopamine D_2 receptor (*DRD2*) genes (Spellicy et al. 2013) and α_{1A}-adrenoreceptor (*ADRA1A*) gene (Shorter et al. 2013b).

Although disulfiram is well tolerated in clinical trials, where subjects are carefully screened for medical and psychiatric comorbidity and closely monitored for adverse events, questions have been raised about its safety in routine clinical practice (Malcolm et al. 2008). Several human laboratory studies give conflicting results on the safety of the cocaine-disulfiram interaction (Baker et al. 2007), although recent studies found no clinically significant adverse effects from the triple interactions of cocaine-alcohol-disulfiram (Roache et al. 2011) or cocaine-methadone-disulfiram (Atkinson et al. 2013). These findings suggest that disulfiram may be a promising treatment for cocaine dependence in some subgroups of patients, although raising a caution about potential adverse drug interactions should patients use cocaine while on the medication.

23.2.2.4 Stimulants

Agonist maintenance treatment of cocaine-dependent patients with stimulant medication might be clinically beneficial in reducing cocaine craving and use (Shearer 2008), by analogy with methadone maintenance treatment of opioid dependence or nicotine replacement treatment of tobacco dependence. As with methadone, advantages might include use of the less medically risky oral route of administration (vs. injected or smoked cocaine), use of pure medication of known potency (thus avoiding adulterant effects or inadvertent overdose), and use of a medication with slower onset and longer duration of action (thus avoiding "rush"/"crash" cycling) (Lile 2006).

Several orally active psychomotor stimulants marketed for the treatment of attention deficit hyperactivity disorder (ADHD) or as appetite suppressants have been used to test the substitution approach (Amato et al. 2011; Mariani and Levin 2012). Sustained-release d-amphetamine (30–60 mg daily) was effective in two small controlled clinical trials, while immediate-release d-amphetamine (20–60 mg daily) and methylphenidate (90 mg daily) were not. A controlled clinical trial of the combination of sustained-release d-amphetamine with modafinil found poorer efficacy than with amphetamine alone or placebo (Schmitz et al. 2012). Mazindol, a stimulant approved for appetite suppression with less abuse potential than amphetamines (classified as Schedule IV controlled substance), was ineffective in three controlled clinical trials. None of these studies reported significant adverse effects, suggesting that stimulant substitution treatment might be safe in cocaine-using patients.

Modafinil, used for the treatment of excessive sleepiness in narcolepsy, obstructive sleep apnea, and shift work sleep disorder, is considered a weak stimulant (Schedule IV). Its mechanisms of action are unclear but include some blockade of presynaptic dopamine transporters as well as increases in brain glutamate release and decreases in GABA release (Ballon and Feifel 2006). A small phase II clinical trial found that 400 mg daily significantly reduced cocaine use (Mariani and Levin 2012). A later multisite clinical trial found no significant reduction in cocaine use in the study sample as a whole. However, in the subgroup of subjects without alcohol dependence, both 200 mg and 400 mg daily of modafinil significantly increased the percentage of abstinent days. Modafinil was safe and well tolerated. It does not

appear to evoke cocaine craving or itself produce euphoria. In phase I human laboratory studies, modafinil does not potentiate the effects of cocaine, nor does it alter cocaine pharmacokinetics, except for a decrease in the area under the cocaine plasma concentration-time curve over the first 3 h after intravenous cocaine administration (Donovan et al. 2005). These findings suggest that modafinil could be safely used in selected subgroups of cocaine-using patients.

Cocaine itself could be used for agonist maintenance treatment in a slow-onset formulation or route of administration (Gorelick 1998), in the same way that slow-onset transdermal or transbuccal nicotine is used to treat dependence on rapid-onset smoked nicotine (cigarettes). Oral cocaine salt capsules (100 mg four times a day) significantly attenuated the response to an intravenous cocaine challenge (25 mg) (Walsh et al. 2000). Both cocaine capsules and coca tea are used to treat addiction to coca paste smoking in Lima, Peru (where oral cocaine products are legal) (Llosa 2009). A case series of 50 coca paste smokers in La Paz, Bolivia, reported that chewing 100–200 g of coca leaf per week for a mean of 2 years substantially improved the mental health of one-third of the patients and improved the socioeconomic functioning of almost half (data on cocaine smoking were not reported) (Hurtado-Gumucio 2000).

23.2.2.5 Antipsychotics

The older (the so-called first-generation) antipsychotics, which are potent dopamine receptor antagonists (chiefly D2 [postsynaptic] subtype), do not significantly alter cocaine craving or use, as evidenced by clinical experience with patients with schizophrenia who abuse cocaine while receiving chronic antipsychotic treatment (Brady et al. 1990; Ohuoha et al. 1997). Greater efficacy was expected from the newer "second-generation" antipsychotics, in part because of their broader spectrum of receptor binding (including dopamine D1 and serotonin receptors). However, this promise has not been confirmed in clinical trials of cocaine users without comorbid psychiatric disorders (Amato et al. 2007). A small open-label trial of olanzapine in 21 patients dually dependent on cocaine and opioids (being treated with methadone) reported a decrease in cocaine use in 53.2 % of patients. However, three more recent controlled clinical trials reported no significant advantage for olanzapine over placebo (Amato et al. 2007; Hamilton et al. 2009). Two controlled clinical trials using oral risperidone and one using long-acting injectable risperidone (Loebl et al. 2008) also found no advantage over placebo.

Any antipsychotic should be prescribed with caution to cocaine users because of their potential vulnerability to the neuroleptic malignant syndrome, based on their presumed cocaine-induced dopamine depletion (Akpaffiong and Ruiz 1991). Cocaine users may also be at elevated risk of antipsychotic-induced movement disorders (Duggal 2007; Henderson et al. 2007).

23.2.2.6 Anticonvulsants

Anticonvulsants might be effective in the treatment of cocaine dependence because they increase inhibitory GABA activity and/or decrease excitatory glutamate activity in the brain, both actions that decrease the response to cocaine in the dopaminergic cortico-mesolimbic brain reward circuit (Brown et al. 2013).

Carbamazepine is the most studied anticonvulsant, but the promise of early open-label studies has not been confirmed in controlled trials. Four of five double-blind outpatient trials found no significant effect on cocaine use (Minozzi et al. 2008). Gabapentin was ineffective in three controlled clinical trials, as were lamotrigine and valproic acid in single trials (Minozzi et al. 2008).

Several other anticonvulsants provide more promising results. Tiagabine, which increases GABA activity by blocking its presynaptic reuptake, significantly reduced cocaine use in two controlled clinical trials at doses of 12 or 24 mg daily, but had no effect in a third trial at 20 mg daily (Minozzi et al. 2008). All three trials used concomitant cognitive behavioral therapy. Topiramate, which decreases glutamate activity by blocking AMPA-type glutamate receptors and increases GABA activity (by an unknown mechanism), significantly reduced cocaine use in a controlled clinical trial at up to 200 mg daily, in conjunction with cognitive behavioral therapy (Minozzi et al. 2008). Vigabatrin (γ-vinyl-GABA), which increases GABA activity by inhibiting the breakdown of GABA by GABA transaminase, reduced cocaine use in three small open-label studies and a controlled clinical trial, but not in a larger controlled clinical trial (Somoza et al. 2013). Phenytoin (300 mg daily) significantly reduced cocaine use in one controlled clinical trial, especially at serum concentrations above 6.0 μg/mL (Minozzi et al. 2008).

Baclofen, approved as an antispasmotic, increases GABA activity by acting as an agonist at $GABA_B$ receptors. One controlled clinical trial found that baclofen (60 mg daily) did not significantly reduce cocaine use, except in the subgroup of subjects with heavier cocaine use (Shoptaw et al. 2003).

23.2.2.7 Nutritional Supplements and Herbal Products

The use of amino acid mixtures, either alone or combined with other nutritional supplements (vitamins and minerals), is attractive because of their relative freedom from regulatory oversight, compared to prescription medications, and their perceived safety and absence of side effects. Proprietary mixtures, including tyrosine (the amino acid precursor of L-DOPA) and L-tryptophan (the amino acid precursor of serotonin), have been marketed with claims of efficacy, but a double-blind, 28-day crossover study found no significant effect of tyrosine and tryptophan (1 g of each daily) on cocaine craving or withdrawal symptoms (Chadwick and Gregory 1990). A more recent controlled clinical trial found L-tryptophan, even when coupled with contingency management treatment, no better than placebo in reducing cocaine use (Jones et al. 2004).

23.2.2.8 Other Medications

A wide variety of other medications have been evaluated for the treatment of cocaine dependence, often on the basis of promising case reports or animal studies suggesting that they influenced the reinforcing effects of cocaine.

Ondansetron, a $5\text{-}HT_3$ receptor antagonist approved for the treatment of nausea and vomiting, significantly reduced cocaine use in a small controlled clinical trial, but only at the highest dose (4 mg twice daily) (Johnson et al. 2006). Varenicline,

a partial agonist at α4β2 nicotinic acetylcholine receptors approved for smoking cessation, significantly reduced cocaine use in a small controlled clinical trial (Plebani et al. 2012).

Naltrexone, a μ-opioid receptor antagonist marketed for the treatment of alcohol dependence and opioid dependence, showed some efficacy at 50 mg/day in cocaine-dependent outpatients without alcohol or opioid dependence, but only when combined with relapse prevention therapy (Schmitz et al. 2001).

Doxazosin, an α_1-adrenergic receptor antagonist approved for the treatment of hypertension, when rapidly titrated over 4 weeks to a daily dosage of 8 mg, significantly reduced cocaine use in a recent small, controlled clinical trial (Shorter et al. 2013a).

Numerous medications were no better than placebo in (usually small-scale) controlled clinical trials (Gorelick 2014). These include amlodipine, a calcium channel blocker; mecamylamine, a nicotinic cholinergic receptor antagonist; the acetylcholinesterase inhibitors donepezil and galantamine; propranolol, a beta-adrenergic receptor antagonist; reserpine, a depleter of presynaptic monoamine neurotransmitters; hydergine, an agonist at dopamine and serotonin receptors and antagonist at alpha-adrenergic receptors that stimulates blood flow; pentoxifylline, a phosphodiesterase inhibitor; riluzole, an inhibitor of glutamate release; memantine, an NMDA glutamate receptor antagonist; *N*-acetylcysteine, which increases brain glutamate levels; celecoxib, a nonsteroidal anti-inflammatory drug; lithium; citicholine, which is neuroprotective and increases phospholipid turnover and monoaminergic neurotransmission; and dehydroepiandrosterone (DHEA), an endogenous steroid precursor of androstenedione, itself a precursor of androgenic and estrogenic hormones. DHEA is also a sigma-1 receptor agonist.

23.2.2.9 Medication Combinations

Concurrent use of two different medications might enhance efficacy while minimizing side effects, either by acting on a single neurotransmitter system by two different mechanisms or by acting on two different neurotransmitter systems (Gorelick 2014). Concurrent open-label use of the dopaminergic agents bupropion and bromocriptine in cocaine-dependent outpatients is safe, albeit with little efficacy. Concurrent use of pergolide (a dopamine D_1/D_2 receptor agonist) and haloperidol (a dopamine D_2 receptor antagonist), designed to produce relatively pure D_1 agonist action, also showed efficacy, as did combined use of amantadine and propranolol. The combination of extended-release mixed amphetamine salts and topiramate was significantly better than placebo in achieving three consecutive weeks of abstinence, but there were no individual drug groups to allow evaluation of the origin of the therapeutic effect. The combination of metyrapone, a cortisol synthesis inhibitor, and the benzodiazepine oxazepam tended to reduce cocaine craving and use in a small controlled clinical trial, but the 50 % dropout rate limits the internal validity of the study.

23.2.2.10 Other Physical Treatments

Acupuncture is an ancient Chinese treatment that involves mechanical (with needles), thermal (moxibustion), or electrical (electroacupuncture) stimulation of

specific points on the body surface. The mechanism of action is unknown; speculation has included stimulation of endogenous opioid systems. Acupuncture of the outer ear (auricular) gained popularity as a treatment for drug withdrawal, especially using five standard locations recommended by the National Acupuncture Detoxification Association (NADA): kidney, liver, lung, shen men, and sympathetic. Meta-analyses of nine published studies (six using the NADA locations) did not find a significant benefit of active acupuncture over sham treatment (Gates et al. 2006; Mills et al. 2005).

23.2.3 Special Treatment Situations

23.2.3.1 Mixed Addictions

Concurrent opioid use, including comorbid addiction, is a common clinical problem among cocaine-dependent individuals. Some individuals use cocaine and opioids simultaneously (as in the so-called speedball) to enhance the drugs' subjective effects. Up to 20 % or more of opioid-dependent patients in methadone maintenance treatment also use cocaine for a variety of reasons, including continuation of prior polydrug abuse, replacement for the "high" no longer obtained from opioids, self-medication for the sedative effects of high methadone doses, or attenuation of opioid withdrawal symptoms (Leri et al. 2003). Three different pharmacological approaches have been used for the treatment of dual cocaine and opioid dependence: (1) adjustment of methadone dose, (2) maintenance with another opioid medication, and (3) addition of medication targeting the cocaine dependence.

Higher methadone doses (usually 60 mg or more daily) generally are associated with less opioid use by patients in methadone maintenance. This relationship also holds in general for cocaine use among patients in methadone maintenance (Peles et al. 2006), although exceptions have been reported. Increasing the methadone dose as a contingency in response to cocaine use can be effective in reducing such use (and more so than decreasing the methadone dose in response to a cocaine-positive urine sample).

Buprenorphine is a partial opioid agonist (μ-receptor agonist/κ-receptor antagonist) used for the agonist substitution treatment of opioid dependence (Mattick et al. 2008). Advantages over methadone (a pure μ-receptor agonist) include a milder withdrawal syndrome and higher therapeutic index (i.e., safety in overdose). Some (but not all) studies in patients concurrently dependent on both opioids and cocaine suggest that cocaine use (as well as opioid use) is reduced at higher buprenorphine doses (16–32 mg daily) (Montoya et al. 2004).

Non-opioid medications for the treatment of cocaine dependence frequently are evaluated in methadone- or buprenorphine-maintained, opioid-dependent outpatients because the opioid agonist maintenance component substantially enhances treatment retention and adherence, improving the internal validity of the trial. A variety of the medications discussed earlier, including desipramine, fluoxetine, amantadine, bromocriptine, disulfiram, and bupropion, have been studied in opioid-maintained, cocaine-dependent patients. There is no evidence that such

maintenance treatment significantly influences medication efficacy, but no studies have directly addressed this issue.

Alcohol dependence is a common problem among cocaine-dependent individuals, both in the community and in treatment settings, with rates of comorbidity as high as 90 % (Gorelick 1992a). Alcohol use by cocaine-dependent patients is associated with poorer treatment outcome due to a variety of factors, including production of the toxic psychoactive metabolite cocaethylene (Pennings et al. 2002), stimulation of cocaine craving by alcohol, or alteration of medication metabolism by the hepatic effects of alcohol.

Two medications used in the treatment of alcohol dependence are also effective in the treatment of outpatients concurrently dependent on cocaine and alcohol. Disulfiram substantially decreased both cocaine and alcohol use in two clinical trials and a small case series, but not in a third clinical trial (Gorelick 2014). Naltrexone, a μ-opioid receptor antagonist approved for the treatment of alcohol dependence and opioid dependence, substantially decreased both cocaine and alcohol use at 150 mg daily, but not at 50 mg daily or 100 mg daily, the doses more typically used in treatment of alcohol or opioid dependence. Combined treatment with both disulfiram (250 mg daily) and naltrexone (100 mg daily) significantly improved abstinence from cocaine and alcohol (Pettinati et al. 2008a).

A recent controlled clinical trial found no significant effect of topiramate compared to placebo in reducing cocaine or alcohol use in outpatients with comorbid dependence, although topiramate-treated participants had better treatment retention and were more likely to be cocaine abstinent during the final 3 weeks of the 13-week trial (Kampman et al. 2013).

23.2.3.2 Psychiatric Comorbidity

Treatment-seeking, cocaine-dependent individuals have high rates of psychiatric diagnoses other than another substance use disorder (i.e., psychiatric comorbidity), with rates as high as 65 % for lifetime disorders and 50 % for current disorders. The most common comorbid disorders tend to be major depression, bipolar spectrum, phobias, and posttraumatic stress disorder (Conway et al. 2006). Personality disorders are common among treatment-seeking, cocaine-dependent individuals, with rates as high as 69 %. The most common of these is antisocial personality disorder (Compton et al. 2005).

Antidepressants vary in their efficacy for reducing cocaine use among patients with comorbid major depression, although there are few direct comparisons or controlled clinical trials (Nunes and Levin 2004; Rounsaville 2004). Desipramine, imipramine, and bupropion have usually, but not always, been found effective, whereas SSRIs (e.g., fluoxetine) and mirtazapine are usually not effective. Venlafaxine (150–300 mg daily) and nefazodone (200 mg twice daily) show some efficacy in small clinical trials (Gorelick 2014).

Both anticonvulsant "mood stabilizers" and antipsychotics are used to treat comorbid bipolar disorder and cocaine dependence. Case series and open-label trials suggest that anticonvulsants such as valproate, divalproex, lamotrigine, and carbamazepine have some efficacy in reducing cocaine use in dually diagnosed

patients (Brown et al. 2012) and are more effective than lithium. Combining lithium with an anticonvulsant may be helpful in treatment-resistant patients.

The second-generation antipsychotics show mixed results in cocaine-dependent patients with comorbid bipolar disorder (Nejtek et al. 2008). Quetiapine reduced cocaine use in one of two clinical trials; risperidone reduced cocaine use in one trial. Switching treated patients to aripiprazole did not reduce their cocaine use.

Up to one-fourth of cocaine-dependent adults have either adult ADHD or a history of childhood ADHD (Kollins 2008). Stimulant and dopaminergic medications are the mainstay of treatment for ADHD, suggesting that some of these patients may be self-medicating their ADHD with cocaine. Case series and clinical trials generally find that such medications successfully treat ADHD symptoms and reduce cocaine use in adults: dextroamphetamine (up to 60 mg/day), methamphetamine (15 mg/day), bupropion (up to 100 mg three times a day), and sustained-release methylphenidate (Gorelick 2014).

Although schizophrenia is not a common comorbid psychiatric disorder among cocaine-dependent individuals, cocaine use and abuse are common among treatment-seeking patients with schizophrenia (San et al. 2007). Clinical experience indicates that first-generation antipsychotics, at doses that are effective in the treatment of schizophrenia, do not significantly alter cocaine craving or use.

Several case series and open-label trials suggest that the second-generation antipsychotics, including clozapine, olanzapine, quetiapine, risperidone, and aripiprazole, may be more effective than older (first-generation) antipsychotics in reducing cocaine and other drug use among patients with schizophrenia (San et al. 2007). However, two head-to-head controlled clinical trials found no difference between olanzapine and haloperidol in reducing cocaine use, with each medication reducing cocaine craving in one of the trials. A controlled clinical trial comparing olanzapine and risperidone found a trend favoring greater reduction in cocaine use by olanzapine.

The use of cocaine can exacerbate or provoke antipsychotic-induced movement disorders (Duggal 2007; Henderson et al. 2007) and increase vulnerability to the neuroleptic malignant syndrome (Akpaffiong and Ruiz 1991).

23.2.3.3 Medical Comorbidity

Few data are available to guide the pharmacotherapy of cocaine dependence in medically ill patients, making this an important issue for future clinical research. Prudent clinical practice requires a careful medical evaluation of any patient before starting medication, with special attention to medical conditions common in cocaine-dependent individuals. Such conditions would include viral hepatitis and alcoholic liver disease, which might alter the metabolism of prescribed medications, and HIV infection. The presence of the latter necessitates caution in prescribing medications with a known potential for inhibiting immune function. Clinical experience suggests that buprenorphine (Carrieri et al. 2000) and bupropion can be used safely in HIV-positive patients, although anti-retroviral medications may decrease bupropion plasma concentrations (Hogeland et al. 2007).

23.2.3.4 Gender-Specific Issues

Women tend to be excluded from or underrepresented in many clinical trials of cocaine dependence pharmacotherapy (Gorelick et al. 1998), in part because of concern over risk to the fetus and neonate should a female subject become pregnant. Thus, there is a substantial lack of information about gender-specific issues of pharmacotherapy in general and the pharmacotherapy of cocaine dependence in particular (Helmbrecht and Thiagarajah 2008). Meanwhile, clinicians must deal on an ad hoc basis with the treatment implications of possible gender differences in medication pharmacokinetics (such as those resulting from differences in body mass and composition) and in pharmacodynamics (such as those related to the menstrual cycle or exogenous hormones such as oral contraceptives).

In the absence of directly relevant and systematically collected data, caution should be used when prescribing medications to pregnant women with stimulant dependence and to those with pregnancy potential, keeping in mind both the risks of medication and the risks of continued stimulant use. Some medications proposed for the treatment of cocaine dependence (such as tricyclic antidepressants, bupropion, and buprenorphine) have little potential for morphologic teratogenicity or disruption of pregnancy, although there are few or no data on behavioral teratogenicity. Some medications do pose at least slight risk, such as amantadine (associated with pregnancy complications), lithium (associated with cardiac malformations and neonatal toxicity), anticonvulsants (associated with increased risk of congenital malformations), and antipsychotics (associated with nonspecific congenital anomalies and neonatal withdrawal).

Some medications (e.g., disulfiram, naltrexone) may generate different treatment responses in men versus women (Carroll et al. 2012; Pettinati et al. 2008b). The reasons for such gender differences are poorly understood but may include differences in medication pharmacokinetics, hormonal interactions, or subjects' psychological or socioeconomic status.

23.2.3.5 Age

Although adolescents make up a substantial minority of heavy cocaine users, they have been largely excluded from clinical trials of cocaine pharmacotherapies because of legal and informed consent considerations. On the basis of the scarcity of published case reports, it is likely that medication is not often used in the treatment of adolescent cocaine dependence.

23.2.4 International Perspectives

The prevalence of cocaine use varies substantially by geographic region, based in part on the relative availability of cocaine and of other stimulants (United Nations Office on Drugs and Crime 2013). In addition, national differences in modes of cocaine use result in variation in cocaine addiction and related problems. The acute psychological effects of cocaine, and therefore its abuse liability, depend greatly on the rate at which drug reaches the brain. The more rapid the onset of effect, the more

intense the psychological effect and the greater the abuse liability (Nelson et al. 2006). This is the so-called rate hypothesis of psychoactive drug effect. As expected from this rate effect, routes of administration that produce rapid onset, such as intravenous and smoked, are associated with greater abuse liability than those with slower onset, such as intranasal and oral (Chen and Anthony 2004; Gorelick 1992b). Thus, the Andean countries in which oral cocaine ingestion is legal and common (e.g., by chewing the leaves, drinking coca tea) tend to have less cocaine addiction than might be expected from their prevalence of cocaine use (Montoya and Chilcoat 1996).

The treatment of cocaine addiction is generally comparable worldwide, with the exception of the Andean countries. The legal availability of oral forms of cocaine in those countries makes possible the agonist substitution approach using cocaine itself (Hurtado-Gumucio 2000; Llosa 2009). However, such treatment has never been evaluated in controlled clinical trials.

23.2.5 Future Prospects

Future progress in pharmacological treatment for cocaine dependence is likely to come from the development of new medications with novel or more selective mechanisms of action. New medications should evolve from an improved understanding of the neuropharmacology of cocaine dependence and animal studies of the interactions of cocaine with novel compounds.

Preclinical studies with compounds that bind to the same presynaptic dopamine transporter site as does cocaine (thereby keeping cocaine from acting), but which do not themselves produce robust reinforcing effects (because of slow onset of effect and tight, long-lasting binding), suggest that such compounds may be useful as functional cocaine "antagonists" (Rothman et al. 2008). Manipulation of brain dopamine activity with selective dopamine receptor ligands, especially for the D_3 type, attenuated the rewarding effects of cocaine in several animal studies (Heidbreder and Newman 2010) and awaits the development of compounds suitable for clinical trials. Medications that presynaptically release both dopamine and serotonin also show promise in animal studies (Rothman et al. 2007).

Cocaine administration, like stress, activates the hypothalamic-pituitary-adrenal (HPA) axis, and stress may play a role in relapse to cocaine use after abstinence. These observations stimulated interest in corticotrophin-releasing factor receptor antagonists, some of which reduce cocaine self-administration in animals (Specio et al. 2008).

The endogenous cannabinoid (endocannabinoid) brain neurotransmitter system modulates the dopaminergic reward system (Parolaro and Rubino 2008). The blockade of cannabinoid CB_1 receptors inhibits relapse to cocaine self-administration after abstinence in animals (Wiskerke et al. 2008). Therefore, CB_1 receptor antagonists (or inverse agonists) have promising therapeutic potential if they become available for clinical research, although this will require compounds without the psychiatric side effects seen with previously available agents.

The failure of existing medications to show consistent efficacy in the treatment of cocaine dependence has prompted growing interest in pharmacokinetic approaches, that is, preventing ingested cocaine from entering the brain and/or enhancing its elimination from the body (Gorelick 2012). The former approach could be implemented by active or passive immunization to produce binding antibodies that keep cocaine from crossing the blood-brain barrier. The latter approach could be implemented by administration of an enzyme (e.g., butyrylcholinesterase) that catalyzes cocaine hydrolysis or by immunization with a catalytic antibody. These pharmacokinetic approaches already show promise in attenuating cocaine's behavioral effects in animals. An anti-cocaine vaccine (i.e., active immunization against cocaine) showed promise in significantly reducing cocaine use in a phase II controlled clinical trial (Martell et al. 2009). Further work is needed to increase the consistency of the antibody response and lengthen the duration that antibody concentrations remain high enough to block cocaine use.

Transcranial magnetic stimulation (TMS) involves activation of the brain cells by magnetic fields generated by electromagnetic coils placed on the scalp. Repetitive TMS (rTMS) is approved as a treatment for depression and is under study as a treatment for addiction (Bellamoli et al. 2013). See sidebar for further information.

23.3 Conclusion

The absence of any medication that meets national regulatory standards for efficacy and safety leaves physicians with little clear-cut guidance for pharmacological treatment of stimulant dependence. Among existing medications marketed for other indications, none has yet been proved broadly effective in replicated controlled clinical trials. Disulfiram appears the most promising, especially for patients with comorbid alcohol abuse. Tricyclic antidepressants such as desipramine and imipramine (but not SSRIs such as fluoxetine) may be of use in patients with milder dependence or with comorbid depression. Anticonvulsants such as topiramate, tiagabine, and phenytoin (but not carbamazepine or gabapentin) show promise in controlled clinical trials and warrant further evaluation. The stimulant maintenance approach also warrants further evaluation using medications with low abuse potential (e.g., modafinil or sustained-release methylphenidate or amphetamine) or perhaps even a slow-onset (e.g., oral or transdermal) form of cocaine itself.

More sophisticated patient-treatment matching could enhance the efficacy of current medications by taking into account both patient characteristics that can influence treatment response (e.g., severity of dependence, withdrawal status, psychiatric comorbidity, or concomitant medications) and characteristics of the psychosocial treatment accompanying the medication. For example, a few studies suggest that some medications (e.g., L-DOPA, SSRIs) that are not effective when used with drug abuse counseling or cognitive behavioral therapy may be effective when combined with contingency management treatment (Moeller et al. 2007; Schmitz et al. 2008).

Improved understanding of the neurobiology of dependence should lead to new and more effective medications in the future, possibly by manipulation of the glutamate or endocannabinoid systems or HPA axis or by a pharmacokinetic mechanism. Regardless of which medications show promise in the future, their adoption into clinical practice should be guided by acceptable scientific proof of efficacy and safety, based on data from replicated, well-designed, adequately powered controlled clinical trials. Clinicians should also keep in mind the distinctions between efficacy (treatment works in a research setting in a selected research population getting close attention) and effectiveness (treatment works in a heterogeneous population in a realistic clinical environment) and between a statistically significant and clinically meaningful treatment effect (Miller and Manuel 2008).

Addiction to Amphetamines and Methamphetamines

24

Ahmed Elkashef

Contents

Abstract

ATS addiction ranks second globally and contributes greatly to the total burden of the disease of addiction. ATS addiction is associated with multiple health problems like HIV and psychiatric diseases like psychosis. Early intervention and treatment provided in an integrated setting promise better outcomes. Data from controlled clinical trials show efficacy for cognitive behavioral therapy (Matrix), motivational enhancement, and contingency management. Agonist medications like d-amphetamine and methylphenidate may have a role in treating ATS withdrawal symptoms and craving, particularly in patients with comorbid ADHD/ADD. Other medications that may be helpful are bupropion and modafinil for low to moderate users. Naltrexone and topiramate are also promising especially for ATS addicts that are also addicted to other substances like nicotine, alcohol, or opiates. Combination of psychotherapy particularly contingency management and pharmacological treatment may offer synergistic effects and have better outcome. The future is promising for better treatments including monoclonal antibodies ad vaccines for the treatment ATS addiction.

24.1 Introduction

According to the 2012 World Drug Report amphetamine-type stimulants (ATS) use is second only to marijuana as the most widely used illicit substance worldwide. An estimated prevalence of 0.3–1.2 % in 2010, or between 14 million and 52.5 million estimated global users, aged 15–64 years have used ATS at least once in the last year. Regions with the highest prevalence are Oceania and North and Central America. Increases in seizure of methamphetamine are also being reported in East, Southeast, and Central Asia and Transcaucasia (UNODC, World Drug Report 2012).

Methamphetamine and amphetamine have very similar pharmacodynamic effects; either can be metabolized to the other (Anglin et al. 2000; Haile 2007; Rasmussen 2008). Methamphetamine was first synthesized in 1919 by the Japanese pharmacologist Akira Ogata (Cho and Segal 1994). Amphetamine was originally synthesized by the Romanian chemist Lazăr Edeleanu in 1887. Both were used during war to reduce fatigue and were available over the counter in Japan as *Philopon* and *Sedrin*.

Both amphetamine and methamphetamine are highly addictive stimulant that can be easily manufactured in clandestine labs. Following recent clamp down on precursor's purchase, most ATS are now manufactured in super labs and smuggled into different countries. Common street names vary from country to country, e.g., "speed," "meth," "ice," "crystal," "crank," "glass," "Yaba," and "Captagon" just to name few.

ATS are potent dopamine uptake as well as vesicular monoamine transporter (VMAT2) blockers. The latter action is unique to ATS and not shared by other addictive stimulants like cocaine. VMAT2 blockers inhibit the incorporation of synthesized monoamines into the neuronal vesicles which lead to high concentrations of dopamine and other amines in the presynaptic terminal. This leads to higher levels of dopamine release and can also cause oxidative stress and damage to the presynaptic terminals. ATS also inhibit both monoamine oxidases A & B, which in turn makes monoamines more available and prolongs their action.

24.2 ATS-Health-Related Problems

Amphetamine and methamphetamine are approved in the USA and other countries worldwide for the treatment of attention-deficit/hyperactivity disorder, narcolepsy, and obesity. The weak isomer L-methamphetamine is used in the over-the-counter Vick's inhaler.

ATS are powerful stimulants, with short-term effects that include increased alertness, energy, and loss of appetite. Cardiovascular effects include irregular heartbeat, increased heart rate, and blood pressure. Hyperthermia, convulsions, and stroke have also been reported with ATS overdose and can result in death if not treated.

Long-term ATS abuse can lead to addiction and psychosis almost indistinguishable from schizophrenia. Other psychiatric symptoms include chronic anxiety, confusion, insomnia, mood disturbances, and violent behavior. PET studies have shown significant changes in striatal dopamine in chronic methamphetamine users in the form of downregulation or degeneration; these changes were associated with cognitive impairment.

Some of the effects of chronic methamphetamine abuse appear to be, at least partially, reversible. A recent neuroimaging PET study (Volkow et al. 2001) showed recovery in striatal dopamine transporter following prolonged abstinence (2 years, but not 6 months). This was associated with improved performance on motor and verbal memory tests. However, function in other brain regions did not display recovery even after 2 years of abstinence, indicating that some methamphetamine-induced changes are very long-lasting.

Withdrawal symptoms have been reported in patients attempting to stop or entering treatment, include depression, anxiety, fatigue, and an increased craving for the drug.

Injection drug use and risky sexual behavior among methamphetamine users have been associated with increase HIV and hepatitis B and C infections, especially among men who have sex with men. Methamphetamine abuse may also worsen the progression of HIV and its consequences, including greater neuronal injury and cognitive impairment compared with nondrug abusers.

Prenatal exposure to methamphetamine can lead to premature delivery, placental abruption, fetal growth retardation, and heart and brain abnormalities. Ongoing research is continuing to study developmental outcomes such as cognition, social relationships, motor skills, and medical status of children exposed to methamphetamine before birth. However the use of other substances or alcohol and maternal poor nutrition and health make the interpretation of these results difficult.

24.3 Treatment of ATS Addiction

The treatment of ATS addiction as any other addiction should by integrated, comprehensive, individualized, and long term. Psychotherapeutic interventions like contingency management, cognitive behavioral therapy, relapse prevention, Matrix, and 12-step-based therapy that have shown effectiveness in the treatment of other addictions have also shown efficacy in treating ATS addictions. These are detailed elsewhere in this book. Combining medications and psychotherapy like CM have been shown to have synergistic effect and should be incorporated in any treatment plan depending on the treatment setting.

Early intervention will also guarantee better outcomes as most addictions start in adolescence. To guarantee the best care, treatment should also be integrated as possible to address the multiple comorbid mental and physical problems that ATS addicts usually suffer.

In this chapter, we will focus in on psychopharmacological interventions that have been tried so far in the treatment of ATS.

24.3.1 Pharmacological Treatment

24.3.1.1 Agonist Medications

Methylphenidate

A dopaminergic stimulant approved for the treatment of ADHD was tried in methamphetamine dependence. An initial report of efficacy of SR methylphenidate (54 mg) against placebo and aripiprazole for intravenous amphetamine dependence in 20-week randomized trial was not replicated in the larger double-blind study of 79 patients (Tiihonen et al. 2007; Miles et al. 2013). High drop out rates and rigid clinic attendance were cited as possible reasons for the negative outcome. Higher doses of methylphenidate were recommended for future studies.

Dextroamphetamine

Another dopaminergic stimulant approved for weight loss, narcolepsy, and ADHD was tried in two double-blind studies in meth-dependent patients. The first trial used 110 mg of sustained release d-amphetamine daily for 12 weeks with gradual reduction over an additional 4 weeks. Medications were administered daily under supervision. The primary outcome was meth concentration in hair samples at baseline compared to follow-up using hair analysis. Although there was no significant effect for the primary outcomes, there was significantly greater reduction in meth withdrawal symptoms and craving compared to placebo (Longo et al. 2010). Another double-blind study (Galloway et al. 2011) used 60 mg sustained release d-amphetamine for 8 weeks showed no effect for the primary outcome of reducing meth use as evidenced by negative urines. Similar to the first study, this study also reported significant effect on reduction of craving and improving meth withdrawal symptoms for the d-amphetamine group.

Bupropion

The safety of coadministering bupropion and methamphetamine was assessed in a clinical pharmacology study with no evidence of cardiovascular adverse events or PK interaction (Newton et al. 2005). Two double-blind controlled outpatient studies investigated the effects of bupropion SR 150 mg BID in methamphetamine-dependent patients (Elkashef et al. 2008; Shoptow et al. 2008). Significantly, a positive effect in reducing meth use was reported in light users defined as use of 18 days or less/month. The effect was not seen in heavy users defined as >18 days of use in a month or more than two positive urines samples per week on screening. Confirmatory studies are underway.

Modafinil

Modafinil is a weak stimulant approved for the treatment of narcolepsy and obstructive sleep apnea. It is proposed to exert its action on the glutamate and hypocretin system; however, recent PET study suggests that it may also bind to the dopamine transporter. 200 mg of modafinil was tested in a double-blind trial for 10 weeks in 80 methamphetamine-dependent patients. The trial outcomes were negative except for a trend of reducing meth use in those who were medication

compliant and attended counseling sessions (Shearer et al. 2009). In another single blind study, modafinil combined with cognitive behavioral therapy (CBT) for treatment of 13 HIV + gay men with methamphetamine dependence. Six of the ten patients who completed the study reduced their methamphetamine use by over 50 % (McElhiney 2009). Another double blind trial of 400mg Modafinil for 12 weeks, in methamphetamine dependant patients (Henizerling et al. 2010) did not show effect on methamphetamine use.

A more recent multisite trial (Anderson et al. 2011) of 210 meth-dependent patients randomized to placebo, 200 mg or 400 mg of daily modafinil for 12 weeks was conducted. The primary outcome was methamphetamine negative urines per week; patients provided three urine samples weekly. The trial was negative; however, a post hoc analysis showed a significant effect for maximum duration of abstinence (23 days vs. 10 days) favoring modafinil among compliant patients. This study highlights the very important issue of measuring compliance in addiction clinical trials as poor compliance could explain some of the negative outcome.

24.3.1.2 Antagonist Medications

Aripiprazole

A partial agonist second-generation antipsychotic was studied in two human laboratory studies with significant effects on attenuation of subjective effects of orally administered d-amphetamine (Stoops et al. 2006). However, outpatient studies with aripiprazole have been negative. One double-blind randomized study of 15 mg daily had to be stopped prematurely because of high dropout rate and increased amphetamine use (Tiihonen et al. 2007). Another double-blind study of aripiprazole in 90 patients for 12 weeks failed to show significant results (Coffin et al. 2012). These studies don't support a role for aripiprazole in initiating abstinence or use reduction in actively using patients but it may have a role as a relapse prevention medication in abstianing patients.

24.3.2 Other Medications

24.3.2.1 GABA Agonists

Baclofen 60 mg and gabapentin 2,400 mg daily were tried in a double-blind study of 25 meth-dependent patients in a three-arm study for 16 weeks. Neither medication had an effect on reducing methamphetamine use compared to placebo. A post hoc analysis suggests a positive effect in patients who took higher doses of baclofen (Heinzerling et al. 2006). Topiramate a GABA agonist/AMPA antagonist medication was tested in an interaction study with methamphetamine which showed that topiramate enhanced some of the positive effects of methamphetamine. This was attributed to possible PK interaction on methamphetamine metabolism (Johnson et al. 2007). A multisite outpatient trial of topiramate 200 mg for reducing meth use was negative for the primary outcome. However, there was a positive effect in the subgroup of patients that had negative urines at randomization suggesting a role in relapse prevention (Elkashef et al. 2012). Vigabatrin (GVG) was tried in an

open-label study of 30 for 9 weeks. 18/30 subjects completed the study, and 16/18 tested negative for methamphetamine and cocaine during the last 6 weeks of the trial (Brodie et al. 2005). A safety clinical pharmacology interaction study was conducted in non-treatment-seeking methamphetamine-dependent patients given 15 and 30 mg i.v. doses of methamphetamine and doses of GVG up to 5 mg (De La Garza et al. 2009). There were no reports of cardiovascular interactions and no effects of GVG on methamphetamine subjective effects. No published reports currently exist of follow-up outpatient trials of GVG for the treatment of methamphetamine addiction.

Antidepressants

Mirtazapine was tried in a double-blind controlled study in 60 meth-dependent patients for 12 weeks with significant effect in reducing meth-positive urines (Colfax et al. 2011). The SSRIs, fluoxetine, paroxetine, and sertraline were each tried in double-blind controlled studies (Batki et al. 1999, 2000; Piasecki et al. 2002; Rawson et al. 2004; Shoptaw et al. 2006) with no effect on meth use.

Calcium Channels Blockers

Two calcium channel blockers isradipine and amlodipine were tried in human laboratory studies (Johnson et al. 1999; Batki et al. 2002) and reported to reduce the subjective and physiological responses to methamphetamine. However, a controlled outpatient clinical trial of amlodipine failed to show any efficacy in reducing methamphetamine use (Batki 2001).

Ondansetron

A serotonin 5-HT3 receptor antagonist was postulated to reduce dopaminergic release in the striatum. A double-blind multisite, randomized trial of three doses of ondansetron (0.25, 1, or 4 mg twice daily) for 8 weeks combined with CBT failed to show an effect over placebo at decreasing methamphetamine use (Johnson et al. 2008).

Naltrexone

In a human lab study of abstinent meth-dependent patients, naltrexone 50 mg significantly reduced the subjective effects of d-amphetamine (Jayaram-Lindstrom et al. 2007).

In a double-blind placebo-controlled outpatient study of 80 patients with amphetamine dependence, naltrexone 50 mg + relapse prevention therapy was effective in reducing amphetamine use (Jayaram-Lindstrom et al. 2008). Naltrexone plus N-acetyl cysteine were tried in adouble blind placebo controlled trail of 31 patients with methamphetamine dependence for 8 weeks. The primary outcome was reduction in craving (Grant et al. 2010). No effect was reported.

Rivastigmine

Acetylcholinesterase inhibitors have been shown in animal studies to reduce methamphetamine-seeking behavior. Rivastigmine was tried in a 2-week double-blind,

placebo-controlled human laboratory study to study its interactions with methamphetamine 30 mg given i.v. Rivastigmine reduced the cardiovascular and subjective effects of methamphetamine. The 3 mg dosage significantly reduced methamphetamine-induced increases in diastolic blood pressure and self-reports of craving and anxiety. In another controlled study, the same dosage reduced the positive subjective effects of intravenous meth self-administered in human volunteers (De La Garza et al. 2008). Outpatient trials are underway to test its efficacy in reducing meth use.

24.3.2.2 Future Medications Options

VMAT2 inhibitors are being developed as methamphetamine antagonists to block its action on the VMAT receptors. Lobeline a nicotinic alkaloid has been shown in animal studies to decrease self-administration of methamphetamine and block meth-induced dopamine release (Dwoskin et al. 2002; Neugebauer et al. 2007). Tetrabenazine, another VMAT2 inhibitor recently approved in the USA for the treatment of Huntington's disease and other hyperkinetic disorders, is being studied in animal models of addiction. Research is also ongoing for more selective VMAT2 compounds.

CRF-1 antagonists have been shown in preclinical data to block stress-induced relapse through control of cortisol release to alcohol, cocaine, and heroin. The search for a safe CRF-1 antagonist to advance to clinical trials is underway.

D3 antagonists have been shown to block priming, cues, and stress-induced self-administration of nicotine, cocaine, and heroin in animal studies, suggesting a role in relapse prevention in humans. Currently there are no selective D3 antagonists for human trials. Buspirone has been reported in PET studies to have D3 antagonist effect in primates, which may warrant some studies in humans untill a more selective D3 becomes avaialbe.

Cannabinoid-1 (CB-1) receptor antagonists e.g., Rimonabant are another compounds that have been reported to reduce or block self-administration and conditioned cues relapse in preclinical models of THC, nicotine, cocaine, MA, opiates, and ethanol.

Other compounds of interest are group I and group II metabotropic glutamate receptors. mGluR5 antagonists and AMPA receptor antagonists have been shown to block cue-induced relapse to cocaine and heroin in animal models.

Further development of these compounds in man will have far-reaching application in treating substance use disorders particularly polysubstance use.

Cognitive enhancers like D1 agonists, 5-HT 6 antagonists, and D-cycloserine may have a role in strengthening the frontal lobes inhibitory controls on impulsive behavior. They are also expected to improve cognition in ATS-addicted patients.

Other area of therapeutic development for addiction is **immunotherapy**. Vaccines and monoclonal antibodies are in early development for nicotine, cocaine, methamphetamine, and heroin, details of which are highlighted in another chapter.

24.4 Summary

- ATS addiction ranks second globally and contributes greatly to the total burden of the disease of addiction.
- ATS addiction is associated with multiple health problems like HIV and psychiatric diseases like psychosis.
- ATS addiction treatment like other addiction treatment should be started early and should be comprehensive, integrated, and long term.
- Psychotherapeutic interventions like CM, MI, CBT, Matrix, RP, and 12 steps are equally effective for the treatment of ATS addiction and should be utilized as appropriate.
- Agonist medications like d-amphetamine and methylphenidate may have a role in treating ATS withdrawal symptoms and craving, particularly in patients with comorbid ADHD/ADD.
- Other medications that may be helpful are bupropion and modafinil for low to moderate users.
- Naltrexone and topiramate are also promising especially for ATS addicts that are also addicted to other substances like nicotine, alcohol, or opiates.
- There are many trials that are currently in progress for ATS addiction; it is highly recommended that clinicians search the literature periodically for updates prior to initiating medication treatment for their patients.

Contents

Abstract

Although rates of tobacco use and dependence have been reduced substantially over the past 40 years, one in five Americans continues to smoke. The prevalence of smoking appears to be substantially higher in persons with

psychiatric and substance use disorders and has remained unchanged, as these smokers have less success in quitting smoking. The epidemiology of tobacco use and dependence and the pharmacological effects of nicotine and tobacco are reviewed followed by a discussion of the clinical assessment of tobacco users. We then review behavioral and pharmacological treatments, including the FDA-approved pharmacotherapies: nicotine replacement therapies (NRTs), sustained-release bupropion, and varenicline. Finally, integration of tobacco dependence treatment into mental health settings is discussed with the view that tobacco dependence is a chronic medical disorder and that more effective treatment of this comorbidity in psychiatric disorders may require targeted treatments based on a better understanding of the pathophysiology of individual psychiatric disorders.

25.1 Introduction

Tobacco smoking is the leading preventable cause of morbidity and mortality in the Western world (Giovino 2007; CDC 2013). In the USA, currently approximately 20 % of the population are tobacco users, which translates to roughly 46 million people. Worldwide, approximately 1.1 billion people use tobacco on a regular basis (George and O'Malley 2004). Around 33 % of those who try cigarettes will become addicted, and 70 % of those people will go on to want to quit completely. Since the release of the Surgeon General's report in 1965, smoking prevalence has been steadily declining, but this reduction appears to have slowed in recent years. Cigarette smoking remains the most common (>90 %) method of tobacco use. In addiction to cigarette smoking, pipe tobacco, cigars, smokeless tobacco, and snus are also common forms of tobacco use. Each year, approximately 450,000 people in the USA die as a result of smoking-attributable medical illnesses such as lung cancer, chronic obstructive pulmonary disease (COPD), cardiovascular disease, and stroke. Additionally, roughly eight million people are sick or disabled because of their cigarette use, and smoking has been estimated to cost the USA $96 billion in smoking-related medical expenses, as well as $97 billion in lost productivity annually (CDC 2013). Smoking is now increasing rapidly throughout the developing world, and it is estimated that current cigarette smoking will cause about 450 million deaths worldwide in the next 50 years. Reducing current smoking by 50 % would prevent 20–30 million premature deaths in the first quarter of this century and 150 million in the second quarter. For most smokers, quitting is the single most important thing they can do to improve their health, and the results of epidemiological studies in Norway suggest that even with sustained reductions (>50 %) in smoking consumption, there is little if any reduction in cardiovascular disease, lung cancer, or other smoking-related cancer risks (Tverdal and Bjartveit 2006), further substantiating the merits of quitting versus reducing smoking.

25.2 The Pathobiology, Clinical Manifestations, and Treatment of Nicotine Dependence

25.2.1 Biology of Nicotinic Receptors

Nicotine is the main psychoactive ingredient in tobacco smoke. When tobacco is smoked, the primary site of action of nicotine is the α4β2 nicotinic acetylcholine receptor (nAChR), which is also activated by the endogenous neurotransmitter acetylcholine. nAChRs in the CNS are pentameric ion channel complexes (Dani et al. 2011) comprised of two α and three β subunits. The seven α subunits are designated α2–α9, and the three β subunits are designated β2–β4. Due to this, there is considerable diversity in subunit combinations, which may explain some of the region-specific and functional selectivity of nicotinic effects throughout the CNS. These pentameric receptors are either homomerically or heteromerically arranged (e.g., $(\alpha4)_3(\beta2)_2$ or $(\alpha7)_5$). Activation of nAChRs leads to Na^+/Ca^{2+} ion channel fluxes and neuronal firing and chronic exposure to nicotine results in desensitization of the receptors. nAChRs are situated presynaptically on several different neurotransmitter secreting neuron types due to their wide dispersement throughout the CNS. Of importance for nicotine addiction are the nAChRs situated on mesolimbic dopamine (DA) neurons that project from the ventral tegmental area (VTA) to the nucleus accumbens (NAc). Activation of nAChRs on mesolimbic DA neurons leads to DA release in the NAc, which helps to facilitate the addictive process involved in chronic tobacco use.

At low concentrations of nicotine, α4β2 nAChR stimulation of afferent GABAergic projections onto mesoaccumbal DA neurons predominates, leading to reduced mesolimbic DA neuron firing and DA release. At higher nicotine concentrations, α4β2 nAChRs desensitize and activation of α7 nAChRs on glutamatergic projections predominates, which leads to increased mesolimbic DA neuron firing and DA secretion. Subsequently, nAChRs desensitize within several milliseconds of activation by nicotine. nAChRs then resensitize after overnight abstinence, which presumably explains why most smokers report that the first cigarette in the morning is the most satisfying. Some recent PET neuroimaging studies have shown that smoking two to three puffs from a cigarette produces saturation of nAChRs in the brain reward system (Brody et al. 2006), while other studies show that smoking to satiety (approximately 2.5 cigarettes) produces saturation (Esterlis et al. 2010). Interestingly, the nAChR saturation levels reached after smoking to satiety are similar to the saturation levels seen after smoking just a few puffs. Therefore, while binding to central nAChRs is an important first step in the effects of nicotine, it is not a complete explanation for continued smoking behaviors.

25.2.2 Clinical Effects of Nicotine and Tobacco

The majority of tobacco users (>90 %) smoke cigarettes. Most of these individuals smoke daily and have some degree of physiological dependence (Rigotti 2002).

However, smoking patterns have changed in recent years, and non-daily smokers now constitute 22–33 % of all adult smokers in the USA (CDC 2008, 2011; SAMHSA 2009). While these non-daily smokers seem dependence resistant, they still show the same difficulty with quitting as daily smokers do (Tindle and Shiffman 2011). Smokers typically describe a "rush" and feelings of alertness and relaxation when smoking, and it is well known that nicotine has both stimulating and anxiolytic effects depending on basal level of arousal. Stimulation of the airway is an aspect of smoking that many individuals will report as reinforcing, and additives such as menthol enhance the experience by increasing the taste and reducing the harshness of smoked tobacco. A diagnosis of nicotine dependence is accomplished clinically by following the criteria outlined in the Diagnostic and Statistical Manual of Mental Disorders IV-TR (DSM IV-TR). These criteria include documentation of daily smoking (typically 10–40 cigarettes per day) for several weeks, evidence of tolerance (e.g., lack of aversive effects of nicotine such as nausea), and the presence of symptoms of nicotine withdrawal upon smoking cessation. Withdrawal symptoms, which peak within 24 hours of cessation and usually subside within 48–72 h, include dysphoria, anxiety, irritability, decreased heart rate, insomnia (waking in the middle of the night), increased appetite, difficulty concentrating, restlessness, and craving for cigarettes. Additionally, most dependent smokers state that they smoke their first cigarette of the day within 5 min of awakening. Use of timeline follow-back procedures (Sobell et al. 1988) and smoking diaries have been used successfully to monitor smoking consumption over time. Scales such as the Fagerstrom Test for Nicotine Dependence (FTND) (Heatherton et al. 1991) allow assessment of the level of nicotine dependence with scores of $\geq$4 on a scale of 0–10 consistent with physiological dependence to nicotine. Nicotine craving and withdrawal can be reliably monitored using validated scales such as the Tiffany Questionnaire for Smoking Urges (Tiffany and Drobes 1991) and the Minnesota Nicotine Withdrawal Scale (Hughes and Hatsukami 1986).

Interestingly, the positive effects of cigarette smoking (e.g., taste, satisfaction) appear to be mediated by non-nicotine components of tobacco such as tar (Dallery et al. 2003). Besides positive reinforcement, withdrawal, and craving, there are several secondary effects of nicotine and tobacco use that may contribute both to maintenance of smoking and to smoking relapse including mood modulation (e.g., reduction of negative affect), stress reduction, and weight control. In addition, conditioned cues can elicit the urge to smoke even after prolonged periods of abstinence (Bedi et al. 2011). Specific effects might be most relevant to individuals high on dietary restraint (weight reduction) and psychiatric disorders (mood modulation, cognitive enhancement, stress reduction). These secondary effects may present additional targets for pharmacological intervention in certain subgroups of smokers (e.g., smokers with schizophrenia, depression, or obesity; George and O'Malley 2004).

25.2.3 Psychosocial Treatments

Several non-pharmacological interventions for smoking cessation are available. These non-pharmacological, or behavioral, treatments available to smokers include telephone quit lines, group and individual counseling, and self-help techniques (Ray et al. 2009a). Behavioral treatments for tobacco dependence can facilitate motivation to quit, provide an emphasis on the social and contextual aspects of smoking, and enhance overall success at smoking cessation (Patten and Brockman 2006). Six-month quit rates with behavior therapies are 20–25 %, and behavior therapy typically increases quit rates up to twofold over control groups. Additionally, providing behavioral support in addition to pharmacotherapy can increase the chance of a successful quit attempt by approximately 10–25 % (Stead and Lancaster 2012). The primary goals of behavioral therapies in the treatment of tobacco dependence include the following: (1) providing necessary skills to smokers to aid them to initiate smoking cessation and (2) teaching skills to avoid smoking in high-risk situations (see Table 25.1).

25.2.3.1 Brief Interventions and Self-help Materials

Brief advice has been found to increase the rate of smoking cessation (USPHS Guidelines, Fiore et al. 2008); therefore, it is recommended that doctors use the five As with all patients (*ask* patients if they smoke, *advise* patients to quit, *assess* patients' motivation level for quitting, *assist* with quit attempts, and *arrange* follow-up contacts). Providing self-help material is a form of brief intervention used to increase motivation to quit and impart smoking cessation skills. Several recent studies have documented that minimal behavioral interventions such as community support groups, telephone counseling, and computer-generated tailored self-help materials can augment smoking cessation rates in controlled settings (Stead and Lancaster 2012). Additionally, the greatest effect may be seen when adding some support (at least four therapy sessions) compared to no support at all (Stead and Lancaster 2012).

25.2.3.2 Motivational Interventions

The goal of motivational interviewing (MI) interventions is to elicit change through addressing ambivalence, increasing intrinsic motivation for change, and creating an atmosphere of acceptance in which patients take responsibility for making changes happen. Brief MI interventions have been developed for smoking cessation (Rollnick et al. 1997), and there is some evidence for increased smoking cessation using MI techniques (Carpenter et al. 2004). MI interventions can also be especially effective for adolescents (Heckman et al. 2010), possibly making MI useful for preventative efforts. Rollnick and colleagues (Rollnick et al. 1997) reported that clinicians found MI interventions to be feasible and acceptable due to the brief nature of the intervention and the focus on patient responsibility and enhancement of the clinician-patient relationship.

Table 25.1 Pharmacological and behavioral treatments for tobacco dependence

Treatment (*FDA-approved)	Mechanism of action	Rating
Nicotine replacement therapies*		
Gum (OTC)	Slow nicotine absorption gradually reduces nicotine craving and withdrawal	1
Transdermal nicotine patch (OTC)	Slow nicotine absorption gradually reduces nicotine craving and withdrawal	1
Lozenge (OTC)	Slow nicotine absorption gradually reduces nicotine craving and withdrawal	1
Vapor inhaler (prescription)	Fast nicotine absorption leads to stimulation of nAChR which rapidly reduces nicotine craving and withdrawal	1
Nasal spray (prescription)	Fast nicotine absorption leads to stimulation of nAChR which reduces craving and withdrawal	1
Non-nicotine pharmacotherapies		
Bupropion SR*	Blocks reuptake of DA and NA; high-affinity, noncompetitive nAChR antagonism reduces nicotine reinforcement, withdrawal, and craving	1
Varenicline*	Acts as a partial agonist of $\alpha_4\beta_2$ nAChRs	1
Nortriptyline	Blocks reuptake of NA and 5-HT; probably reduces withdrawal symptoms and comorbid depressive symptoms; side effects limit utility	1–2
Clonidine	α_2-Adrenoreceptor agonist reduces nicotine withdrawal symptoms	2
Mecamylamine	Noncompetitive, high-affinity nAChR antagonist combined with TNP reduces nicotine reinforcement, craving, and withdrawal	2
Cytisine	Acts as a partial agonist of $\alpha_4\beta_2$ nAChRs, but might have limited efficacy at dose necessary for cessation	2
Naltrexone	Endogenous μ-opioid peptide receptor antagonist reduces nicotine craving and withdrawal in combination with TNP; may reduce alcohol use and obviate cessation-induced weight gain	3
Nicotine vaccine	Limited evidence of efficacy for smoking cessation in early human trials, may also have utility in relapse-prevention	2
Behavioral treatments		
Self-help materials	Increase motivation to quit and impart cessation skills (e.g., community support, telephone counseling)	2
Cognitive behavioral therapy	Behavioral strategies are developed to manage triggers; cognitive coping strategies target maladaptive thoughts to prevent relapse	1
Motivational enhancement therapy	Promotes patient's self-motivational statements, and in turn, patient gains greater awareness of the problems with smoking; increases intention for smoking cessation	2

Effectiveness ratings: 1 = strong evidence to support efficacy; 2 = moderate evidence to support efficacy; 3 = little evidence to support efficacy

25.2.3.3 Cognitive Behavioral Therapies

In CBT (cognitive behavioral therapy), patients learn strategies to anticipate and cope with situations in which they are likely to relapse to smoking. Some degree of efficacy of cognitive behavioral therapies in smokers with and without

psychiatric and substance use disorders has been observed for both individual (Lancaster and Stead 2006) and group (Stead and Lancaster 2005) counseling formats. Additionally, work by Brody and colleagues (2013) has shown that reduced smoking with CBT (without pharmacotherapies) can reduce nAChR densities to normal receptor levels.

25.2.3.4 Relapse Prevention

A large number of smokers relapse within 6 months of quitting, with the majority of smokers relapsing within the first week after a quit attempt (Hughes et al. 2004). Focusing on relapse prevention skills including recognizing high-risk situations and coping with lapses can be included in initial smoking cessation treatment or following a quit attempt. Recent studies have not found an overall benefit for including relapse prevention with smokers after a quit attempt and suggest that more work is needed in this area of treatment research.

25.2.4 Pharmacological Treatments

There are three FDA-approved classes of smoking cessation pharmacotherapies – nicotine replacement therapies (NRTs), sustained-release bupropion, and varenicline. According to the 2008 update to the Public Health Service *Treating Tobacco Use and Dependence Clinical Practice Guideline* (Fiore et al. 2008), five NRTs, as well as bupropion SR and varenicline, all reliably increase cessation rates in comparison to placebo. Several other off-label and novel medications are also discussed in this section (see Table 25.1).

25.2.4.1 Nicotine Replacement Therapies

The goal of nicotine replacement therapy (NRT) is to relieve tobacco withdrawal, by providing nicotine without the harmful effects of cigarette additives, which allows smokers to focus on habit and conditioning factors when attempting cessation. After the acute withdrawal period, nicotine replacement therapy is gradually reduced so that little withdrawal should occur. NRTs rely on systemic venous absorption and so do not produce the rapid high levels of arterial nicotine achieved when cigarette smoke is inhaled. Thus, individuals are unlikely to become addicted to NRTs. NRTs should be discontinued if the person restarts smoking, although safety concerns regarding smoking on patch appear to be less serious than previously thought. All commercially available forms of NRT are effective and increase quit rates by approximately 1.5–2.5-fold compared to placebo (Silagy et al. 2004). The transdermal patch, gum, and lozenge are over-the-counter (OTC), while the nasal spray and inhaler are by prescription. At the time of the writing of this chapter, there are significant changes being proposed for the use of NRTs, including extending their duration of use past 6–12 weeks and removing the recommendation to stop patch use when a smoker relapses to smoking (Sims and Fiore 2002).

Nicotine Gum

Nicotine ingested orally is extensively metabolized on first pass through the liver. Nicotine polacrilex gum avoids this problem via buccal absorption. Because of the ad-lib nature of the nicotine gum, smokers are able to respond immediately to any stressors or cues that may be present in their environment (Piper et al. 2007). Nicotine gum was approved as an OTC medication in the USA in 1996 and contains 2 or 4 mg of nicotine that can be released from a resin by chewing. Nicotine gum should be administered by scheduled dosing (e.g., one piece of 2-mg gum/h). The original recommended duration of treatment was 3 months, though many experts believe longer treatment is more effective. Nicotine absorption from the gum peaks 30 min after beginning to use the gum. Venous nicotine levels from 2- and 4-mg gum are about one third and two third, respectively, of the steady-state (i.e., between cigarettes) levels of nicotine achieved with cigarette smoking. Nicotine via cigarettes is absorbed directly into the arterial circulation; thus, arterial levels from smoking are five to ten times higher than those from the 2- and 4-mg gums. Absorption of nicotine in the buccal mucosa is decreased by an acidic environment, and patients should not use beverages (e.g., coffee, soda, juice) immediately before, during, or after nicotine gum use.

Several placebo-controlled trials established the safety and efficacy of nicotine gum for smoking cessation [reviewed in (Silagy et al. 2004)]. There appears to be some evidence to support using higher doses of nicotine gum (4-mg pieces) in more highly dependent cigarette smokers ($\geq$25 cpd), which supports the idea of matching nicotine gum dose to dependence level of the smoker (Stead et al. 2012).

Side effects from nicotine gum are rare and are mostly limited to those of mechanical origin (e.g., difficulty chewing, sore jaw) or of local pharmacological origin (e.g., burning in the mouth, throat irritation). Tolerance develops to most side effects over the first week, and education about how to properly use the gum (e.g., do not chew too vigorously) decreases side effects.

Nicotine Polacrilex Lozenges

Nicotine lozenges that deliver nicotine (2- and 4-mg preparations) by buccal absorption were approved for OTC use in the USA in 2002. Because of the ad-lib nature of use (similar to that of the nicotine gum), lozenges are able to offer further flexibility for nicotine replacement options for smokers and are known to allow great absorption of nicotine as compared to nicotine gum. Just as with the gum, mild throat and mouth irritation have been reported in preliminary trials (Shiffman et al. 2002). A 6-week double-blind, placebo-controlled RCT of 2- and 4-mg nicotine lozenges has shown their superiority to placebo lozenge (Shiffman et al. 2002), with significant reduction in nicotine craving and withdrawal. Furthermore, high doses of lozenge may be more efficacious in heavily dependent smokers suggesting that lozenge dose can be matched with dependence level.

Nicotine Transdermal Patch

The four transdermal nicotine formulations take advantage of ready absorption of nicotine across the skin. Three of the patches are for 24-h use and one is for 16-h use.

Starting doses are 21–22 mg/24-h patch and 15 mg/16-h patch. Patches are applied daily each morning. Nicotine via patches is slowly absorbed so that on the first day venous nicotine levels peak 6–10 h after administration. Thereafter, nicotine levels remain fairly steady with a decline from peak to trough of 25–40 % with 24-h patches. Nicotine levels obtained with the use of patches are typically half of those obtained by smoking. After 4–6 weeks on high-dose patch (21 or 22 mg/24 h and 15 mg/16 h), smokers are tapered to a middle dose (e.g., 14 mg/24 h or 10 mg/16 h) and then to the lowest dose after 2–4 more weeks (7 mg/24 h or 5 mg/16 h). Most studies suggest that abrupt cessation of the use of patches often causes no significant withdrawal; thus, tapering does not appear to be necessary (Silagy et al. 2004). The recommended total duration of treatment is usually 6–12 weeks.

The overall efficacy of the nicotine transdermal patch (NTP) for smoking cessation has been well documented (Silagy et al. 2004). A meta-analysis of 17 RCTs in 1994 (Fiore et al. 1994) reported end of treatment abstinence rates for NTP of 27 % versus 13 % for placebo patch (OR 2.6) and 22 % versus 9 % at 6-month follow-up (OR 3.0). The effects of active NTP were independent of patch type, treatment duration, tapering procedures, and behavioral therapy format or intensity, though it should be noted that behavioral treatment enhanced outcomes with patch compared to patch alone. Additionally, combining the patch with nicotine lozenge has been shown to produce the greatest benefit for smoking cessation relative to placebo (above that of lozenge alone, patch alone, bupropion SR, and bupropion + nicotine lozenge relative to placebo) (Piper et al. 2009).

Significant adverse events with nicotine patches have not been found, with the most common minor side effects being skin reactions (50 %), insomnia and increased or vivid dreams (15 % with 24-h patches), and nausea (5–10 %). Tolerance to these side effects usually develops within a week of use. Rotation of patch sites helps to decrease skin irritation. Insomnia reported in the first week post-cessation appears to be mostly due to nicotine withdrawal rather than the nicotine patch itself. A 24-h patch can be removed before bedtime to determine if the insomnia is due to the nicotine patch. Without treatment, insomnia usually abates after 4–7 days. There appears to be little dependence liability associated with patch use as only 2 % of patch users continue to use this product for an extended period after a cessation trial (West et al. 2000), and this continued abstinence may be due to the desire to maintain abstinence (Shiffman et al. 2003).

Nicotine Nasal Spray

Nicotine nasal spray is a prescribed NRT that is formulated as a nicotine solution in a nasal spray bottle similar to those used with saline sprays. This NRT was approved for treatment of nicotine dependence in the USA in 1996. Nasal spray delivers droplets that average about 1 mg per administration and is administered (10 mg/ml) to each nostril every 4–6 h. The nicotine spray produces a more rapid rise in nicotine levels than that of nicotine gum but falls below the levels achieved by cigarettes. Peak nicotine levels occur within 10 min, and venous nicotine levels are about two third those of between-cigarette levels. Smokers may use the nasal spray ad lib up to 30 times/day for 12 weeks, including a tapering period.

Randomized, double-blind, placebo-controlled trials of nasal spray versus placebo spray (Silagy et al. 2004) have established the safety and efficacy of the nasal spray for smoking cessation. Both trials employed treatment for 3–6 months, and active nasal spray led to a doubling of quit rates during active use relative to placebo use. Differences were reduced or absent with extended follow-up suggesting the need for maintenance use of this agent. However, maintenance studies with nicotine nasal spray have yet to be published.

The major side effects associated with the use of nicotine nasal spray are nasal and throat irritation, rhinitis, sneezing, coughing, and watering eyes. Nicotine nasal spray may have some dependence liability; in a controlled study by West et al. (2001), prolonged use of nasal spray was determined to be the case in 10 % of smokers using the nasal spray, so follow-up of smokers using nasal spray is recommended.

Nicotine Vapor Inhalers (NVI)

NVI are cartridges (plugs) of nicotine (containing about 1 mg of nicotine each) placed inside hollow cigarette-like plastic rods. When warm air is passed through the cartridges, a nicotine vapor is produced, which is then inhaled. Absorption from nicotine inhaler is primarily buccal rather than respiratory. More recent versions of inhalers produce a rise in venous nicotine levels more rapidly than with nicotine gum but less rapidly than with nicotine nasal spray, with nicotine blood levels of about one third that of between-cigarette levels. Smokers are instructed to puff continuously on the inhaler (0.013 mg/puff) during the day, and recommended dosing is 6–16 cartridges daily. The inhaler is to be used ad lib for about 12 weeks.

No serious medical side effects have been reported with nicotine inhalers. Fifty percent of subjects report throat irritation or coughing. Double-blind, placebo-controlled RCTs (Silagy et al. 2004) have demonstrated the superiority of NVI to placebo inhalers for smoking cessation. Results revealed a two- to threefold increase in quit rates (17–26 %) at trial endpoint compared to placebo inhalers and smaller differences at follow-up periods of 1 year or longer. These data support the short-term efficacy of NVI in cigarette smokers, but longer-term trials with the inhaler are needed, and there is some modest concern about abuse liability, due to long-term use of the product in less than 10 % of smokers (West et al. 2001).

25.2.4.2 Sustained-Release Bupropion

The phenylaminoketone, atypical antidepressant agent bupropion, in the sustained-release (SR) formulation (Zyban®), is a non-nicotine first-line pharmacological treatment for nicotine-dependent smokers who want to quit smoking. The mechanism of action of this antidepressant agent in the treatment of nicotine dependence likely involves dopamine and norepinephrine reuptake blockade (Ascher et al. 1995), as well as antagonism of high-affinity nAChRs (Slemmer et al. 2000). The exact mechanism for bupropion's anti-smoking effects is unclear. The goals of bupropion therapy are as follows: (1) smoking cessation, (2) reduction of nicotine craving and withdrawal symptoms, and (3) prevention of cessation-induced weight gain.

The target dose of this agent in nicotine dependence is 300 mg daily (150 mg bid), and it is typically started 7 days prior to the target quit date (TQD) at 150 mg daily, then increased to 150 mg bid after 3–4 days. Unlike the NRTs, there is no absolute requirement that smokers completely cease smoking by the TQD, though many smokers report a significant reduction in urges to smoke and craving, which facilitates cessation at the time of the TQD when drug levels reach steady-state plasma levels. Some smokers gradually reduce their cigarette smoking over several weeks prior to quitting. Smokers who are faster metabolizers of nicotine (as determined by genetic variation at the CYP2A6 allele) may benefit more from bupropion therapy, as opposed to NRT or counseling (Ray et al. 2009b).

A pivotal multicenter study by Hurt and colleagues (1997) established the efficacy and safety of sustained-release (SR) bupropion for treatment of nicotine dependence which led to its FDA approval in the USA in 1998. In a 7-week double-blind, placebo-controlled multicenter trial, three doses of bupropion SR (100, 150, and 300 mg/day in bid dosing) in combination with weekly individual cessation counseling were given to 615 cigarette smokers using at least 15 cigarettes per day. The end of trial 7-day point prevalence cessation rates for each of the bupropion doses, placebo, 100 mg/day, 150 mg/day, 300 mg/day, were 19.0 %, 28.8 %, 38.6 %, and 44.2 %, respectively. At 1-year follow-up, cessation rates were 12.4 %, 19.6 %, 22.9 %, and 23.1 %, respectively. Bupropion treatment also dose dependently reduced weight gain associated with smoking cessation and significantly reduced nicotine withdrawal symptoms at 150 and 300 mg/day doses.

The primary side effects reported with bupropion administration in cigarette smokers are headache, nausea and vomiting, dry mouth, insomnia, and activation. Many of these side effects are observed in the first week of treatment. The main contraindication for the use of bupropion is a past history of seizures of any etiology. The rates of de novo seizures are low with this agent (<0.5 %) at doses of 300 mg daily or less but have been observed when daily dosing exceeds 450 mg/day.

The combination of bupropion SR with nicotine transdermal patch (NTP) was evaluated in a double-blind, double placebo-controlled, randomized multicenter trial (Jorenby et al. 1999). A total of 893 cigarette smokers, using at least 15 cigarettes per day (cpd), were randomized to one of four experimental groups: (1) placebo bupropion (0 mg/day) + placebo patch; (2) bupropion (300 mg/day) + placebo patch; (3) placebo bupropion + nicotine patch (21 mg/day for 4 weeks, with 2 weeks of 14 mg/day and 2 weeks of 7 mg/day); and (4) bupropion + patch. Bupropion was administered 1 week prior to the target quit date (Day 15) at which time patch treatment was initiated for a total of 8 weeks. All subjects received weekly individual smoking cessation counseling. Cessation rates at the 1-year follow-up assessment were 15.6 % for placebo, 16.4 % for active NTP alone, 30.3 % for bupropion alone, and 35.5 % for the combination of patch and bupropion. Both bupropion + patch and bupropion-alone groups were significantly better than the placebo and patch-alone conditions, but the combination was not significantly better than bupropion alone. Weight suppression after cessation was most robust in the combination therapy group. Side effects were consistent with the profiles of

patch and bupropion, and the combination was well tolerated. However, a higher than expected rate of treatment-emergent hypertension (4–5 %) was noted with the combination of bupropion and patch (Jorenby et al. 1999). Of note, patch-alone treatment was significantly different from placebo at the end of the trial, but not at the follow-up assessments.

Hays et al. (2001) examined the effects of bupropion versus placebo on the prevention of smoking relapse in 784 cigarette smokers who achieved smoking abstinence after a 7-week open-label trial of bupropion (300 mg/day). Abstinent smokers were then randomized to bupropion (300 mg/day) or placebo for a total of 45 weeks. Fifty-nine percent of smokers enrolled in the open-label phase of the trial quit smoking. Significantly more smokers were abstinent at the end of the 52-week treatment period in bupropion versus placebo groups (55.1 vs. 42.3 %, $p < 0.01$), but not at the 1-year follow-up assessment. In addition, days to smoking relapse were higher in the bupropion versus placebo group (156 vs. 65 days, $p < 0.05$). Weight gain was significantly less in the bupropion group at both the end of treatment and 1-year follow-up. The results of this study suggest the efficacy of bupropion in preventing smoking relapse. Data regarding the optimal duration of bupropion therapy for maintenance treatment requires further study.

25.2.4.3 Varenicline

Varenicline tartrate (Chantix® in the USA, Champix® in Europe and Canada), an $\alpha_4\beta_2$ nAChR partial agonist and weak $\alpha 7$ agonist, was approved as a first-line smoking cessation agent by the USFDA in 2006. The results of two independent but identical 12-week Phase III trials comparing varenicline (1 mg bid) to bupropion SR (150 mg bid) and placebo have recently been published (Gonzales et al. 2006; Jorenby et al. 2006). The quit rate for both studies were similar for continuous abstinence over the last 4 weeks (weeks 9–12) of the study: Study 1 (Jorenby et al. 2006) varenicline, 43.9 %; bupropion SR, 29.8 %; and placebo, 17.6 %; Study 2 (Gonzales et al. 2006) varenicline, 44.0 %; bupropion SR, 29.5 %; and placebo, 17.7 %. Quit rates were significantly higher for participants taking varenicline compared to bupropion SR ($ps < 0.0001$), and both drugs resulted in significantly higher quit rates than placebo. Continuous abstinence over the follow-up period (weeks 9–52) was lower, and participants taking varenicline continued to show a higher rate of abstinence (Study 1, 22.1 %; Study 2, 23.0 %) than participants taking bupropion (Study 1, 16.4 %, $p < 0.001$ compared to varenicline; Study 2, 15.0 %, $p = 0.064$ compared to varenicline) and placebo (Study 1, 8.4 %; Study 2, 10.3 %). A third study examining the efficacy of the drug on smoking relapse-prevention used a 12-week open-label varenicline phase followed by randomization to 12 weeks of varenicline or placebo (Tonstad et al. 2006). These investigators found that participants taking varenicline versus placebo were more likely to be continuously abstinent during weeks 13–24 (70.5 % vs. 49.6 %, $p < 0.001$) and weeks 13–52 (43.6 % vs. 36.9 %, $p = 0.02$). Varenicline was found to reduce cravings and smoking satisfaction and to be safe and well tolerated. There were similar discontinuation rates for varenicline and bupropion, and the most common adverse event reported by the varenicline group was nausea (Study 1, 28.1 %; Study 2, 29.4 %).

There have been significant concerns about treatment-emergent neuropsychiatric adverse events such as suicidal and homicidal ideation, psychosis, mania, and aggression with the use of varenicline for smoking cessation. However, reviews of the evidence in clinical treatment (McClure et al. 2010) and evidence from controlled smoking cessation clinical trials in psychiatric populations such as schizophrenia (Williams et al. 2012; Pachas et al. 2012) and bipolar disorder (Wu et al. 2012) suggest the safety of this agent for smoking cessation including in high-risk psychiatric populations. Further research on the safety and utility of these agents in psychiatric and addicted populations is clearly warranted.

25.2.4.4 Off-Label Medications

Cytisine

Cytisine (Tabex® in Europe) is a nicotinic partial agonist that binds with high affinity to the $\alpha_4\beta_2$ nicotinic acetylcholine receptor. West and colleagues (2011) assessed the safety and efficacy of cytisine in the first randomized, placebo-controlled trial for the drug and found that it was significantly more effective for smoking cessation than placebo. Additionally, cytisine is a low-cost treatment and may be an option for those who cannot afford other pharmacotherapy.

Nortriptyline

Nortriptyline is a tricyclic antidepressant which has been shown in several double-blind, placebo-controlled trials to be superior to placebo (Hall et al. 1998; Prochazka et al. 1998) and to have comparable efficacy to bupropion (Hall et al. 2002). Higher intensity behavioral therapies may help to improve its efficacy. The mechanism of action is thought to relate to norepinephrine and serotonin reuptake blockade. Side effects include dry mouth, blurred vision, constipation, and orthostatic hypotension. It appears to have some utility in smokers with past histories of major depression, but its potential for fatal overdose has likely limited its utilization in smokers. However, nortriptyline can be recommended as a second-line agent after nicotine replacement therapies and bupropion, though more study of this agent is necessary.

Clonidine

Clonidine is a presynaptic alpha-2 receptor agonist that dampens sympathetic activity originating at the locus ceruleus. It appears to have efficacy for treating opioid withdrawal and thus was tested with nicotine withdrawal during smoking cessation trials. The most common side effects of clonidine are dry mouth, sedation, and constipation. Postural hypotension, rebound hypertension, and depression are rare with smoking cessation treatment. Several clinical trials tested oral or transdermal clonidine in doses of 0.1–0.4 mg/day for 2–6 weeks with and without behavior therapy and have suggested clonidine is more effective in women than in men. In general, the effects of clonidine have not proven to be as robust as NRTs. An initial study in $n = 71$ heavy smokers by Glassman et al. (1988) showed that at doses up to 0.4 mg/day, cessation rates were doubled in comparison to placebo, and in a follow-up study by this group in $n = 300$ smokers, this initial finding was replicated (Glassman et al. 1993). In fact, a meta-analysis by Covey and Glassman (1991) of

nine placebo-controlled studies and 813 patients found short-term quit rates of 39 % on clonidine versus 21 % on placebo (OR 2.4, 1.7–32.8) and suggested that clonidine was effective in the transdermal preparation and more helpful in female smokers. A subsequent meta-analysis by Gourlay and Benowitz (1995) found long-term follow-up quit rates in four subsequent studies of 31 % on clonidine and 17 % on placebo (OR 2.0, 1.3–3.0). It appears to be useful in reducing nicotine withdrawal symptoms acutely and may have a role in smokers who have high levels or anxiety during early cessation (Niaura et al. 1996). This agent should be considered as a second-line therapy for smokers failing initial treatment with NRTs or bupropion.

Mecamylamine

Mecamylamine (MEC) is a noncompetitive blocker at the ion channel site of both high-affinity central nervous system and peripheral nAChRs. When MEC is given to smokers who are not trying to stop smoking, they initially increase their smoking in an attempt to overcome the blockade produced by this drug. MEC does not precipitate withdrawal in humans perhaps because it is a noncompetitive nAChR antagonist. Common side effects included abdominal cramps, constipation, dry mouth, and headaches. Based on the idea that combined blockade and agonist therapy at the nAChR might be beneficial (similar to the nAChR partial agonist profile of varenicline), two randomized trials were conducted comparing MEC in combination with nicotine patch to placebo and nicotine patch. The rationale of these trials was that MEC would reduce the rewarding effects of nicotine, and the patch would reduce nicotine withdrawal symptoms (Rose et al. 1994, 1998). In the first trial (Rose et al. 1994), MEC (up to 10 mg/day, 5 mg bid for 5 weeks) or placebo was given in combination with nicotine patch (21 mg/day) for up to 8 weeks, and cessation rates were significantly higher in the combination group than the patch-alone group (12/24 [50.0 %] vs. 4/24 [16.7 %], $p < 0.05$). Mecamylamine was reported to reduce cigarette craving and negative affect and appetite increases associated with tobacco withdrawal. In a subsequent study of 80 cigarette smokers (Rose et al. 1998), MEC at doses of up to 10 mg/day was given as a pretreatment for 4 weeks prior to nicotine patch initiation at the TQD, and the combination of MEC and patch was continued for 6 weeks. Similar to the first study, the combination of MEC with NTP increased continuous abstinence rates after the TQD compared to NTP alone (19/40 [47.5 %] vs. 11/40 [27.5 %], $p < 0.05$). These data suggest the efficacy of the combination of MEC with NTP, and this combination should be considered a second-line therapy.

Naltrexone

Naltrexone is a long-acting congener of the μ-opioid receptor antagonist naloxone. The rationale for using naltrexone for smoking cessation is that the performance-enhancing and other positive effects of nicotine may be opioid-mediated (Pomerleau 1998; Krishnan-Sarin et al. 1999). Early studies observed that naltrexone monotherapy increases smoking, presumably an attempt to overcome blockade; however, a study of naltrexone in heavy-smoking alcoholics found that cigarette smoking was decreased modestly (Rosenhow et al. 2003). Adverse events include

elevated liver enzymes, nausea, and vomiting. A trial by Covey and colleagues (1999) in 68 cigarette smokers using at least 20 cpd and highly motivated to quit compared naltrexone (up to 75 mg/day) initiated 3 days prior to the TQD to placebo for a total of 4 weeks. Cessation rates in the naltrexone group were nonsignificantly higher than placebo (46.7 % vs. 26.3 %, $p < 0.10$), and at 6-month follow-up there were no group differences. Recently, treatment with naltrexone has been shown to reduce post-cessation weight gain among women, but not men (King et al. 2012).

Additional promising data with naltrexone was observed with the combination of naltrexone and NRT. A preliminary study by Krishnan-Sarin et al. (2003) suggested that the combination of naltrexone and NTP is superior to NTP alone when NTP administration precedes that of naltrexone (presumably to decrease naltrexone-related withdrawal). In a larger trial of the combination of nicotine patch (21 mg/day) with four active doses of naltrexone (0, 25, 50, and 100 mg/day), it was shown that the highest dose of naltrexone with patch significantly improves continuous smoking abstinence rates compared to placebo (O'Malley et al. 2006), but these effects appeared to be confined to the first weeks of treatment. Further studies of naltrexone either alone or in combination with the patch are needed, including in patients with concurrent alcohol misuse.

Nicotine Vaccines

Nicotine vaccines (Hatsukami et al. 2005) are being developed by a number of companies, but these are not currently available for public use. A systematic review of smoking cessation trials conducted by pharmaceutical companies as part of the drug development process showed that nicotine vaccines, while well tolerated, did not enhance long-term cessation rates (Hartmann-Boyce et al. 2012), and recent Phase III trials of one nicotine vaccine preparation (Nabi Biopharmaceuticals) suggested that these agents did not increase rates of smoking cessation in nicotine-dependent smokers. However, the nicotine vaccine may have promise for the prevention of smoking relapse or initiation of smoking and could be developed for these indications in the future. Side effects include soreness at the injection site and hypersensitivity reactions to vaccine components.

25.2.5 Integration of Tobacco Dependence Treatment into Mental Health-Care Settings

As the high rates of tobacco use and dependence and low rates of smoking cessation are becoming increasingly appreciated in psychiatric and addicted populations (Lasser et al. 2000; Grant et al. 2004; Kalman et al. 2005), it is increasingly evident that mental health and addiction clinics have done little to address the tobacco culture that permeates these institutional environments. However, smoking bans are becoming increasingly common in psychiatric hospitals and addiction treatment programs and appear to be successfully implemented in the majority of reported cases (Lawn and Pols 2005), but these developments have shown little uptake and application in community settings (Mackowick et al. 2012).

The utilization of standard tobacco dependence treatments such as behavioral therapies, NRT, bupropion, and varenicline has been increasingly reported in psychiatric and substance-abusing smokers. For example, various formulations of NRT including nicotine patch (Addington et al. 1998; George et al. 2000; Chou et al. 2004) and nasal spray (Williams et al. 2004) as well as sustained-release bupropion (Evins et al. 2001, 2005; George et al. 2002) and varenicline (Williams et al. 2012; Pachas et al. 2012) have been reported to be well tolerated and efficacious in increasing rates of both smoking reduction and cessation in patients with schizophrenia, when combined with cognitive behavioral and motivational enhancement therapies. Both NRTs and bupropion have also been studied in smokers with major depression (Kinnunen et al. 1996; Hayford et al. 1999; Chengappa et al. 2001), posttraumatic stress disorder (Hertzberg et al. 2001; McFall et al. 2005), and alcohol (Hurt et al. 1995; Hughes et al. 2003; Kalman et al. 2004) and opioid (Shoptaw et al. 2002) dependence to be well tolerated and effective; small trials with bupropion SR (Weinberger et al. 2008) and varenicline (Wu et al. 2012) have suggested their safety and effectiveness in smokers with bipolar illness. Moreover, studies which compared integration of behavioral and pharmacological treatments in a mental health setting for smokers with PTSD found enhanced quit rates compared to nonintegrated smoking cessation therapies (McFall et al. 2005, 2006), suggesting that provision of integrated mental health and tobacco treatment produces enhanced cessation outcomes.

Finally, a better understanding of the pathophysiology of mental disorders may lead to improved treatments for this population. There is increasing evidence that available pharmacological and behavioral treatments, modified for those with mental disorders, can be used safely and effectively in these populations (Mackowick et al. 2012). For example, schizophrenia is associated with a broad range of cognitive deficits particularly those related to prefrontal lobe dysfunction, and atypical antipsychotic drugs (e.g., clozapine, olanzapine) which improve certain cognitive deficits associated with schizophrenia may facilitate reduction of smoking (George et al. 1995; McEvoy et al. 1995; Procyshyn et al. 2002) or smoking cessation with standard pharmacotherapies such as nicotine patch (George et al. 2000) or bupropion SR (George et al. 2002). The development of novel medications which target the underlying pathophysiology of psychiatric or substance use disorders may well lead to important advances in the management of tobacco dependence in these special populations of smokers.

25.3 Conclusion

Tobacco dependence remains one of the leading preventable causes of morbidity and mortality in the Western world. Nonetheless, smoking cessation therapies are among the most cost-effective and proven therapies in psychiatry and medicine. Yet, most health-care providers do not identify tobacco use in their patients. In fact, a survey of psychiatric practices found that only 9.1 % of smokers under the care of psychiatrists received treatment for nicotine dependence (Montoya et al. 2005).

Nonetheless, the American Psychiatric Association has recently published an update of its Clinical Practice Guidelines for Nicotine Dependence (Kleber et al. 2006) which should provide standards for the field of psychiatric in the assessment and treatment of tobacco dependence. Furthermore, while medication and behavioral treatments have documented efficacy in treating tobacco dependence, it is important that these therapies be used in combination to achieve the best overall results and ensure adequate skill acquisition and treatment adherence. Future challenges include developing safer and more effective smoking cessation therapies and making these therapies available to all smokers who want to quit.

25.3.1 Key Points

- Tobacco dependence rates have decreased substantially, but many of the remaining smokers appear to have comorbidities that reduce their chance of quitting such as psychiatric and substance use disorders.
- Identification of smokers in clinical settings is of critical importance to the treatment of tobacco dependence.
- There are effective pharmacological and behavioral therapies for tobacco dependence, which work best when used in combination.
- A better understanding of the pathophysiology of mental health and addictive disorders may lead to improved treatment approaches for tobacco dependence in these smoking populations.
- Smokers with psychiatric and substance use comorbidity may be best treated in settings which integrate smoking cessation treatments with mental health and addiction treatment.

Addiction to Caffeine and Other Xanthines

26

Thierry Favrod-Coune and Barbara Broers

Contents

Abstract

Xanthine (3,7-dihydro-purine-2,6-dione) is a purine base that can naturally be found in human body tissues and fluids as well as in plants and other organisms. Methylated xanthines (methylxanthines) are phosphodiesterase inhibitors and adenosine receptor antagonists. Methylxanthines have thus different effects: reduce inflammation and immunity, reduce sleepiness and increase alertness, but also stimulate the heart rate and contraction and dilate the bronchi. The most

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment: International Perspectives*, DOI 10.1007/978-88-470-5322-9_18,

well-known methylxanthines are caffeine, methylbromine, and theophylline. Coffee and caffeine withdrawal symptoms exist and are often not recognized, especially in treatment settings, where caffeine withdrawal can be confounded with other symptoms. Caffeine intoxication and withdrawal are recognized clinical entities, but caffeine dependence is currently not. Caffeine withdrawal occurs in half of regular coffee drinkers, even at moderate caffeine intake. The most common symptoms are headache, fatigue, and difficulty to concentrate. Health professionals and patients should be better informed about these symptoms and the risk of occurrence of caffeine withdrawal. There is little research of treatments for clinical problems associated with xanthine use or abuse.

26.1 Introduction

For professionals in the addiction field, discussing the issue of caffeine, in a private or professional context, is a pleasure. Finally there is a domain that allows us to have a sort of positive message: "drink your coffee, it's probably good for you, it's probably good for your patients."

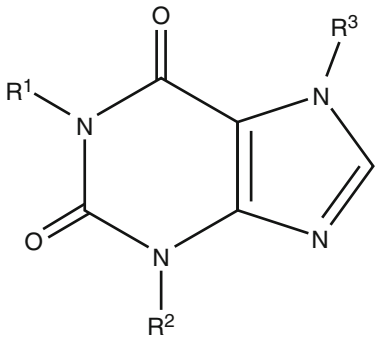
Our image of "controllers" telling in general frightening stories about the risks of smoking, drinking, sniffing, or injecting different psychoactive substances can be slightly improved if we can enchant the benefits of a few cups of espresso in the morning. And it is even better if we can carefully formulate the recommendation not to forget the daily bit of dark chocolate, full of theobromine, another member of the methylxanthine group.

But is this really so? Are we sure there are no acute or long-term risks related to caffeine use? Is there a safe level of use? Should we talk about coffee or caffeine use? Are there subgroups of patients that should avoid xanthine use? And what about caffeine addiction, is it a clinical entity or a popular but misused term?

In this chapter we will focus mostly on caffeine and marginally on other methylxanthines. The objective of this chapter is to describe the effects, risks, and benefits of use of caffeine; discuss "caffeinism and chocoholism"; and provide some clinical recommendations.

26.2 Caffeine and Methylxanthines

Xanthine (3,7-dihydro-purine-2,6-dione) is a purine base that can naturally be found in human body tissues and fluids as well as in plants and other organisms. Methylated xanthines (methylxanthines; *see* Fig. 26.1 *for chemical structure*) are phosphodiesterase inhibitors (increasing intracellular cAMP, activating protein



Caffeine: R1 = R2 = R3 = CH3

Theobromine: R1 = H, R2 = R3 = CH3

Theophylline: R1 = R2 = CH3, R3 = H

Fig. 26.1 Chemical structure of methylxanthines (Source: http://en.wikipedia.org/wiki/File:Methylxanthin_%28R1,_R2,_R3%29.svg)

kinase A, inhibiting the synthesis of tumor necrosis factor (TNF)-alpha and leukotriene) and adenosine receptor antagonists (inhibiting sleepiness-inducing adenosine). Methylxanthines have thus different effects: reduce inflammation and immunity, reduce sleepiness and increase alertness, but also stimulate the heart rate and contraction and dilate the bronchi. The most well-known methylxanthines are caffeine, methylbromine, and theophylline.

Caffeine can be found naturally in coffee beans but also in tea leaves, guarana, and mate plants or kola nuts. Theobromine and theophylline are found in cacao beans and mate plants; tea leaves contain some theophylline. Caffeine and other methylxanthines can be manufactured. Theophylline is a well-known asthma medication, currently used mostly as second line.

Caffeine is absorbed rapidly and completely through the gastrointestinal tract. After oral consumption the plasma peak is after 30–45 min, and the half-time elimination is around 3.5–6 h (Greden 1992) with high variability related to age, hormones, use of nicotine or medications, etc. Metabolization takes essentially place in the liver through the cytochrome P450 pathway, especially through the cytochrome CYP1A2. The deficiency of CYP1A2 enzymes has been shown to impair caffeine metabolism and prolong caffeine half-life (Cornelis et al. 2006), as can certain medications, such as disulfiram (Beach et al. 1986) or quinolones, through CYL1A2 inhibition. Also during pregnancy, the half-life of caffeine increases, with one study suggesting that in the last month of pregnancy, half-life increases to 10.5 h on average (Knutti et al. 1982). Smokers seem to metabolize caffeine more quickly through acceleration of demethylation steps, with normalization of the enzyme-inducing effects of nicotine occurring after 4 days of abstinence (Brown et al. 1988).

Caffeine is metabolized in the liver into 10 % theobromine, 4 % theophylline, and 80 % paraxanthine (Cornish and Christman 1957), so this means that theobromine can be found in the human body even without intake of chocolate.

Only 3 % of caffeine is excreted through the urine.

26.3 Caffeine, Coffee, Tea, and Energy Drinks

Caffeine (1,3,7-trimethylxanthine) taken in coffee and tea can be considered the world's most widely consumed psychostimulant. Over 80 % of the population takes these beverages daily, with important regional differences (Greden and Walters 1992). Coffee is preferred to tea in most developed countries (except in England and Ireland) where 71.5 % of the total amount of coffee of consumed. Tea is (until now) preferred in the developing countries, particularly in Asia, Argentina, Chile, Paraguay, and Uruguay. These countries count for over three quarters of the tea consumption in the world. The total quantity of tea consumed is much higher than coffee, and tea is thus the second beverage consumed after water.

The use of the so-called energy drinks seems to be on the rise especially among young people in the developed world (Reissig et al. 2009; Wolk et al. 2012) and in the sports population, with between 50 % and 70 % of elite athletes taking these drinks (Del Coso et al. 2012). In the USA the sale of energy drinks increased from 100 to 600 million dollars between 2002 and 2006 (Reissig 2009).

It should be kept in mind that coffee and tea contain several other components that can be responsible for potential beneficial and adverse health effects, such as antioxidants (e.g., polyphenols, catechins, flavonoids). Also, the way the beverages are prepared (filtered or unfiltered coffee) and what is added (sugar, milk, creamer, flavors) will have a potential impact on health. Caffeine (mostly artificial) is also added in different soft and energy drinks, as well as in prescribed and over-the-counter medications.

In Europe, the typical dose of caffeine for a cup a coffee is around 60–70 mg; for a cup of tea, 35 mg; for a glass of Coca-Cola, 46 mg; and for an energy drink, about 80 mg (Favrod-Coune and Broers 2010).

In the United States, the average consumption of caffeine is 280 mg per day, which is the equivalent of two cups of filtered coffee per day. Soft drinks contain variable amounts of caffeine, but official FDA limits are 71 mg per drink of 12 oz (355 mL). The so-called energy drinks can contain up to 300 mg of caffeine per drink of 250 mL and up to 500 mg for a bottle (Reissig 2009) (*see* Table 26.1 *for caffeine content of selected foods, beverages, and drugs*).

Individuals taking four or more cups of coffee per day (over 1,000 mg of caffeine daily) are considered to be heavy coffee users (Kabagambe et al. 2013).

With regard to chocolate consumption, inhabitants of Central Europe are considered the champions with over 10 k of chocolate taken per year, whereas in most Asian countries the average citizen takes less than 200 g of chocolate

Table 26.1 Caffeine content in selected food, beverages, and drugs

Product	Serving size	Caffeine per serving (mg)	Caffeine (mg/L)
Percolated coffee	207 mL (7 US fl oz)	80–135	386–652
Drip coffee	207 mL (7 US fl oz)	115–175	555–845
Coffee, decaffeinated	207 mL (7 US fl oz)	5–15	24–72
Coffee, espresso	44–60 mL (1.5–2.0 US fl oz	100	1,691–2,254
Coffee, espresso decaffeinated			
Tea – black, green, and other types – steeped for 3 min	177 mL (6 US fl oz)	22–74	124–416
Guayakí yerba mate (loose leaf)	6 g (200 US fl oz)	Approx. 358	
Hot cocoa	207 mL (7 US fl oz)	3–13	14–62
Hershey's special dark chocolate (45 % cacao content)	1 bar (43 g or 1.5 oz)	31	–
Hershey's milk chocolate (11 % cacao content)	1 bar (43 g or 1.5 oz)	10	–
Coca-Cola classic or diet	355 mL (12 US fl oz)	34	96
Mountain dew	355 mL (12 US fl oz)	54	154
Guaraná Antarctica	355 mL (12 US fl oz	30	100
Red Bull	250 mL (8.5 US fl oz)	80	320
Cocaine energy drink	250 mL (8.5 US fl oz)	288	1,152
Caffeine tablet (regular strength)	1 tablet	100	–
Caffeine tablet (extra strength)	1 tablet	200	–
Excedrin tablet	1 tablet	65	–

per year. According to the International Cocoa Organization (www.icco.org), the world per caput consumption of cocoa has increased over the last 10 years, from 0.54 kg in 2002/2003 to 0.61 kg in 2010/2011. For the average Brit, German, or Swiss, cocoa consumption is estimated to be around 5 k per year (13 g daily).

26.4 Main Effects of Caffeine

Caffeine is mostly taken for its psychostimulating properties: it increases alertness, energy, and ability to concentrate, also in those working in night shifts and suffering from jetlags (Ker et al. 2010).

A normal portion of chocolate has also this "arousing" effect, probably through the combined effect of caffeine and theobromine (Smit et al. 2004). The counter side of the stimulating effect of caffeine is the occurrence of sleeping difficulties, with little or no tolerance developing for this effect.

Caffeine increases physical performance, with different studies suggesting that even at 1–2 mg of caffeine per kg of body weight (around one 250 mL serving of an energy drink), reaction time, alertness, and aerobic and anaerobic performance are improved. At higher dose (3 mg caffeine/kg body weight), the ability to repeatedly sprint and the distance covered at high intensity improve, and the jump height increases (Del Coso et al. 2012).

The cardiovascular effects of caffeine include mainly the acceleration of heart rate and increase of force of contraction, with heavy caffeine use potentially triggering tachycardia and arrhythmia in susceptible persons. Anxiety and panic attacks occurring after (in general high dose of) coffee intake can be related to both the psychostimulating effect and tachycardia induced by caffeine (Kabagambe et al. 2013).

With regard to gastrointestinal effects, caffeine will increase gastric secretion and gastric acidity, possibly influencing absorption of different nutritional and pharmacological elements (e.g., iron), but most studies have been inconclusive. Caffeine stimulates the smooth muscles, thus impacting on bowel function and decreasing constipation (Kabagambe et al. 2013).

Caffeine definitely has a diuretic effect, an effect that is rapid and strong. Probably both gastric and urinary discomforts contribute to spontaneous cessation of coffee intake in the elderly (Greden 1992).

26.5 Risks of Caffeine Use

26.5.1 Acute Risks

Caffeine has a low risk profile, but after intake of large quantities (over 250 mg), especially in non-tolerant subjects, an overstimulation of the central nervous and the cardiovascular system can occur, resulting in what is called a "caffeine intoxication." This clinical entity is mentioned in both the Diagnostic and Statistical Manual of Mental Disorders (DSM) and International Classification of Diseases (ICD).

In DSM-IV, the caffeine-related disorders are as follows:

292.89 – induced anxiety disorder
292.89 – induced sleep disorder
305.90 – intoxication
292.9 – related disorder NOS

For the ICD-10 criteria of caffeine intoxication, please see Table 26.2.

The incidence of caffeine intoxication seems to be increasing; it occurs mainly in young patients, mainly due to the use of caffeine-containing medications or energy drinks (not due to coffee intake), and when hospitalization is necessary, there is in general co-occurring use of other psychoactive substances or pharmaceutical products (McCarthy et al. 2008). Death from caffeine overdose has been described (Holmgren et al. 2003), but it is not clear if in these cases patients have taken medications or have genetic cytochrome abnormalities

Table 26.2 ICD 10 criteria for intoxication and withdrawal state of caffeine and other stimulants (other than cocaine, F 14.0)

F15.0 Acute intoxication due to use of other stimulants, including caffeine
A. The general criteria for acute intoxication (F1x.0) must be met
B. There must be dysfunctional behaviour or perceptual abnormalities, as evidenced by at least one of the following
(1) Euphoria and sensation of increased energy
(2) Hypervigilance
(3) Grandiose beliefs or actions
(4) Abusiveness or aggression
(5) Argumentativeness
(6) Lability of mood
(7) Repetitive stereotyped behaviours
(8) Auditory, visual, or tactile illusions
(9) Hallucinations, usually with intact orientation
(10) Paranoid ideation
(11) Interference with personal functioning
C. At least two of the following signs must be present
(1) Tachycardia (sometimes bradycardia)
(2) Cardiac arrhythmias
(3) Hypertension (sometimes hypotension)
(4) Sweating and chills
(5) Nausea and vomiting
(6) Evidence of weight loss
(7) Pupillary dilatation
(8) Psychomotor agitation (sometimes retardation)
(9) Muscular weakness
(10) Chest pain
(11) Convulsions
F15.3 Withdrawal state from other stimulants, including caffeine
A. The general criteria for withdrawal state (F1x.3) must be met
B. There is dysphoric mood (for instance, sadness or anhedonia)
C. Any two of the following signs must be present
(1) Lethargy and fatigue
(2) Psychomotor retardation or agitation
(3) Craving for stimulant drugs
(4) Increased appetite
(5) Insomnia or hypersomnia
(6) Bizarre or unpleasant dreams

From ICD-10 (2013)

inhibiting caffeine metabolism. Based on animal studies, the median lethal dose was estimated to be 192 mg/kg; when extrapolating to humans, this should correspond to an intake of around 10 g of caffeine, corresponding to 80–100 cups of coffee (Peters 1967), making the occurrence of overdose with regular coffee not very probable.

26.6 Chronic Risks of Caffeine Use

26.6.1 Caffeine Dependence and Addiction

"Caffeine dependence" and "caffeine abuse" are not included in the DSM-IV, even if these terms are frequently used in the lay and medical literature. In general there are not sufficient criteria to establish the diagnosis of caffeine dependence, even if 50 % of regular caffeine users will present with withdrawal symptoms in case of acute abstinence. As for caffeine intoxication, the caffeine withdrawal syndrome is included in both DSM and ICD classifications. The ICD-10 criteria for the caffeine withdrawal state (F15.3) are found in Table 26.2.

During the preparation of the new DSM5 classification discussions on the inclusion of caffeine dependence and/or withdrawal syndrome have taken place, but caffeine was not included as a DSM-5 substance abuse disorder (see www.dsm5.org).

The caffeine withdrawal syndrome is probably largely underdiagnosed. It can occur after sudden abstinence from regular caffeine even at rather low intake of 100 mg daily (Juliano and Griffiths 2004). The most frequent symptoms are headache, fatigue, decreased energy/activeness, decreased alertness, drowsiness, decreased contentedness, depressed mood, difficulty concentrating, irritability, and being foggy/not clearheaded. Symptoms occur after 12–24 h of abstinence and last for several days. The severity and duration of symptoms are related to the amount of regular caffeine intake. Juliano and Griffiths (2004) suggest that expectancies are not a prime determinant of caffeine withdrawal and that avoidance of withdrawal symptoms plays a central role in habitual caffeine consumption.

Patients who are hospitalized and depending on their state or inpatient regulations (decaffeinated coffee only in psychiatric settings) can find themselves in caffeine withdrawal with symptoms that can be misinterpreted or unrecognized. For instance, for a patient suffering from head trauma and not receiving his daily coffee, the severity of the headache can very well be influenced by the lack of caffeine.

The same misinterpretation can occur during expeditions at high altitude. For practical reasons or fear of increasing sleeplessness and risk of dehydration, caffeine intake is often stopped in this context. Several symptoms of altitude sickness and caffeine withdrawal are common, such as headache, fatigue, and lassitude (Hackett 2010). Hackett suggests that during expeditions caffeine likely will have more beneficial than negative effects, especially in regular coffee drinkers.

26.6.2 Other Chronic Risks

Heavy caffeine use is often associated with increased risk for use, misuse, or dependence on other substances or addictive behaviors. This correlation does absolutely not mean causality, but different studies suggest a two- to threefold increase of prevalence of tobacco dependence or problematic alcohol use for those

consuming more than 6–7 cups of coffee per day compared to those taking 1–2 cups (Greden 1992; Kabagambe 2013). The combined (and increasing) use of energy drinks with alcohol in adolescents and young adults deserves specific attention.

Caffeine can induce panic attacks in some individuals, but seems not be correlated to the occurrence of negative outcomes of chronic psychiatric problems. A link between heavy caffeine use and schizophrenic relapse has been suggested but not confirmed (Greden 1992).

Several studies suggest a correlation between high caffeine intake (>5 cups of coffee daily) and risk of lower bone density and increased risk of fracture, especially in lean elderly women and/or those having low calcium intake, but with tea intake correlated to higher bone density (Korpelainen 2003; Kagambe 2013).

The use of unfiltered coffee has been associated with increased level of cholesterol, a major risk factor for cardiovascular disease (Rodrigues 2003). Still, the effect of filtered and unfiltered coffee on other risk factors is not fully clear, and even if caffeine can induce tachycardia and arrhythmia, the available literature suggests that caffeine has more benefits than risks for cardiovascular disease.

The same seems to be true for the oncology field (see below).

26.7 Benefits of Methylxantine

26.7.1 Caffeine

As said before, when considering the benefits of caffeine, we remind that there is a difference between the benefits of caffeine itself and the benefits of coffee or other caffeine-containing drinks. Coffee contains hundreds of other compounds that are antioxidants (polyphenols, flavonoids, catechins, melanoidins, etc.) that pass through coffee filters.

Moreover, it is globally difficult to speak only of caffeine because only few publications are about caffeine itself. Most scientific evidence is related to studies on coffee and do not consider the biologic effect of caffeine. In energy drinks, the consequences of caffeine are difficult to isolate from those due to the high content of sugar and other components like vitamins or the amino acid taurine.

First of all, there are strong suggestions that taking caffeine from coffee is associated with a diminution of the risk of total or specific mortality (Freedman et al. 2012). This study is based on the follow-up of more than 229,000 men and 173,000 women for 13 years. At inclusion, participants' age varied between 50 and 71 years. After adjustment for tobacco-smoking status and other possible biases, the risk of death was inversely correlated to coffee consumption. The benefit became significant at one cup of coffee per day for men (hazard ratio 0.94, 95 % confidence interval 0.86–0.93) and at two or three cups of coffee for women (hazard ratio 0.87, 95 % confidence interval 0.83–0.92). The benefit tended to rise with the amount of coffee taken, with a statistical inverse correlation between caffeine and mortality. An inverse correlation was also observed for death from respiratory disease, injuries, diabetes, and infection. No association was found between caffeine and

cancer-related mortality. These results were confirmed in subgroups, including people in very good health at inclusion. In this study, the inverse correlation for heart disease and stroke was at the limit of statistical significance. Cardiovascular diseases will be discussed later in the chapter.

When searching specific potential benefits of coffee for several diseases, the most impressive observed effect is on liver disease. A large cohort study (Klastky et al. 2006) (more than 129,000 subjects) was conducted over 20 years, from the 1980s in the USA. A strong inverse correlation was found between cirrhosis and coffee drinking especially when the origin of the cirrhosis was alcohol. In this case, there was a 40 % risk reduction in 16-year cirrhosis incidence when people drank 1–3 cups of coffee (relative risk 0.6, 95 % confidence interval 0.4–0.8) and an 80 % risk reduction for four or more cups (relative risk 0.2, 95 % confidence interval 0.1–0.4). For nonalcoholic cirrhosis there was no significant risk reduction of caffeine on mortality and a nonsignificant 30 % risk reduction for people drinking four or more cups (relative risk 0.7, 95 % confidence interval 0.4–1.3). This relation was not observed for tea drinkers. Other cohort and case-control studies found strong reduction in the risk of liver cancer in coffee drinkers, with an increase in consumption of two cups of coffee per day being associated with a 43 % reduced risk of liver cancer (relative risk 0.57, 95 % confidence interval 0.49–0.67) (Larsson and Wolk 2007).

Coffee use is also inversely correlated to progression of fibrosis in hepatitis C liver disease (Freedman et al. 2009). This is important since the prevalence of hepatitis C is estimated to be at least 12 % in the addiction field, also among non-injecting drug users (Macias et al. 2008). The relative risk of two-point increase in fibrosis was 0.70 (0.48–1.02) for one or two cups of coffee a day and 0.47 (0.27–0.85) for three or more cups per day (significant trend). Although these are observational data (for evident ethical reasons, randomized studies will be difficult to realize), it is probable that people suffering from chronic hepatitis C are partially protected from fibrosis progression if they drink coffee on a regular basis.

Furthermore, the same authors found later that drinking coffee was a predictor to response to hepatitis C treatment with pegylated interferon and ribavirin (Freedman et al. 2011). The probability to achieve sustained virological response was almost twice for coffee drinkers of three or more cups of coffee daily (odds ratio 1.8, 95 % confidence interval 0.8–3.9).

Patients suffering from drug addiction (legal or illegal) have a higher prevalence cardiovascular risk factors and disease than the general population.

Tobacco smoking is more common in this population; one study suggests there is not a lower physical activity or unbalanced diet (Berg and Høstmark 1996), but this study included few and young participants (22-year-olds). Interventions promoting cardiovascular and heart health are important in the addicted population.

For the general population, caffeine consumption was considered to have a negative impact on the cardiovascular system until the 1990s. More recent studies suggest that coffee has no effect on the incidence of cardiovascular events and even suggest a small benefit for people without preexisting cardiac disease.

While people drinking coffee had a trend (at the limit of statistical significance) for beneficial cardiovascular effect in the first study discussed in this section

(Freedman et al. 2012), other studies have detected no association concerning men and a reduction in the cardiovascular mortality for women (relative risk of death 0.83, confidence interval 0.73–0.95) (Lopez-Garcia et al. 2008). For stroke, a 20 % reduction of relative risk has been found in a cohort study of women (Larsson et al. 2011); this was consistent with the results of another study concerning men (Larsson et al. 2008).

The effect of caffeine on insulin resistance is controversial and probably depends on the source of caffeine and the duration of exposition. At short term, caffeine has been shown to diminish insulin sensitivity (Beaudoin and Graham 2011). In a randomized controlled study, a dosage from 400 mg caffeine per day for a week showed a diminution of 35 % (95 % confidence interval 7–62 %) of insulin sensitivity (MacKenzie et al. 2007). In another study, sweet caffeinated beverages tended to increase type 2 diabetes (Malik et al. 2010). Still, it was not possible to separate the effect of sugar or caffeine. The long-term effect of pure caffeine from other sources than tea or coffee seems to have the opposite effect in animal models, ameliorating the insulin sensitivity and neutralizing the negative metabolic of sucrose in rats (Park et al. 2007). The limitations of this study are that it was conducted not in humans but in type I diabetic rats. In humans, the regular consumption of coffee has been clearly linked to decrease incidence of type 2 diabetes (Huxley et al. 2009). In this study, the relative risk was diminished by 7 % for any additional cup of coffee or tea absorbed. This effect was not associated with certainty to caffeine as it was also observed with decaffeinated coffee.

Caffeine also influences the metabolism of uric acid and occurrence of gout (Choi et al. 2007). In this large observational study, more than 50,000 men without former episode of gout were followed for 12 years. The relative risk of incidental gout was reduced by almost 60 % (relative risk 0.41, 95 % confidence interval 0.19–0.88) for the group consuming a large amount of coffee (six cups a day or more). The smallest efficient dose for gout protection was 4–5 cups of coffee a day with a 40 % risk reduction (relative risk 0.60, 95 % confidence interval 0.41–0.87). This was clearly linked to coffee and not caffeine, as this protective effect was not observed with tea or other sources of caffeine.

Tea and coffee (at a dosage of 300 mg caffeine per day) have been shown to protect against Parkinson disease, with a risk reduction of 25 % (relative risk 0.75, 95 % confidence interval 0.68–0.82) (Costa et al. 2010), excluding women taking hormonal replacement after menopause.

A neuroprotective effect of coffee on Alzheimer disease seems to exist, but this assumption is based on a small number of observational studies (Barranco Quintana 2007). The risk reduction could be 30 % (relative risk 0.7, 95 % confidence interval 0.55–0.9).

A recent case-control study in Australia confirmed the potential benefit of caffeine to prevent road accidents (Sharwood et al. 2013). More than 500 professional drivers involved in crash accidents were compared to controls. After adjustment for confounding factors, drivers who consumed caffeine (from coffee, tea, energy drinks, or tablets) had a risk reduction of 63 % of being involved in an accident (odds ratio 0.37, 95 % confidence interval 0.27–0.50). This is probably due to the psychostimulant properties of caffeine (increase alertness, lessen fatigue, promote memory, prevent

errors to people who are tired or working on night shift (Ker 2010). Also in light drinkers, the accident reduction was found; this is an argument against that it was only an effect of the reversal of withdrawal (Childs and de Wit 2006).

Another well-established positive effect from caffeine is the enhancement of physical capacities (Burke 2008). The most effective dosage for this purpose seems to be around 3 mg caffeine per kilogram of weight. Positive impact was found on intermittent effort sports (e.g., soccer), continued effort sports lasting until 1 h (e.g., swimming), or endurance sports (e.g., running). The enhancing effect of caffeine is so significant that for a long time, caffeine was considered a doping substance controlled by the World Anti-doping Agency (WADA). In 2004 caffeine was removed from the list (www.wada-ama.org).

The potential analgesic properties of caffeine are subject of debate. Caffeine is successfully used in the treatment of headache or migraine (Goldstein et al. 2006) and is a frequent component of combined analgesics or other medication (e.g., when mixed with paracetamol or salicylates or antihistamines). On the other hand, it can be the cause of headache (Bigal et al. 2002). This phenomenon can take place when people chronically consume caffeine or in withdrawal conditions.

Coffee and tea also seem to present benefit for mental health based on a data of a large cohort from the Nurses' Health Study. More than 50,000 women not suffering from depression at baseline were followed for 10 years, between 1996 and 2006, and stratified by their consumption of caffeine (Lucas et al. 2011). During the follow-up, a 20 % risk reduction for depression was found for women consuming 550 mg of caffeine or more when compared to the group consuming 100 mg or less (multivariate relative risk 0.80, 95 % confidence interval 0.68–0.95). This effect is quite clearly related to caffeine itself as it was not observed for women drinking decaffeinated coffee. Such results are coherent with data from other studies showing an inverse correlation between coffee, depression, and suicide (Kawachi et al. 1996).

26.7.2 Theophylline

Theophylline, another methylxanthine (1,3-dimethylxanthine), is found in medication form and in small quantity in tea, coffee, chocolate, mate, and guarana. Its principal indications are related to its bronchodilatative properties and immunomodulatory effects (Somerville 2001). It is known to restore the sensitivity to corticosteroids in asthma. Consequently theophylline is used in asthma and chronic obstructive pulmonary disease. It seems that it could also be useful for the prevention of acute kidney injury caused by radiologic contrast product (Dai et al. 2012). It is not as psychoactive as caffeine and not known to be a substance of abuse.

26.7.3 Theobromine

There is a popular belief that theobromine, a third methylxanthine, found principally in guarana, cacao, and chocolate, has a euphoric effect, but no studies can

confirm this. The appetite for chocolate would be more linked to other methylxanthine such as caffeine and taste or cultural influences. So up to know, there are no proven benefits for theobromine (Smith 2011).

26.7.4 Caffeine Abuse Treatment

In case of acute intoxication (Yew and Laczek 2011), which necessitates more than 70 mg/kg (Bronstein et al. 2010), clinical management should be "supportive." The first action is to give standard protocols for cardiac life or other support (ABCs) (Pohler 2010). Then give oxygen to the patient and check the blood glucose. In case of extreme anxiety, agitation, or seizure and lack of effect of non-pharmacological interventions, give short-acting benzodiazepines (e.g., lorazepam orally when possible or intravenously/intramuscularly).

Activated charcoal is effective in reducing the absorption of methylxanthine and recommended early in the treatment. Then transfer the patient to an emergency unit where the care will be supportive, depending on the symptoms. Cardiovascular or neurologic toxicities are the most frequent. Sinus tachycardia occurs but does, in general, not require any intervention, but arrhythmia does. In case of extremely high caffeine levels, a dialysis or hemofiltration may be necessary.

Gastric lavage is rarely done because of aspiration risk. Caffeine is rapidly absorbed, and gastric lavage should not be considered unless in the first hour after intake.

In case of withdrawal, no specific treatment or intervention was found in scientific publications. Anyway, caffeine withdrawal is not dangerous and self-limited. Intervention would then not be crucial. A wait-and-see approach could be used. Nevertheless, the main problems during caffeine withdrawal could be fatigue, lack of concentration, or headache. We can recommend general interventions such as rest, physical activity, and good fluid and electrolyte supply. In case of severe headaches, simple analgesia (e.g., paracetamol) could be used. If the time to go through withdrawal is really not adequate, for example, in case of professional or familial obligations, caffeine (in a limited dose) could be taken in the form of coffee, a caffeine-containing drink, or a tablet, and complete withdrawal conducted later. For regular caffeine users who will be exposed to a period of caffeine abstinence (e.g., planned medical intervention), a decrease of daily caffeine intake days before is recommended (Favrod-Coune and Broers 2010).

26.8 International Perspectives

Currently, coffee, tea, and other caffeine-containing drinks are legally available in all countries and not subjected to regulation. Based on our review of benefits and risks of methylxanthines, we believe that there is no rationale to change this. This seems neither necessary nor useful in a public health or cultural perspective, as prohibition certainly will have a number of unwanted side effects. Nevertheless,

information and warning (on package of food or drinks) are probably warranted, indicating the risk of high doses of caffeine and when mixed with alcohol and when relevant the risk of sugar, calories, or other compounds.

The FDA has warned four companies about adding caffeine to alcoholic beverages in 2010 (Herndon 2010) and stated that a further action, including the seizure of products, is possible under federal law. The FDA stated that caffeine is an "unsafe food additive" when mixed with alcohol.

Another international measure that we consider useful would be a limitation of the amount of caffeine in energy drinks. It seems difficult to reach toxic levels of caffeine when a drink contains 50–100 mg of caffeine. Nevertheless, content of 500 mg caffeine in one drink can represent a real danger, especially for children or teenagers, given their lower body weight and the propensity to like those drinks.

26.9 Conclusion

Safe caffeine use is possible and moderate caffeine use (200–300 mg per day) probably has more benefits than risks. Relative contraindications for caffeine intake are uncompensated heart disease, anxiety, and sleeping problems. Since most studies on caffeine use are observational, we can of course not recommend the use of caffeine or other methylxanthines for medical reasons to those who do not drink. The studies are merely based on cohorts of individuals drinking coffee and tea, so we should recommend the use of these beverages and not of energy drinks. Energy drinks lack several compounds found in coffee or tea (antioxidants) and contain others that possibly have a negative impact on health (sugar). In case of liver disease, especially if related to alcohol and HCV, a daily intake of at least five cups of coffee can be recommended to diminish the progression of the disease.

Coffee and caffeine withdrawal symptoms exist and are often not recognized, especially in treatment settings, where caffeine withdrawal can be confounded with other symptoms. Caffeine withdrawal occurs in half of regular coffee drinkers, even at moderate caffeine intake. The most common symptoms are headache, fatigue, and difficulty to concentrate. Health professionals and patients should be better informed about these symptoms and the risk of occurrence of caffeine withdrawal.

Caffeine intoxication and withdrawal are recognized clinical entities, but caffeine dependence is currently not. Some individuals can meet difficulties in controlling their caffeine intake and present withdrawal symptoms in case of abstinence, but most often other criteria of dependence are lacking. In some cases such behavior seems close to an obsessive-compulsive or eating disorder.

In psychiatric inpatient settings, often only decaffeinated coffee is available. We recommend, for the reasons mentioned above, that both caffeinated and decaffeinated coffee be at the disposition of the patients, with restriction for those who suffer from anxiety or insomnia. Caffeine taken from coffee seems to be without risk for most psychiatric patients. Personalized recommendations (maximum daily quantity of caffeine, time limit) are probably more appropriate than constraining all patients to abstain from coffee consumption.

Finally, we highly recommend more and better information to the population about the risk of acute intoxication of caffeine, the nutritional and metabolic risks of energy drinks, and the problems of mixing these with alcohol. Warning messages on caffeine-containing food or drinks as well as a legal limitation of the content of caffeine (e.g., maximum 200 mg per unit) are certainly justified. They should be promoted in all countries.

Contents

Abstract

Khat refers to the young and tender leaves and shoots of the khat tree (*Catha edulis*). It is an evergreen tree that can be found in the Abyssinian highlands, the Horn of Africa, Eastern and Southern Africa, the Arab peninsula, and Afghanistan.

The alkaloid cathinone (S-(-)-a-aminopropiophenone) is considered to be the main psychoactive compound. The leaves and tender stems are usually chewed and kept in a tight wad in the cheek pocket. Within about 15–30 min, the user experiences physiological excitability, euphoria, talkativeness, and flow of ideas. Today, cathinone is listed in Schedule I and cathine in Schedule III of the international Convention on Psychotropic Substances of 1971, but the khat leaves are not internationally controlled. A problem with diagnosis of khat addiction is that established dependence criteria are not easily applicable as is the case for other traditional substances. More research information is needed about the prevalence of a khat dependence, its consequences, and its treatment.

27.1 Introduction

Khat refers to the young and tender leaves and shoots of the khat tree (*Catha edulis*). It is an evergreen tree of the *Celastraceae* family, normally reaching 6 m in height, but in an equatorial climate it might grow to 25 m. *Catha edulis* can be found in the Abyssinian highlands, the Horn of Africa, Eastern and Southern Africa, the Arab peninsula, and Afghanistan. Khat has many names including *qat* (Yemen), *jad*/*chat* (Ethiopia, Somalia), *miraa* (Kenya), or *marungi* (Uganda, Rwanda).

The khat leaves have been consumed for centuries for their mildly stimulating properties caused by several alkaloids contained in the leaves. Among more than 40 known compounds, the alkaloid cathinone (S-(-)-a-aminopropiophenone) is considered to be the main psychoactive compound, but it is unstable and swiftly decomposes after harvesting. Cathinone resembles amphetamine in chemical structure and affects the central and peripheral nervous system and behavior similarly (Kalix 1990). Recently, synthetic cathinone derivates such as mephedrone have been introduced to the drug market, often under the label "legal highs" (EMCDDA 2012). More stable compounds of the khat leaves are cathine (*S*,*S*-(+)-norpseudoephedrine) and other alkaloids which are at the same time metabolites of cathinone and less potent central and peripheral stimulants.

While chewing the fresh leaves has ever since been the preferred use form, in the past it was often only available in dried form, powder or paste. Today, soon after harvesting, the twigs and shoots are artfully rolled into bundles and wrapped into banana leaves in order to retain moisture; today, deep frozen transports are more and more common. In most instances, bundles are the traded units, but leaves of lower quality might also be marketed in standardized plastic bags. The leaves and tender stems are usually chewed and kept in a tight wad in the cheek pocket. Within about 15–30 min the user experiences physiological excitability, euphoria, talkativeness, and flow of ideas known in Arabic as "mirquaan." This is followed by a quieter, more introvert phase, giving way to a gradual comedown, and among excessive chewers often restlessness, irritability, and depressive reaction. Users often experience sleep problems during the following night and a hangover the next morning. These unpleasant aftereffects motivate some khat chewers to carry on chewing without stopping.

27.2 The Khat Controversy

The controversy around khat and especially the question whether it is a *drug* versus a part of *culture* or *tradition* is probably as old as use itself (Krikorian 1984). It has been condemned by the Ethiopian orthodox church and the more fundamentalist Islamic schools of thought particularly in Saudi Arabia, who consider it "haram." Islamic scholars in Yemen, Somalia, and Ethiopia by contrast integrated khat use into religious life, including the study of the Holy Koran or to enhance religious experience as practiced by Sufi mystics. During the colonial era, arguments about moral degeneration, falling economic productivity, and the association with political unrest motivated official and largely unsuccessful bans on khat (Gatter 2012; Warfa et al. 2007). Strong pro-khat movements prevented in most countries legal restrictions.

The scientific discourse on khat shows similar fissures, usually along the lines of academic discipline (Odenwald et al. 2010a). Medical and pharmacological research approached khat with the underlying assumption that it is analogous to other psychoactive drugs; consequently, research focused on the discovery of the addictive substance in the leaves and on the laboratory-based study of cathinone. Today, cathinone is listed in Schedule I and cathine in Schedule III of the international Convention on Psychotropic Substances of 1971, but the khat leaves are not internationally controlled.

Anthropologists and social scientists, by contrast, stressed the cultural functions and traditional values (Anderson et al. 2007). They often oppose the medical position, e.g., arguing that the physical effects cannot explain the functions of its use and that addiction is a western concept that does not fully grasp the case of khat.

27.3 The History of Khat Use

Medieval writings and legends confirm its longstanding use but also ambivalent attitudes towards its effects described as helpful and joyful as well as noxious (Krikorian 1984). Before the eighteenth century, its use was confided to certain ethnic groups and producing areas where khat was an integral part of the culture, i.e., religious ceremonies and rites of passage, but there only the rich and the farmers themselves were regular chewers. The former used khat to get inspiration for artistic expression in poetry and songs, chewed communally, in dedicated rooms within private households often called "mafrishes." The latter as well as long-distance travelers used khat to overcome tiredness and hunger. But it was also chewed during Muslim prayers and ceremonies as well as by students to be able to study all night. The traditionally moderating khat culture regulated its use and prevented large-scale misuse by rules such as restriction to afternoon and evening hours and weekends as well as rites of passage. Outside the few traditional producing areas, it was very rare, e.g., for medicinal purposes, and not noticed by European travelers before the Swedish botanist Peter Forsskål (1732–1763). Since then, its use became more and more prevalent and by the year 1900 the "khat party"

has emerged as a central social institution of the respective regional populations, especially in Yemen: a controlled, formalized, and exclusive group setting of adult males where politics and business are discussed and social status was demonstrated (Weir 1985). Since then, khat chewing has successively become a regular part of social life outside these confined groups and regions, and the moderating khat culture is gradually being lost.

27.4 From a Niche Crop to a Cash Crop

Since the end of the nineteenth century with successive transport innovations, the railway network, road haulage, and air cargo, khat has made its way from a niche crop to a cash crop. For commercial purposes, nowadays, it is grown in the highlands around the Horn of Africa, Southern Arabia, and along the Eastern African coast in altitudes of 1,500–2,500 m above sea level. Within centuries, an amazing variety of khat types have developed out of regional climatic and environmental conditions and local cultivation habits which has been the base for the recent marketing of different khat brands. After decades of steeply increasing production, now the khat sector has economic significance for Ethiopia and Yemen and to a smaller extent for Kenya too, where it provides more than two million jobs, for farmer, pickers, packers, and traders, i.e., the source of income for up to 15 million (Anderson et al. 2007; Gatter 2012). Within a few decades, khat has become a large regional and international market without the involvement of multinationals. Today, production is rising in traditional khat countries, while at the same time expanding to other African countries (e.g., Uganda, Rwanda). But the production increase and the accompanying development have considerably contributed to environmental and social problems, e.g., deforestation and food insecurity in Ethiopia or groundwater decline due to massive increase of irrigation farming in Yemen (Gatter 2012).

27.5 The Development from Traditional to Binge Use Patterns

Estimating the prevalence of khat use is difficult, as the consumption in the different countries still largely depends on socioeconomic, ethnic, and geographic factors. The current literature is a patchwork of different studies produced with different methods. The general trend suggests use is spreading across the general population, including groups who have no tradition of khat consumption. This includes countries where it was previously unknown altogether. It is estimated that more than ten million people are using khat recreationally on any one day (Odenwald et al. 2010a).

In Yemen different prevalence estimates vary between 60 % and 90 % of adult males and between 10 % and 50 % of adult women. Different Household Budget Surveys indicated that Yemenite households spent on average 9–10 % of their income on buying khat, but this proportion was up to 40 % in the lowest income section (Gatter 2012).

In Ethiopia, different studies found prevalence estimates between 40 % and 75 % among adult males and between 16 % and 35 % among adult women (e.g., Alemseged et al. 2012). A representative national assessment of 16,606 adolescents and young adults found a 4-week prevalence of 16.2 % (Kebede et al. 2005). Other studies among Ethiopian high school or university students revealed current prevalence rates of 10–65 %. All studies revealed great differences between urban and rural areas as well as between different ethnic groups.

In Kenya, no prevalence data for the general population are available. Studies of treatment-seeking patients in different parts of the country disclosed a lifetime prevalence rate of 10.7 % in a region without khat production (Othieno et al. 2000) and a current prevalence rate of approximately 30 % in a khat-producing region (Ndetei et al. 2009).

Cross-sectional assessments of khat use in Somalia reported regular or current khat use between 31 % and 64 % of adult males in the north of the country and 21 % in the south, and excessive khat use patterns were especially found among militia members (Elmi 1983; Odenwald et al. 2005).

Other countries where khat is traditionally used include Djibouti, Saudi Arabia, Tanzania, Madagascar, and South Africa. Because of mass migration, khat use spread to the European Community, North America, Australia, and Israel. Khat use in western countries is almost exclusively limited to immigrant groups. Among Somalis in the UK, a lifetime history of khat use was found among 38–78 % (58–79 % of males, 16–76 % of females), and current use was found among 34–67 % of males and 17 % of females (e.g., Bhui and Warfa 2010).

The pattern of khat use has changed significantly over recent decades due in part to the combined effects of urbanization, commodification, and the accompanying social change (Anderson et al. 2007). Arguably, the dissolution of traditional, formal regulations has led to the rise of more excessive and extensive khat use, including "binge sessions" of lasting more than 24 h in a row, use in the morning as eye opener, and parallel use of other drugs, e.g., benzodiazepines or alcohol (Odenwald et al. 2010b). While khat chewers used to be traditionally "initiated" at around 20 years of age, nowadays, they start using the drug as early as 8 years in life and consumption has become part of the youth culture (Odenwald et al. 2010b). Furthermore, what was reportedly an exclusively male habit is now practiced more and more by women, including at times during pregnancy and breastfeeding (Odenwald et al. 2010b).

27.6 What Is Known About Khat Addiction?

The compulsive use of the khat leaves has been described since colonial times (Halbach 1972). Compared to other substances with misuse potential, experts consider the khat leaves, however, to have a low potential for addiction and physical and social harms (Nutt et al. 2007), and they are not recommended to be scheduled or controlled under the international conventions (World Health Organization 2006). In some countries, however, they are illegal, in others the status is not clear, while they are not controlled at all in the traditional khat

countries (Griffiths et al. 2010). While the khat leaves are considered to produce only mild psychological addiction, cathinone is believed to have a higher addiction potential than amphetamine (Kalix 1991).

The current opinion on withdrawal symptoms upon discontinuation is that they are expected to be mild, to be brief, and to occur only after prolonged use (World Health Organization 2006) and include profound lassitude; anergia; difficulty in initiating normal activity; slight trembling lasting for several days after cessation; and nightmares, often paranoid in nature, for example, being attacked, strangled, or followed (e.g., Kennedy et al. 1980). However, the existing empirical base is meager and not related to current excessive use patterns.

In the same token, today it is generally believed that khat use does induce some tolerance (World Health Organization 2006). It has been argued that the chewing mode of ingestion limits the possible amount to consume in a certain time and, thus, tolerance development is usually prevented. This view can be criticized based on recent definitions of tolerance. Among stimulant users, tolerance development, the upward shift in the set point for reward, and the subsequent dysphoria ("opponent process") are closely related to the development of "binge" consumption patterns: Users need to increase the dose and the frequency of drug administration in order to experience the desired psychological effects. Thus, khat tolerance development might not only include increases in the amount of consumption per time unit but rather the extension of the time spent for consuming it which leads to an increase of the absolute amount ingested. Recent studies and personal observations indicate that a growing group of binge users consume khat for more than 24 h in a row in such large quantities a novice would never manage (Patel et al. 2005; Nabuzoka and Badhadhe 2000; Widmann 2012). While the development of tolerance to physiological effects was reported (Nencini et al. 1984), no study has ever directly targeted the topic of tolerance to desired psychological effects, e.g., euphoria.

Researchers early on recognized the potential of khat to induce psychological dependence (e.g., Kennedy et al. 1980). This is best illustrated in descriptions of typical scenes of inner city khat markets at the Horn of Africa or in Eastern Africa at the time just before a khat delivery arrives (Hansen 2010). At theses hours of day, users speed to khat markets frequently causing traffic accidents; an aggressive and nervous atmosphere prevails until the khat trucks arrive. In contrast, khat users who visit foreign countries are said to abstain without any difficulties without replacement.

Observational data confirm the existence of a specific Patois among Somali khat users (Odenwald et al. 2010b): "xaraaro" means feelings of craving and nervousness which are experienced by habitual chewers at the time of day before their usual khat intake starts; "dubaab", i.e. nightmares involving the sensation of being suffocated, are usually experienced by heavy chewers in the first days after cessation. The phenomenon of "jibane" involves the use of khat in a group setting in order to reduce aversive symptoms in the morning. The term "bac," which literally means "plastic bag," refers to a transitory phenomenon involving paranoid anxiety and illusions when khat users on their way home at night mistake litter on the street for enemies or dangerous animals.

In recent years khat has increasingly been used in combination with other substances like alcohol or benzodiazepines. Khat chewers usually smoke tobacco during khat sessions and consume carbonated soft drinks; this goes so far that it is difficult to find any khat chewer who doesn't smoke. Inversely, there are many occasional smokers that do only smoke during khat sessions (al'Absi and Grabowski 2012). In a recent study, khat chewers used more tobacco, khat dependence correlated with tobacco dependence, and there were signs of an enhancement effect (Kassim et al. 2011).

27.7 Measurement and Diagnosis of Khat Addiction

A problem with diagnosis of khat addiction is that established dependence criteria are not easily applicable as is the case for other traditional substances. Besides the previously mentioned lack of knowledge on withdrawal and tolerance, some of the other criteria outlined in DSM-IV (or ICD-10 research criteria) need further specification to adapt to societies where daily social khat use is rather the rule than the exception and where social khat use is the most widely used leisure activity, i.e., "a great deal of time is spent in activities necessary to get drugs (e.g., visiting multiple doctors, driving long distances), using drugs, or recovering from its effects" or "important social, occupational, or recreational activities given up or reduced because of drug use." It needs studies and/or conventions that set the borders of what is normal and what is socially not sanctioned any more.

Consequently, less information is available from cross-sectional studies on the prevalence of a khat dependence syndrome as defined by the simple application of ICD or DSM criteria. An Ethiopian study (Awas et al. 1999), using the WHO's Composite International Diagnostic Interview, found a prevalence of khat dependence according to the criteria of ICD-10 of 5 % among males (among females 1.3 %) in a representative sample drawn in a traditional khat-producing area. Using the same instrument among a group of 25 chronic psychotic patients in Somalia revealed a percentage of 84 % (Odenwald et al. 2012). Using the criteria as outlined in the Mini International Neuropsychiatric Interview, 100 % among 33 khat-using male Somali refugees in Nairobi (Widmann 2012) had to be considered dependent. All of these studies developed their own conventions to adapt dependence criteria to the reality of khat use.

Validated self-report instruments to assess and measure aspects of khat addiction are rare and few standardized questionnaires have ever been applied in khat users. Recently, an Arab version of the Severity of Dependence Scale, a five-item instrument thought to measure the psychological component of dependence, has been adapted and validated for the study of khat addiction (Kassim et al. 2010). It was shown that khat chewers scoring high on this instrument show more khat-related behaviors and have higher khat alkaloid levels in their saliva (Kassim et al. 2012). In different studies, 10–39 % of khat users scored at a level comparable with a clinical population with severe heroin dependence in need for treatment (Kassim and Croucher 2006). A Somali version of this instrument has also been developed (Odenwald et al. 2012).

27.8 Khat-Associated Neurocognitive Deficits

A common characteristic of chronic central stimulant abuse is marked neurocognitive deficits. A recent review found that there is only one study on neurocognitive deficits among khat users before 2009 (Hoffman and al'Absi 2010). Khattab and Amer (1995) assessed aircrew members of an Arabic Airline who were daily khat chewers (25), occasional chewers (39), and non-chewers (24) presented for the Standard Aviation Medical Examination and participated in a standardized neuropsychological test battery. Daily khat chewers performed worst in subtests for perceptual speed, long-term memory, visual memory, and visual perception and had a faster EEG background activity compared to occasional khat chewers and non-chewers. Duration and amount of khat use were negatively correlated with performance. Recently, several studies found poorer working memory among severe khat users compared to controls (Hoffman and al'Absi 2012; Colzato et al. 2011; Mikulica 2012). Other studies reported different other executive functions being impaired among khat users: inhibitory control (Colzato et al. 2010), problem solving (Mikulica 2012), cognitive flexibility (Colzato et al. 2011), cognitive control (Colzato et al. 2012), and processing speed (Hoffman and al'Absi 2012).

27.9 Treatment of Khat Addiction

The UNODC's annual World Drug Reports list khat in the statistics of "primary substances of abuse". According to these reports, khat-addicted individuals constitute the largest group in Ethiopia and the second largest group in Kenya (United Nations Office on Drugs and Crime 2012). However, the UNODC statistics have to be treated with caution as they reflect the reporting of governmental statistics to the UN and as the absolute numbers of provided treatments is very small in these countries. But single research reports verify the existence of this group of patients not just in the countries mentioned above but also in Uganda. Khat-dependent individuals who seek treatment are usually admitted to psychiatric and general substance treatment units. But the number of cases is small and the psychiatric and addiction treatment facilities in this region of the world are few. Specialized khat addiction programs or treatment facilities are nonexistent. Studies from these countries describing the development or evaluation of khat addiction treatment are lacking. But khat users in the traditional khat countries frequently report motivation to and failed attempts to quit its use (Odenwald et al. 2012). We reported before the observation that during the last 12 years, various local nongovernmental organizations in Ethiopia, Somalia, Kenya, and Uganda have started to address khat addiction as shown by many hand-painted billboards in Somali towns promoting "khat counseling" together with other psychosocial services such as "HIV counseling" (Odenwald et al. 2007). This reflects the demand for khat-related treatment in the traditional khat countries. However, no studies exist that addressed this counseling approach.

In western countries, khat addiction has been targeted by projects in the UK, Denmark, and Sweden. While some of the projects included khat addicts into the general addiction treatment settings, i.e., together with people dependent on other types of substances, others developed programs specifically for homogeneous ethnic subgroups, mostly Somalis. Observations from these projects confirm that patients with khat addiction usually are immigrants from the traditional khat countries, that utilization is poor, and that those who utilize these treatment facilities have comorbid other substance-related and psychiatric problems. Recently, khat addiction treatment has been included into web-based advertisements of private substance treatment centers; among a range of different explanations, this might suggest that there is a certain demand for this kind of treatment. Scientific publications from western countries on khat addiction treatment are missing. Systematic research on medication to treat khat addiction is equally nonexistent. There are only a few reports that mentioned the use and effect of certain psychopharmacological drugs in single cases.

27.10 Other Psychiatric Disorders and Somatic Problems Associated with Khat Use

Khat use has been associated to the presence of mental distress or disorders (Belew et al. 2000). While there is no evidence for a simple causal relationship or a noxious effect of khat use per se (Warfa et al. 2007), functional substance use to counteract symptoms of depression, posttraumatic stress disorder, as well as medication side effects have been described (Teferra et al. 2011). In these individuals, khat use may be a risk factor for the development of suicidal thoughts (Bhui et al. 2003) and psychotic symptoms (Odenwald et al. 2009). Today, more than 20 case descriptions of khat-induced brief psychotic episodes are available in the medical literature. Most reported excessive khat use before the onset of psychotic symptoms and violent behavior in the course of the acute psychiatric development. Most of them had completely remitted after 2–4 weeks, given abstinence is maintained even without medication. But, most of these cases had repeated such episodes. Also the exacerbation of psychotic symptoms in patients with preexisting psychotic disorders has been reported (Bimerew et al. 2007; Teferra et al. 2011). A few and weak studies found first support in favor of the hypothesis that early, chronic and severe khat use might be a causal factor for the development of chronic psychotic disorders (Odenwald et al. 2005).

Besides psychiatric sequelae, numerous somatic health problems have been associated with khat use (Al-Motarreb et al. 2010; for detailed review see Al-Habori 2005). As with mental health, moderate khat use seems not to be noxious in most users and adverse effects are commonly linked with the currently growing excessive use. There are many reports of severe physical harms among chronic users, but other explanations have not been systematically ruled out, for example, tobacco smoking which is frequently combined with *khat* use and pesticide content in the leaves. Observed negative somatic consequences associated to khat use

include mucosal problems, hypertension, cardiovascular complications, duodenal ulcers, sexual dysfunction, hepatoxicity, and reduced birth weight of infants born to *khat*-chewing mothers. By the same token, the argument for possible medicinal uses has only been touched on.

27.11 Conclusion

In sum, the topic of khat addiction urgently needs further empirical studies. Current evidence supports the hypothesis that excessive and prolonged khat use can produce a dependence and neurocognitive deficit syndrome qualitatively similar to that produced by amphetamine. But the question of khat-related withdrawal and tolerance needs further studying, especially related to current binge use patterns. For the application of diagnostic criteria to khat, conventions are needed as well as the development of reliable and valid research instruments. The current knowledge on khat addiction treatment is very poor especially as khat users seldom utilize addiction treatment services. It is urgently needed to develop effective and adequate treatment concepts to be applied in the traditional khat use countries and among immigrant communities elsewhere in the world; there are millions of people who potentially benefit from such knowledge. Like amphetamines khat can be associated to psychosis and other psychological and somatic disorders. Therefore, strong research designs are needed to rule out alternative explanations and develop public health strategies.

Opioid Addiction: Short- and Long-Acting Opioids

28

Marta Torrens, Francina Fonseca, Liliana Galindo, and Magi Farré

Contents

Abstract

Opium is the natural product obtained from the juice of the opium poppy (*Papaver somniferum*). Opiates include all natural plant alkaloids, such as morphine, codeine, and thebaine, and many semisynthetic derivatives. An opioid is any compound, regardless of the structure, which has the functional and pharmacological properties of an opiate. Endogenous opioids are natural ligands for opioid

receptors found in animals. Synthetic compounds include hydrocodone; oxycodone; hydromorphone; heroin; antagonists such as naloxone, naltrexone, and nalmefene; and partial agonists such as buprenorphine. Opioid use disorders are a public health problem worldwide. They include intoxication, withdrawal, and dependence. Intoxication is the main cause of mortality of these disorders and can be treated with the opioid antagonist naloxone. Opioid withdrawal can be treated with opioid agonist such as methadone, buprenorphine, or LAAM. A depot formulation of naltrexone is approved to prevent a relapse prevention intervention. Research studies are underway with the goal of discovering and developing safer and more effective medications to treat these disorders.

28.1 Introduction

The objective of this chapter is to review the pharmacological (pharmacodynamics and pharmacokinetic) aspects of exogenous opioids involved in opioid-related disorders. The pharmacological treatment of opioid overdoses, opioid withdrawal, and opioid addiction including psychosocial therapy is also reviewed.

28.2 Opioids: Pharmacology and Treatment

28.2.1 Pharmacology of Opioids and Endogenous Opioid System

Opium is the natural product obtained from the juice of the opium poppy (*Papaver somniferum*). Opiates include all natural plant alkaloids, such as morphine, codeine, and thebaine, and many semisynthetic derivatives. An opioid is any compound, regardless of the structure, which has the functional and pharmacological properties of an opiate. Endogenous opioids are natural ligands for opioid receptors found in animals. Synthetic compounds include hydrocodone; oxycodone; hydromorphone; heroin; antagonists such as naloxone, naltrexone, and nalmefene; and partial agonists such as buprenorphine (Yaksh and Wallace 2011).

Opiates and opioids act on three opioid receptors (mu, kappa, and delta) which are widely distributed in the brain and are associated with reward stimuli (Kristensen et al. 1995). Endogenous opioids, called endorphins, are the ligands of these receptors and play a central role in establishing habits and responses for survival and pain relief; the opioid endogenous system plays an important role in opioid addiction (Mayer and Hollt 2006), and also it has been implicated in the pathophysiology of dependence of alcohol and cocaine (Kreek et al. 2009). The three opioid receptors belong to G protein receptor family, and its structure has an extracellular N-terminus, seven transmembrane domains, three extra- and intracellular loops, and an intracellular C-terminus. Agonist binding to these receptors results in conformational changes of the receptor and the activation of the G protein cycle, affecting the intracellular effectors: adenylate cyclases and Ca^{2+}/K^{+} ion channels. The final effect in the cell is the reduction of cAMP levels, the inhibition of the Ca^{2+} current, and the increase in the

extracellular K^+ current. These changes tend to decrease the excitation of the neuron and inhibit the neurotransmission. Depending on the capacity to promote changes in the G protein, ligands are classified into full opioid agonists, partial agonists, antagonists, and agonists–antagonists (Table 28.1) (Schäfer 2011).

- An **agonist** is a substance that is capable of binding to a receptor, producing their activation and causing a biochemical or cellular response.
- An **antagonist** is the opposite of an agonist in the sense that as an antagonist it also binds to a receptor, but does not activate the receptor and blocks its activation by agonists.
- A **partial agonist** activates the receptor, but does not cause much effect as a full agonist, and has a ceiling of maxim effect inferior than the agonist.

28.2.1.1 Opioid Classification

Exogenous opioids can be classified according to their origin (natural, semisynthetic, and synthetic), their chemical structure, and/or their affinity/efficiency on opioid receptors. The latter is most often used, in which exogenous opioid drugs are divided into:

- **Pure agonist:** opioid agonists, receptor mu fundamentally, with high efficacy (intrinsic activity). This is the group of morphine, heroin, pethidine, methadone, fentanyl, and its derivatives.
- **Mixed agonist–antagonists**: act as agonists in one receptor (kappa) and as partial agonists or antagonists in another (mu). When administered together with a pure mu agonist, it may antagonize the effects and may reduce or

eliminate their analgesic effect. In opioid-dependent subjects, agonists (heroin) cause withdrawal symptoms. This is the group of pentazocine, butorphanol, or nalorphine.

- **Partial agonists**: act on mu receptors with lower efficacy than pure agonists. They are analgesic when administered alone but antagonize the effects of a pure agonist. The most characteristic of this group is buprenorphine.
- **Pure antagonists**: possess affinity for the receptors but not exhibit efficacy. Inhibit or reverse the action of the agonists and do not have analgesic effects. In subjects with opioid dependence, withdrawal symptoms occur. They are used in cases of poisoning or overdose by its ability to reverse the effects of exogenous opioids. They are naloxone and naltrexone.

28.2.1.2 Morphine

Morphine is a natural product of the seeds of the poppy plant. Chemically, morphine is an alkaloid that belongs to the class of phenanthrenes. Morphine is prescribed primarily as a high-potency analgesic. Morphine is metabolized by glucuronide conjugation to morphine-6-glucuronide (M6G) and morphine-3-glucuronide. M6G has mu receptor agonist activity and is approximately twice as potent as morphine in humans. In chronic administrations, M6G has a significant portion of the analgesic actions of morphine, and its plasma concentration exceeds those of morphine.

During the last years, slow-release oral morphine (SROM) has been proposed as an alternative maintenance pharmacotherapy for treatment of opioid dependence with retention rates similar to methadone (from 80.6 % to 95 %); also, uncontrolled studies showed improvements in quality of life, withdrawal symptoms, craving, and additional drug consumption (Jegu et al. 2011).

Pharmacodynamics

Morphine is the prototype for opioid agonist actions. Morphine is a selective agonist at the mu-opioid receptor at lower doses. There are described central and peripheral actions.

The main central actions are:

(a) **Sedation**: at higher doses, it could produce stupor, sleep, and coma. It worsens the psychomotor performance. At very high doses, convulsions can appear.
(b) **Euphoria**: it produces euphoria, pleasure, and a well-being feeling and reduces anxiety. The euphoria has been linked to the abuse potential of opioids.
(c) **Analgesia**: morphine can reduce the sensorial and affective components of pain. It can relieve and suppress acute and chronic pain. This action is related with the mu agonist action; mu receptors control the pain pathways in the medulla. Also, it has actions in the limbic and cortical systems that reduce the negative perception of pain.
(d) **Respiratory depression**: morphine can reduce the activity at the pontine respiratory center. It reduces the sensitivity to CO_2 and hypoxemia. It reduces the number of breaths per minute and can end in an apnea. This effect is dose dependent and directly relates with the mu agonism.

(e) **Antitussive**: it depresses the cough reflex at least in part by a direct effect on the cough center in the medulla. This mechanism is not well known and has no relation with analgesia or respiratory depression.
(f) **Miosis**: this effect is related with the disinhibition of the Edinger–Westphal nucleus at the oculomotor nerve. This effect does not show tolerance and could be adequate to detect recent use of opioids.
(g) **Nausea and vomit**: it is observed more frequently after the first administrations. It is caused by direct stimulation of the chemoreceptor trigger zone for emesis in the area postrema of the medulla.
(h) **Neuroendocrine actions**: morphine actions in the hypothalamus inhibit the release of gonadotropin-releasing hormone and corticotrophin-releasing hormone, producing a decrease in the luteinizing hormone, follicle-stimulating hormone, adrenocorticotropic hormone (ACTH), and beta-endorphin. It also stimulated the secretion of the antidiuretic hormone (ADH). By its effects in the hypothalamus, also a central hypothermia is observed.
(i) **Muscular tone**: myoclonus is a rare side effect, ranging from mild twitching to generalized spasm. In anesthetic use muscular rigidity can be observed.

The main peripheral actions are:

(a) **Gastrointestinal**: morphine can produce an increase in the tone of muscles of the gastrointestinal tract, including the sphincters, and a reduction in the motility. As a consequence, there is a reduction in the gastric emptying and in the peristaltism and a contraction of sphincter. Clinically it is related with constipation.
(b) **Cardiovascular**: it could produce hypotension by its action in the vasomotor center and by vasodilatation. Also a vagal bradycardia has been described. Also, there is a potential to increase intracranial pressure.
(c) **Histamine release**: in the face, neck, and upper thorax, there is a feeling of heat, flushing, and pruritus.
(d) **Renal**: morphine increases the tone of the detrusor muscle of bladder.

Pharmacokinetics

The pharmacokinetic properties of morphine and the rest of opioids described in this chapter are summarized in Table 28.2. The pharmacokinetics of morphine and its metabolites vary, depending on the route of administration. The oral bioavailability ranges from 35 % to 75 %, with a plasma half-life ranging from 2 to 3.5 h. The half-life is less than the time course of analgesia, which is 4–6 h, thus reducing the accumulation. Morphine as other opioids presents a significant first-pass metabolism in the liver with oral dosing. Morphine is biotransformed mainly by hepatic glucuronidation to the major but inactive metabolite morphine-3-glucuronide (M3G) and the biologically active morphine-6-glucuronide (M6G) compound in a lower percentage (10 %). The M6G has a longer elimination half-life than morphine (4 h vs. 2 h) and has a more powerful analgesic activity. This metabolite is related with both the pharmacological effect and the toxicity of morphine. Thus, the equivalence between parenteral and oral morphine varies depending on the frequency of the administration, being 1:6 after a single administration and 1:2 or 1:3 after multiple doses; this is due to the high concentrations of M6G that are reached after oral treatment.

Table 28.2 Pharmacokinetic properties of main opioids

Opioid	Oral bioavailability (%)	Half-life (h)	Plasma protein binding (%)	Duration of action (h)	10 mg morphine equivalence (analgesia)

[a]Half-life for 6-β-naltrexone

A study on MST pharmacodynamic and pharmacokinetic properties compared to methadone showed that it can be administered once a day and could be a good alternative in patients nonresponders to methadone (Mitchell et al. 2003), but there is still a lack of controlled studies in opioid-dependent patients (Jegu et al. 2011).

28.2.1.3 Diacetylmorphine (Diamorphine, Heroin)

Heroin was developed in the 1870s by Bayer Laboratories as a treatment for injected morphine dependence. It is synthesized from morphine by acetylation at the three and six positions and is twice more active than morphine at equivalent doses due to its higher lipophilic properties. It has analgesic and antitussive activities and also was used as a remedy in the late phases of tuberculosis.

There are several types of heroin in the market depending on its origin and characteristics:

(a) **Base heroin or Tsao-ta**: comes from Southeast Asia. Its color is white or dark and is used for injection or smoking.
(b) **The brown sugar**: is the heroin used to be smoked. It has been mixed with other substances as caffeine, strychnine, sugars, etc. Its heroin contents vary from 25 % to 50 %.
(c) **White heroin or hydrochloride**: is also known as the Thai heroin. Its use is predominantly intravenous. It has the higher active content, sometimes more than 90 %.

(d) **Black heroin or black tar heroin**: as its name indicates, its aspect is similar to tar; it is a black and sticky substance. It comes from America and its purity is around 20 %. It is used for injection.

Pharmacodynamics

Heroin acts as a mu agonist through its metabolites 6-monoacetylmorphine (6-MAM) and morphine. The effects of heroin are the same as other mu-opioid agonists. With heroin use, thyroid hormone levels may be elevated because of raised thyroid-binding globulin; thus, there are increased measures without abnormal function (Kreek 1978). Heroin, as other short-acting opioids, reduces rosettes formed by human T lymphocytes (Kreek 1978). The possible explanation could be the increase of cortisol levels during opioid withdrawal and the consequent suppression of immune function (Novick et al. 1989).

Pharmacokinetics

Heroin itself has no intrinsic opioid activity; but it is a very effective prodrug and metabolized in humans to active opioid compounds first by deacetylation to the active 6-monoacetylmorphine (6-MAM) and then by further deacetylation to morphine, when administered by parenteral route (Inturrisi et al. 1984). The bioavailability of diacetylmorphine, when measured by morphine concentrations, is 80 % by intranasal route, 89 % by the smoked route, and 45 % in the *chasing the dragon* type of use (Hendriks et al. 2001). Oral heroin has complete first-pass metabolism (Inturrisi et al. 1984) with an oral bioavailability of 20–50 % and has very limited systemic bioavailability (only 6-MAM and morphine can be found in the blood). Compared to morphine, heroin given intramuscularly is about two times as potent as morphine for pain relief with a faster onset of peak mood effect; however, it has less sustained effect (Cone et al. 1993).

Heroin has an average half-life in blood of 3 min after intravenous administration; the half-life of 6-monoacetylmorphine in humans appears to be 3–10 min (Inturrisi et al. 1984). The blood clearance of heroin is greater than the upper range of hepatic blood flow in humans, indicating that organs other than the liver are likely involved in the metabolism of heroin, such as the gastrointestinal wall and the kidney (Inturrisi et al. 1984), as well as hepatic carboxylesterases such as butyrylcholinesterase (Kamendulis et al. 1996).

The use of intranasal, intramuscular, and subcutaneous heroin all produces peak blood levels of heroin or 6-monoacetylmorphine within 5 min; however, intranasal use has about half the relative potency (Cone et al. 1993).

28.2.1.4 Methadone

Pharmacodynamics

Methadone is a semisynthetic opioid agonist that is used in the chronic treatment of pain and in the opioid dependence disorder. It was first synthesized by Bayer as an analgesic in Germany in the late 1930s and first studied for human use in the 1950s in the United States. It has been used as a maintenance treatment for heroin addiction since the first years of the 1960s (Dole et al. 1966).

Its mechanism of action is mediated by the activation of the opioid receptors, mainly the mu type. At higher doses it can effectively block the euphoric effects of exogenous opioids (Dole et al. 1966). Methadone is an agonist at mu-, delta-, and, to a lesser extent, kappa-opioid receptors (Kristensen et al. 1995). Methadone also displays *N*-methyl-D-aspartate (NMDA) receptor antagonist properties, which affect the development of tolerance (Davis and Inturrisi 1999).

Methadone and its main metabolites, 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine (EDDP) and 2-ethyl-5-methyl-3,3-diphenyl-1-pyrrolidine (EMDP), are chiral molecules, which means that methadone has an asymmetrical carbon atom in its structure, implying that it exists in two enantiomeric forms, having the same chemical structure but different spatial arrangements, with one enantiomer being the mirror image of the other. Methadone is usually administered as a racemate, a 50:50 mixture of two enantiomers called (*R*)- or levo- or L-methadone and (*S*)- or dextro- or D-methadone. (*R*)-methadone has a higher affinity for opioid receptors and an increased analgesic potency than the (*S*)-enantiomer (Eap et al. 2002). Despite lacking strong opioid effects, (*S*)-methadone may be a clinically important determinant of (*R, S*)-methadone's therapeutic and adverse responses (negative mood effects – tension, fatigue, confusion, etc.) (Mitchell et al. 2004). Although (*R*)-methadone is believed to account for most, if not all, of the therapeutic effects of methadone maintenance treatment, (*R, S*)-methadone is normally used in therapeutics due to its lower production costs and an evidence that it produces similar therapeutic outcomes when compared with (*R*)-methadone alone (Eap et al. 1996; de Vos et al. 1998).

The adverse events of methadone are similar to those of morphine. In general, they are mild and not severe; the most common are constipation, sweating, and insomnia which tend to lessen due to the development of tolerance (Kreek et al. 1983; Kreek 1973). There is also a central effect, consisting in the persistence of the pulsatile increase in prolactin related to the peak level of methadone, which occurs approximately 2–4 h after daily administration (Kreek 1978).

There are two important adverse events related to methadone: the risk of respiratory depression and the risk of cardiac rhythm disorders related to QT interval prolongation (Eap et al. 2002; Chugh et al. 2008). A QT interval longer than 500 ms increases the risk of polymorphic ventricular tachycardia, such as torsade de pointes (TdP) (Schwartz et al. 1993). Other authors have also described QT prolongation and/or TdP appearance in MMT (Andrews et al. 2009; Krantz et al. 2009). The mechanism of this increase has been related to the inhibitory action of methadone on the hERG voltage-gated potassium channel and also could be related to the blockade of calcium channels in the cardiac myocyte membrane and the induction of bradycardia. Usually, patients with QTc prolongation present other risk factors and are exposed to higher doses of methadone (Fonseca et al. 2009).

Chronic administration of methadone (as with other long-acting opioids) leads to the gradual development of tolerance to the effects on hypothalamic-releasing factors, with resumption of normal menses and return of plasma levels of testosterone to normal within 1 year as well as return to normal levels and activity of

anterior pituitary-derived ACTH and beta-endorphin and normal ACTH stimulation in approximately 3 months. Prolactin levels still rise after oral methadone dosing; however, both peak plasma levels of methadone and also prolactin are found at 2–4 h after dosing; prolactin levels usually do not exceed the upper limit of normal (Kreek 1973).

Pharmacokinetics

Methadone is rapidly absorbed after an oral dose, it can be detected in the blood at 15–45 min after oral administration, and peak plasma concentrations occur at 2–4 h after dosing (Eap et al. 2002). The oral bioavailability of methadone was found to be around 70–80 % in a range of doses of 10–60 mg with large intersubject variations. Methadone is highly bound to plasma proteins, including albumin, lipoproteins, and mainly to alpha-1-glycoprotein. Enantiomeric differences are also relevant in protein binding (the unbound fraction for (*S*)-methadone is 10 % while for the (*R*)-enantiomer is 14 %) and its metabolic disposition. Although administered as a racemic mixture that contains the same amounts of (*R*)-methadone and (*S*)-methadone, the (*R*)-/(*S*)-methadone ratio varies significantly over the 24-h administration interval in steady-state conditions; and also, large interindividual differences can be seen in the (*R*)-/(*S*)-methadone ratio (Eap et al. 1996). All these variables might contribute to interindividual response differences to methadone treatment. Methadone is extensively metabolized in the body, mainly by CYP3A4 in liver, and in the intestinal epithelium, and to a lesser extent by CYP2B6 and CYP2D6. Its main metabolite (2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine (EDDP)) is inactive: it is formed by *N*-demethylation and spontaneous cyclization methadone half-life is about 28 h with a large interindividual variability (between 4 and 91 h). (*R*)-methadone has a longer half-life than (*S*)-methadone (38 vs. 29 h, respectively). After chronic administration, a reduction in half-life (from 55 to 22 h) has been detected because it induces its own metabolism regulated by cytochrome P450 CYP3A4 (Wolff et al. 2000).

The elimination of methadone is mostly due to metabolic clearance. The limited amounts of circulating drug that undergo glomerular filtration are partially reabsorbed by the kidney tubules, and this reabsorption is pH dependent. Methadone clearance varies from 23 to 210 ml/min, and there are significant differences between both enantiomers (158 ml/min vs. 129 ml/min for (*R*)- and (*S*)-methadone, respectively). Urinary pH has profound effects on methadone excretion and on the volume of distribution of the drug. By keeping the urinary pH constant, the interindividual differences of methadone elimination and plasma concentrations are considerably reduced.

28.2.1.5 Codeine

Codeine is one of several naturally occurring alkaloids found in opium. It is methylmorphine, with methyl substitution on the phenolic hydroxyl group of morphine. It is more lipophilic than morphine and thus crosses the blood–brain barrier faster. Its oral bioavailability is greater than that of morphine.

Pharmacodynamics

Codeine has very low affinity for opioid receptors; it is active because it is metabolized in part to morphine. Codeine is commonly used to suppress cough at doses lower than used for analgesia (starting with 10–20 mg given orally), which can be increased to higher doses for chronic (lower airway) cough. Codeine reduces cough via a central mechanism, with doses greater than 65 mg not indicated owing to little increased effect with increasing side effects (Yaksh and Wallace 2011).

Pharmacokinetics

Codeine undergoes *O*-dealkylation to morphine. The conversion is catalyzed by CYP2D6 (the same enzyme also converts dihydrocodeine, hydrocodone, and oxycodone). Other metabolites are mostly inactive and excreted in the urine; about 10 % are demethylated to morphine via CYP2D6, which are mostly responsible for the analgesic effect of codeine. Genetic variations in this enzyme system, complete or partial lacking of CYP2D6 (poor metabolizers), may result in lower or no production of morphine, and the subjects carrying this polymorphism would experience less effects of codeine, but those with multiple duplications of CYP2D6 (ultra metabolizer, ultrafast metabolizer) can transform abnormally large amounts of codeine into morphine and have the risk of intoxication. Repeated doses of codeine may result in the accumulation of the active metabolite M6G in patients with renal disease.

28.2.1.6 Buprenorphine

Buprenorphine is a semisynthetic opioid that, like oxycodone, is derived from thebaine. The chemical structure of buprenorphine is that of an oripavine with a C7 side chain, which contains a tert-butyl group. It is primarily mu-opioid receptor partial agonist and a kappa antagonist with a ceiling effect. Buprenorphine alone and in combination with naloxone was approved in 2002 by the FDA as an office-based sublingual treatment for heroin and opioid addiction (Borg et al. 2009). Norbuprenorphine is a major metabolite of buprenorphine in humans, with activity at the mu-opioid receptor (Huang et al. 2001).

Pharmacodynamics

Initially developed as an analgesic, buprenorphine has been shown in most studies to be as effective as morphine in many situations. It is 25–50 times more potent than morphine. Buprenorphine has some modest kappa-opioid receptor activity, and it has been shown that the kappa activity of buprenorphine is that of an antagonist (Cowan 2007). Also, an agonistic effect on the opioid receptor-like (ORL1) receptor has been described that has been also related to its characteristic ceiling effect (Lutfy and Cowan 2004). Buprenorphine has high affinity for, but low intrinsic activity at, mu receptors and displaces some full opioid agonists from receptors (Strain et al. 2002). For this reason, and because of buprenorphine's higher affinity for the mu receptor, full agonists cannot displace it and therefore will not exert a dose-related opioid effect on the receptors already occupied by buprenorphine, and also it can induce a withdrawal syndrome in subjects using full opioid agonists (Comer et al. 2001; Strain et al. 1995).

Owing to its ceiling effect, increasing doses in humans beyond 32 mg sublingually has no greater opioid agonist effect. Two important properties of buprenorphine are relevant: its apparent lower severity of withdrawal signs and symptoms on cessation, compared with heroin and methadone (San et al. 1992), and its reduced potential to produce lethal overdose when used alone in opiate-naive or nontolerant persons because of its partial agonist properties. However, it is not clear whether there is a ceiling for this effect; the respiratory depression and other effects of buprenorphine can be prevented by prior administration of naloxone, but they are not readily reversed by high doses of naloxone once the effects have been produced (Megarbane et al. 2010). This suggests that buprenorphine dissociates very slowly from opioid receptors.

As a partial mu agonist, it may cause symptoms of abstinence in patients who have been receiving receptor agonists for several weeks.

Pharmacokinetics

Buprenorphine has poor gastrointestinal bioavailability and fair sublingual bioavailability (Brewster et al. 1981). FDA-approved formulations of the drug for the treatment of opioid addiction are in the form of sublingual tablets that are held under the tongue and absorbed through the sublingual mucosa; also, a sublingual buprenorphine–naloxone film has been recently approved in some countries (Lintzeris et al. 2013). Concentrations in blood peak within 5 min of intramuscular injection and within 1–2 h of oral or sublingual administration. About 96 % of the circulating drug is bound to protein. Both *N*-dealkylated and conjugated metabolites are detected in the urine, but most of the drug is excreted unchanged in the feces.

Like morphine, the major metabolic pathway for buprenorphine is glucuronidation, not the oxidation. Buprenorphine is metabolized to norbuprenorphine, which occurs by dealkylation in the cytochrome P450-related enzyme 3A4 system, of which buprenorphine itself is a weak inhibitor (Yaksh and Wallace 2011). Buprenorphine undergoes extensive first pass in the liver; thus, it is administered sublingually with 50–60 % bioavailability.

A high percentage of buprenorphine is bound to plasma protein. The 3A4 metabolism involves some possible interactions with other drugs as antiretrovirals being less than with methadone; however, buprenorphine has not been so extensively studied (McCance-Katz and Mandell 2010).

The terminal elimination half-life of buprenorphine is long, and there is considerable variation in reported values (mean values ranging from 3 to 44 h). Most of a dose of buprenorphine is eliminated in the feces, with approximately 10–30 % excreted in urine (Elkader and Sproule 2005). Buprenorphine has a long duration of action (24–48 h) when administered on a chronic basis, not because of its pharmacokinetic profile but because of its very slow dissociation from mu-opioid receptors.

Despite the ceiling effect of buprenorphine as previously described, there have been a number of reported cases of deaths in Europe with concurrent benzodiazepine abuse (Lintzeris et al. 2007). After the report in many countries of the buprenorphine diversion and the intravenous misuse, a new formulation was developed in combination with naloxone (Yokell et al. 2011). In this formulation,

naloxone will not precipitate withdrawal when taken sublingually because of its limited oral bioavailability; however, it may block the initial euphoric effects of buprenorphine if abused by the intravenous route and may also then precipitate acute opioid withdrawal (Mendelson and Jones 2003). The 4:1 ratio of buprenorphine to naloxone reduces any pleasurable effects of intravenous buprenorphine by blocking a small percentage of opioid receptors and may also produce modest withdrawal symptoms (Mendelson and Jones 2003). However, this effect is reduced in the presence of benzodiazepines.

28.2.1.7 Oxycodone

Oxycodone is a semisynthetic compound derived from thebaine, with agonist activity, primarily at mu receptors. Oxycodone has been used clinically since the early 1900s. It is combined with aspirin or acetaminophen for moderate pain and is available orally without coanalgesic for severe pain. It is a popular drug of abuse, especially in the controlled-release formulation, which can be crushed for a potentially toxic, rapid "high" comparable to the effects of the immediate-release formulation (Webster et al. 2012).

Pharmacokinetics

The onset of action begins after 1 h, and in controlled-release form, it lasts for approximately 12 h, with a plasma half-life of 3–4 h for the immediate release. Stable plasma levels are achieved within 24 h. Oral bioavailability ranges from 60 % to 87 %, with 45 % protein bound. Oxycodone is mostly metabolized in the liver, with the remainder as well as the metabolites metabolized in the kidneys. It is *O*-demethylated (CYP2D6) to oxymorphone and *N*-demethylated (CYP3A4 and CYP3A5 mediated) to noroxycodone (more abundant) (Lugo and Kern 2004). Oxymorphone is also a potent analgesic, and noroxycodone is a weaker analgesic (Lugo and Kern 2004).

In terms of protein binding and lipophilicity, oxycodone is similar to morphine, with slightly longer half-life and greater bioavailability. Unlike morphine, oxycodone is metabolized mostly by the cytochrome enzyme CYP2D6.

28.2.1.8 Hydromorphone

Hydromorphone is a semisynthetic opioid agonist and a hydrogenated ketone of morphine. It was first synthesized in Germany in 1921 and was introduced into clinical practice by 1926 (Murray and Hagen 2005). Hydromorphone has commonly been viewed as a second-line drug in the treatment of pain, although being more potent than morphine (five times more potent when given orally and 8.5 times as potent when given intravenously) (Murray and Hagen 2005). It is used for the treatment of acute pain, chronic cancer pain, and, to a lesser extent, chronic nonmalignant pain (Murray and Hagen 2005). It is excreted along with its metabolites by the kidney. It can be given intravenously, by infusion, orally, and per rectum, with low oral bioavailability.

Recently, an osmotic controlled-release oral delivery system (OROS) hydromorphone extended release has been designed, which allows once-daily dosing. Some clinical trials have been performed to evaluate the convertibility of other opioids in chronic pain. The side effects are comparable to other opioids.

Pharmacokinetics

Hydromorphone is shorter acting than morphine. It is derived from morphine, although it may also be produced in the body in small amounts by *N*-demethylation of hydrocodone. It has an oral bioavailability of 30–40 %, with an analgesic onset after 10–20 min, which peaks at about 30–60 min and persists for about 3–5 h. The oral–parenteral ratio is about 5:1, with an equivalency of 1.5 mg of hydrocodone to 10 mg morphine (Murray and Hagen 2005).

28.2.1.9 Hydrocodone

Hydrocodone is a prescription drug frequently used for relatively minor (such as dental) pain. It is often used in combination with acetaminophen; thus, there can be hepatotoxicity associated with its abuse. Hydrocodone has the same potency as morphine on a milligram-for-milligram basis.

Pharmacokinetics

Hydrocodone is well absorbed from the gastrointestinal tract. The peak plasma concentration appears after 1.3 h of its administration and has a half-life of 2–4 h, with a peak effect at 0.5–1 h (McEvoy 2007). Its duration of action is 3–4 h. It is metabolized by CYP3A4 and CYP2D6, and its main metabolites are norhydrocodone and hydromorphone. Codeine may show up as trace quantities of hydrocodone in urine testing as up to 11 % of codeine is metabolized to hydrocodone (Oyler et al. 2000), which could be misinterpreted as hydrocodone abuse.

28.2.1.10 Meperidine

Meperidine or pethidine is a phenylpiperidine. It was first developed as an anticholinergic agent. It is mostly effective in the CNS and bowel; however, it is no longer used for treatment of chronic pain owing to concerns regarding toxicity of its metabolite and should not be used for more than 48 h or at doses above 600 mg/day. It has serotonergic activity when combined with monoamine oxidase inhibitors (MAOIs), which can produce serotonin toxicity (clonus, hyperreflexia, hyperthermia, and agitation); besides, the analgesic effects of meperidine are not pronounced (Latta et al. 2002).

Pharmacodynamics

Meperidine is a potent mu agonist yielding strong analgesic actions. Peak respiratory depression is observed within 1 h of intramuscular administration, and there is a return toward normal starting at 2 h, approximately. Like other opioids, meperidine causes pupillary constriction, increases the sensitivity of the labyrinthine apparatus, and has effects on the secretion of pituitary hormones similar to those of morphine. Meperidine sometimes causes CNS excitation, characterized by tremors, muscle twitches, and seizures; these effects are due largely to the accumulation of a metabolite, normeperidine. Meperidine has well-known local anesthetic properties, particularly noted after epidural administration. As with morphine, respiratory depression is responsible for an accumulation of CO_2.

Meperidine can release histamine following parenteral administration. Due to its effects on the smooth muscle, meperidine can slow gastric emptying; however, it does not cause as much constipation as morphine.

Pharmacokinetics

Meperidine is absorbed by all routes of administration, but the rate of absorption may be erratic after intramuscular injection. By the oral route, the onset of analgesia begins after 15 min, with peak in 1–2 h, which is close to the peak level in plasma, with duration of about 1.5–3 h (Yaksh and Wallace 2011). It is absorbed by all routes, but intramuscular administration results in a less reliable peak plasma level after 45 min, with a wide range of plasma concentrations. After oral administration, about 50 % of the drug enters the circulation without first-pass metabolism, with peak at 1–2 h. Sixty percent of meperidine is protein bound, and little is excreted unmetabolized (Latta et al. 2002). Meperidine is mostly metabolized in the liver, with half-life of about 3 h. In humans, meperidine is hydrolyzed to meperidinic acid, which in turn is partially conjugated. Meperidine also is *N*-demethylated to normeperidine, which then may be hydrolyzed to normeperidinic acid and subsequently conjugated. Normeperidine has modest analgesic properties, but it is a potent CNS stimulant and can cause seizures (Yaksh and Wallace 2011).

28.2.1.11 Pentazocine

Pentazocine was approved in the late 1960s, both the oral and the parental formulations. It is a partial agonist or antagonist at mu receptor and also a kappa receptor partial agonist. For analgesia, it has been manufactured also with acetaminophen. Later, it was manufactured in combination with naloxone to diminish its intravenous use. Its abuse declined after this change in the formulation according to DAWN emergency room register (Fudala and Johnson 2006).

Pharmacodynamics

The pattern of CNS effects produced by pentazocine generally is similar to that of the morphine-like opioids, including analgesia, sedation, and respiratory depression. The analgesic effects of pentazocine are due to agonistic actions at opioid receptors but present a ceiling effect. The cardiovascular responses to pentazocine differ from those seen with typical receptor agonists, in that high doses cause an increase in blood pressure and heart rate. Pentazocine does not antagonize the respiratory depression produced by morphine. However, when given to patients dependent on morphine or other *mu* agonists, pentazocine may precipitate withdrawal due to its partial agonist–antagonist actions at the *mu* receptor. At high doses (60–90 mg), pentazocine elicits dysphoric and psychotomimetic effects, probably due to its kappa agonist properties.

Pharmacokinetics

Pentazocine is a mixed agonist–antagonist that can be given intramuscularly or orally but is not currently available in the oral formulation. Because it can cause psychotomimetic effects, it has a very limited role in the treatment of chronic pain.

Its duration of action is 3–6 h. Its peak effect is at 0.5–1 h when given intramuscularly and 1–2 h when given orally. Sixty percent of the drug is bound to protein. Pentazocine is metabolized by the liver via oxidative and glucuronide conjugation with an extensive first-pass effect. When administered orally, the bioavailability of pentazocine is about 10 %, except in patients with cirrhosis, which increases bioavailability to 60–70 %. The drug half-life is 2–3 h. Small amounts of unchanged pentazocine are excreted with urine (Yaksh and Wallace 2011).

28.2.1.12 LAAM

Levacetylmethadol or levomethadyl acetate or levo-α-acetylmethadol (LAAM) is a synthetic, longer-acting (48-h) congener of methadone that also is orally effective. LAAM was first studied in the 1970s for the treatment of heroin addiction and approved in 1993 by the FDA after a large multicenter safety trial (Kreek and Vocci 2002). Postmarketing, after reports of prolonged QTc intervals on electrocardiogram leading to torsade de pointes that may have been caused by LAAM, a black-box warning was added to the product label and marketing continued in the United States until 2003. LAAM was withdrawn from the European countries at 2001. This effect may have been the result of preexisting cardiac disease or undefined drug interactions (Kreek and Vocci 2002). At this moment, LAAM is not marketed by any pharmaceutical company.

LAAM acts as a pure opioid agonist, active mostly at the mu-opioid receptor (Yaksh and Wallace 2011; Kreek and Vocci 2002).

Pharmacokinetics

LAAM shares with methadone the properties of long duration of effect (48 h vs. 24 h for methadone), in part owing to its active metabolites nor-LAAM and dinor-LAAM, as well as its steady-state perfusion of mu-opioid receptors. LAAM was previously considered a prodrug, but this was refused in a study (Walsh et al. 1998) showing that intravenous LAAM produced significant subjective and physiological effects that appeared within 5 min, whereas the effects of oral LAAM appeared more slowly within 1–2 h after drug administration; the pharmacokinetic data indicate that the immediate effects of intravenous LAAM could be attributable to the parent drug rather than the active metabolites.

Oral LAAM undergoes extensive first-pass metabolism to the active demethylated metabolite nor-LAAM, which is further demethylated to a second active metabolite, dinor-LAAM. These metabolites are more potent than the parent drug. Oral bioavailability is less than 50 %. Nor-LAAM and dinor-LAAM accumulate with chronic administration. In addition, LAAM and its metabolites bind to tissue proteins. The clearance of nor-LAAM and LAAM is similar, whereas the clearance of dinor-LAAM is more prolonged than that of its parent compound. The peak pharmacological effect of LAAM as measured by the amount of pupillary constriction occurred at 8 h and then diminished at a rate most like that of nor-LAAM metabolism (Borg et al. 2009).

LAAM is metabolized in the gut wall and liver to active metabolites, nor-LAAM and dinor-LAAM, through sequential demethylation (Walsh et al. 1998).

Because of the metabolism of LAAM by the cytochrome P450 3A4 system-related microsomal enzymes to nor-LAAM and dinor-LAAM, drug interactions can occur (e.g., rifampin and long-term alcohol abuse tend to induce this enzyme system). In their presence, increased biotransformation of LAAM could accelerate the production of nor-LAAM and dinor-LAAM. LAAM metabolism theoretically could be retarded if hepatic drug metabolism is diminished, as occurs either in the presence of very large quantities of ethanol or perhaps with large doses of benzodiazepines or with intake of cimetidine (Borg et al. 2009).

28.2.1.13 Tramadol

Tramadol is a synthetic codeine and morphine analog that is a weak mu agonist. It also exerts some capacity to inhibit the uptake of norepinephrine and serotonin. It is more effective in the treatment of the mild and moderate pain than in the treatment of severe and chronic pain (Yaksh and Wallace 2011). Misuse, diversion, physical dependence, abuse, addiction, and withdrawal have been reported in conjunction with the use of tramadol. Tramadol has been shown to reinitiate physical dependence in some patients who have previously been dependent on other opioids; thus, it should be avoided in patients with a history of addiction (Mayor 2013).

Pharmacodynamics

Tramadol is a chiral molecule, administered as a racemic mixture; the (R)-enantiomer and the metabolite (*R*)-*O*-desmethyltramadol (M1) are agonists of the μ-opioid receptor, and they inhibit serotonin reuptake. The (*S*)-enantiomer inhibits norepinephrine reuptake and stimulates two adrenergic receptors (Lewis and Han 1997). As a consequence, the (S) form enhances the inhibitory effects on pain transmission in the spinal cord.

The pharmacological effects are similar to those of morphine, and the main adverse effects include nausea, vomiting, dizziness, dry mouth, sedation, and headache. Respiratory depression and constipation are mild compared to morphine. Tramadol can cause seizures and possibly exacerbate seizures in patients with predisposing factors. Some effects of tramadol can be reversed by naloxone as respiratory depression, but not the analgesia. There is an increased risk of seizures with the combined use of tramadol and naloxone.

Pharmacokinetics

Tramadol has a bioavailability of 100 % after an intramuscular dose and 68 % after an oral dose. Its affinity for the mu-opioid receptor is weaker than morphine, but the *O*-demethylated metabolite M1 is two to four times as potent as the parent drug and may account for part of the analgesic effect.

Tramadol is metabolized in the liver, mainly by CYP2D6 and CYP3A4, thus explaining some reported cases of interactions with methadone (Leavitt 2005), and also undergoes conjugation and renal excretion. Poor metabolizers of CYP2D6 have less analgesic effects due to lower levels of *O*-desmethyltramadol (M1). The elimination half-life is 6 h for tramadol and 7.5 h for its active metabolite. Analgesia begins within an hour of oral dosing and peaks within 2–3 h. The duration

of analgesia is approximately 6 h. The maximum recommended daily dose is 400 mg (Yaksh and Wallace 2011).

28.2.1.14 Tapentadol

Tapentadol is a centrally acting synthetic analgesic, indicated for the management of moderate to severe acute pain in adults. The recommended doses are 50 mg, 75 mg, or 100 mg every 4–6 h depending upon pain intensity. Daily doses greater 600 mg are not recommended. In the case of the extended-release preparation, usual doses are 100–250 mg twice daily. Tapentadol immediate release was originally approved by the FDA in November 2008, and in 2011, the extended-release formulation (Hartrick and Rozek 2011; Hoy 2012).

Pharmacodynamics

Tapentadol exact mechanism of action is unknown. Preclinical studies have shown that tapentadol is a mu-opioid receptor agonist and a norepinephrine reuptake inhibitor. It is 18 times less potent than morphine in binding to the human mu-opioid receptor and is two to three times less potent in producing analgesia in animal models. Tapentadol has been shown to inhibit norepinephrine reuptake resulting in increased norepinephrine concentrations. The principal therapeutic action of tapentadol is analgesia. As other opioids, tapentadol causes respiratory depression, tolerance, and dependence (Hartrick and Rozek 2011; Hoy 2012).

Pharmacokinetics

Absolute bioavailability is approximately 32 % due to extensive first-pass metabolism. Maximum serum concentrations of tapentadol are observed at around 1.25 h after dosing. In extended-release formulations, maximum serum concentrations are observed between 3 and 6 h after administration.

The major pathway of tapentadol metabolism is conjugation with glucuronic acid. After oral administration approximately 70 % of the dose is excreted in the urine in the conjugated form (55 % *O*-glucuronide and 15 % sulfate of tapentadol). Only 3 % of drug was excreted in the urine as unchanged drug. In addition, tapentadol is metabolized to *N*-desmethyl tapentadol (13 %) by CYP2C9 and CYP2C19 and to hydroxyl tapentadol (2 %) by CYP2D6, which are further metabolized by conjugation. None of the metabolites contribute to the analgesic activity. Tapentadol and its metabolites are excreted almost exclusively (99 %) via the kidneys. The terminal half-life is on average 4–5 h after oral administration (Hartrick and Rozek 2011; Hoy 2012).

28.2.1.15 Naloxone

Naloxone is a pure opioid antagonist for parenteral use. It is an *N*-allyl derivative of oxymorphone. Naloxone is competitive antagonist at all opioid receptors, but it has greatest affinity for mu receptors. Naloxone is usually administered in the emergency department to revert heroin overdoses and also as an aid to distinguish causes of coma (if patient does not respond to naloxone, nonopioid causes should be considered) (Boyer 2012).

Pharmacodynamics

Small doses of naloxone reliably reverse or prevent the effects of pure opioid agonists and most mixed agonists–antagonists (Schäfer 2011; Mitchell et al. 2003). However, given alone, naloxone is nearly devoid of clinically demonstrable effects. In humans, extremely large doses (4 mg/kg) cause a mild increase in heart rate and systolic blood pressure, as well as slowing of EEG alpha-wave activity.

Pharmacokinetics

Naloxone is widely distributed and rapidly achieves effective concentrations in the CNS after parenteral administration. Plasma and brain concentrations fall precipitously because of rapid redistribution. The drug is rapidly cleared by hepatic biotransformation, mainly to the 3-glucuronide. The clearance is very high (approximately 30 ml kg^{-1} min^{-1}), which suggests that extrahepatic elimination may be occurring. The terminal half-life is 1–2 h. The onset of antagonist effect is extremely rapid, but the duration of action is quite brief. The duration of naloxone is nearly always shorter than that of the opioids whose effects it is intended to antagonize. It has to be taken into account that opioid reversal can sometimes have important hemodynamic consequences. Increases in systemic pressure, heart rate, and plasma levels of catecholamines can occur. Oral or sublingual administration of naloxone has very low systemic bioavailability due to marked hepatic first-pass metabolism. Enteral naloxone can block opioid action at the intestinal receptor level but has no general effects.

28.2.1.16 Naltrexone

Naltrexone is an opioid antagonist, chemically related to naloxone. Compared to naloxone, it has higher oral bioavailability and a longer duration of action. Naltrexone has been used for relapse prevention in opioid dependence because of its ability to antagonize all the actions of opioids. Also, there is evidence that naltrexone blocks activation by alcohol of dopaminergic pathways in the brain that are thought to be critical to reward, so it is used also in the treatment of alcohol dependence, as relapse prevention substance.

A depot formulation of naltrexone that provides 30 days of medication after a single injection has been approved for the treatment of alcoholism and heroin dependence in detoxified patients (Lobmaier et al. 2011). This formulation eliminates the necessity of daily pill-taking and prevent relapse when the recently detoxified patient leaves a protected environment (Krupitsky et al. 2011).

Pharmacodynamics

If administered at doses of 25 mg/day, it blocks completely the *mu*-opioid receptor, impeding the effects of the opioid agonists. If administered in alcohol-dependent subjects (doses of 50 mg/day), patients experience less craving for alcohol and less feelings of reward if they drink alcohol. A pharmacogenomic-related response to naltrexone in opioid-dependent subjects at mu receptor gene (OPRM1) has been described: those patients carrying the Asp40 allele had an increased percentage of days abstinent and a decreased percentage of heavy drinking days if treated with

naltrexone versus placebo, while those with the Asn40/Asn40 genotype showed no medication differences (Anton et al. 2008).

The most common side effect of naltrexone is nausea. An increase of transaminases could be observed, and if the dose is excessive, it can cause liver damage (Rosow and Dershwitz 2011).

Pharmacokinetics

Naltrexone is rapidly absorbed and undergoes 95 % first-pass metabolism to 6-β-naltrexol. This is an active metabolite that probably accounts for most of the naltrexone activity. The metabolite accumulates during chronic treatment and has a terminal half-life of 12.9 h, so significant antagonist effects may persist for 2–3 days after naltrexone is stopped.

28.2.1.17 Nalmefene

Nalmefene is another long-lasting opioid antagonist. It is the 6-methylene derivative of naltrexone. It is an antagonist at the mu- and delta-opioid receptors and a partial agonist at the kappa receptors (Soyka and Rosner 2010); there is no evidence of activity in any other receptor. Some advantages over naltrexone have been described, including greater oral bioavailability (Gal et al. 1986), longer duration of action (Gal et al. 1986; Ingman et al. 2005), and lack of dose-dependent liver toxicity (Mason et al. 1999).

As said previously, nalmefene also exerts a kappa partial agonism; the kappa-opioid system has been associated with motivational aspects in alcohol dependence, and nalmefene has been associated with a decreased alcohol self-administration in preclinical studies (Walker and Koob 2008).

Pharmacokinetics

Nalmefene is rapidly absorbed; the mean half-life was 13.4 h after single and repeated dosing, meaning that it has linear pharmacokinetics (Soyka and Rosner 2010). A slow dissociation of the drug from the mu-opioid receptor has been described. A clearance half-life of 28.7 ± 5.9 h has been reported for central opioid receptors and a plasma elimination half-life of 8.30 ± 0.34 h. Oral nalmefene may block receptors for longer and have a longer half-life over 24 h than naltrexone (Soyka and Rosner 2010). There is no evidence of any serious adverse drug reactions in hepatic or other body systems.

28.2.2 Treatment of Opioid-Related Disorders

Opioid addiction is a chronic and relapsing disorder with high costs to individuals, families, and society. Opiates, including the increasing abuse of prescription opioids, continue to be the main problem drug worldwide. The total number of opiate users at the global level is now estimated around 16.5 million people or 0.4 % of the population aged 15–64. A high prevalence for opiate use has been reported from Southwest and Central Asia, Eastern and

Table 28.3 Main strategies in opioid-related disorder treatment

	Type	Objective	Process	Pharmacological treatment
Opioid acute intoxication	Opioid overdoses	Decrease mortality	Revert opioid intoxication	Naloxone
Opioid withdrawal	Opioid detoxification	Avoid withdrawal syndrome	Detoxification	Methadone Buprenorphine Clonidine/lofexidine
Opioid addiction	Total abstinence oriented	Remove the opioid	Detoxification + Continued total abstinence	Methadone Buprenorphine Clonidine/lofexidine +/− Naltrexone
	Opioid agonist maintenance	Stabilization Harm reduction	Stabilizes brain neurochemistry Functional improvement	Agonist maintenance treatment Needle exchange and other risk reduction strategies

Southeastern Europe, and North America (United Nations Office on Drugs and Crime 2013).

The text revision of the fifth edition of Diagnostic and Statistical Manual of Mental Disorders (DSM-5) divides opioid-related disorders into opioid addiction, opioid intoxication, opioid withdrawal, and other opioid-induced disorders (i.e., induced depression, induced anxiety, etc.)

Opioid addiction includes physiological, behavioral, and cognitive symptoms, ending in a repeated use of opioid drugs, despite significant problems related to such use, and is characterized by compulsion to seek and take the drug; as in other drug dependence, there is a loss of control in limiting the intake and emergence of a negative emotional state (i.e., dysphoria, anxiety, irritability) reflecting a motivational withdrawal syndrome when access to the drug is prevented (Koob and Volkow 2010). Opioid addiction can be mild, moderate, or severe depending on the number of criteria fulfilled.

In this section we present the main therapeutic strategies used in the treatment of opiate overdose, withdrawal, and addiction (Table 28.3).

28.2.2.1 Opiate Overdose

Opiate overdose is a life-threatening emergency. Typical signs are depressed consciousness, depressed respirations, and miotic pupils. The treatment goal is to sustain or restore vital functions and to immediately reverse the overdose with an opioid antagonist (naloxone).

First, it is essential to maintain the air pathway, and then, to avoid aspiration, put the patient in lateral decubitus position; if necessary, in case of cardiopulmonary arrest, mechanical ventilation should be applied.

The administration of naloxone 0.2–0.4 mg intravenously will begin to reverse the effects of an opiate overdose within 1 min. If there is no response to the initial dose, repeat doses may be administered every 2–3 min (0.5 mg, 2 mg, 4 mg, and 10 mg).

If the patient has no response to 10 mg, then an opioid likely is not responsible for the respiratory depression.

Finally, once the consciousness level is reverted, it is important to investigate a possible suicide intention risk of the patient and to perform a psychiatric assessment.

28.2.2.2 Opiate Withdrawal Syndromes

The withdrawal syndrome for short-acting opiates (heroin or morphine) begins 6–12 h after last use. Early symptoms include opiate craving, anorexia, anxiety, and irritability. These are coupled with clinical signs of increased respirations and blood pressure, sweating and yawning, rhinorrhea, lacrimation, piloerection (gooseflesh), tremor, and dilated pupils. After 48–72 h, the symptoms progress to include nausea, vomiting, diarrhea, insomnia, tachycardia, abdominal cramps, and involuntary muscle spasms and limb movements. Signs subside over 5–7 days. Signs and symptoms associated with withdrawal from long-acting opioids such as methadone are similar to those described above, but they may not begin until 24–48 h after the last dose and may last for 2–3 weeks or more. Withdrawal syndrome of buprenorphine is similar to other long-acting opioids, but it is usually less intense and of shorter duration. Withdrawal can also appear when an opioid antagonist, such as naloxone or naltrexone, is provided to a subject under any opioid agonist drug use; this is called precipitated withdrawal.

28.2.2.3 Treatment of Opioid Addiction

Opioid dependence is a complex and relapsing disorder with high rates of comorbidity (psychiatric disorders, infections such as HIV and hepatitis C), mortality (overdose), and legal and social problems (Sellman 2010). The two main therapeutic strategies in opioid dependence are as follows: abstinence-oriented treatments and maintenance treatments (Veilleux et al. 2010).

28.2.2.4 Total Abstinence-Oriented Treatments

In the abstinence-oriented treatments, the goal is to remove the opioid in a controlled fashion, with a complete eradication of the opioid agonist treatment. Abstinence is usually achieved in two stages: detoxification and relapse prevention.

Detoxification

Detoxification involves the substitution of the abused opioid by other long half-life opioid agonist or partial agonist (methadone or buprenorphine, usually) or an alpha2-adrenergic agonist (clonidine or lofexidine) and a progressive reduction in order to reduce the intensity of the withdrawal syndrome (Amato et al. 2005a; Gowing et al. 2009a, b).

When comparing detoxification treatments, methadone versus alpha2-adrenergic agonist treatments, studies showed similar results by means of withdrawal intensity and treatment completion (Gowing et al. 2009b). However, participants stayed in treatment for longer and experienced fewer adverse side effects on methadone and buprenorphine (Ziedonis et al. 2009). Also, clonidine, the most frequently tested

alpha2-adrenergic agonist, has been associated with potentially hazardous side effects as sedation and hypotension (Gowing et al. 2009b).

Methadone detoxification guidelines recommend to start with an initial dose of 10–45 mg/day, orally, depending on the severity of opioid withdrawal symptoms. Every 2 h it is necessary to assess the intensity of withdrawal and ensure that the dose will not exceed 60 mg/day. The same dose of the first day should be administered for 2–3 days and then reduced to 5–10 mg/day until total suppression. The detoxification usually lasts 10–20 days.

When buprenorphine (or buprenorphine–naloxone) is used in the detoxification treatment, initial doses of 4–6 mg of buprenorphine are recommended, and then increase the dose until 8–10 mg/day. After 2–3 days, the recommendation is to reduce the dose to 2 mg every 1–2 days until complete suppression. It is important to administer the first dose 24 h after the last heroin use, when the first withdrawal symptoms appear, in order to avoid a precipitated withdrawal.

In general, the use of long-acting opioids (such as methadone) is recommended in opioid detoxification, with a long and slow tapering, medical supervision, ancillary medications, and psychosocial treatment to improve the outcomes and reduce the risk of relapse (Amato et al. 2005a). However, there is a low rate of success in detoxification treatments with high prevalence of relapse in heroin use.

Rapid and ultrarapid protocols for detoxification are described. These inpatient protocols involve a rapid clonidine taper combined with a transition to narcotic antagonist treatment with naltrexone. Ultrarapid detoxification protocols require the use of general anesthesia or heavy sedation. A review of the evidence on rapid and ultrarapid detoxification concluded that the studies were inadequate because of the small number of subjects included, variations in protocols utilized, lack of randomized design and/or control groups, and lack of long-term follow-up (O'Connor and Kosten 1998). In addition, deaths and psychotic syndromes have been reported during the 16–40 h following ultrarapid detoxification (Kaye et al. 2003; Shreeram et al. 2001); for this reason alone, ultrarapid detoxification procedures cannot be recommended.

Continued Total Abstinence

Naltrexone is a full opioid antagonist used after complete opioid detoxification to maintain the total abstinence. Its high affinity for the mu-opioid receptor produces a blockade of the pharmacological effects of heroin during 24–48 h with 50 mg of naltrexone. To initiate naltrexone treatment, a naloxone test to assure the complete detoxification is recommended.

The main advantages of naltrexone include the following: decrease in opioid craving, can be administered in a standard outpatient office setting, and the absence of abuse potential. Also, it is well tolerated with few adverse effects, except for the risk of increase of liver enzymes. Despite all these advantages, naltrexone has shown low rates of efficacy, with poor retention and high relapse rates (Minozzi et al. 2011; Sullivan et al. 2006).

To improve the described problems with retention and relapse with naltrexone, a sustained-release formulation has been developed in the form of implants and

depot injections. A Cochrane review identified a trial where a dose of 384 mg of depot naltrexone was associated with better retention than placebo (Lobmaier et al. 2008). Another study performed in Russia (Krupitsky et al. 2011) also showed better rates of abstinence and retention in the depot naltrexone compared to placebo. Only one study has compared the efficacy of depot naltrexone versus methadone maintenance treatment (Lobmaier et al. 2010) in 46 volunteers in a prison setting. The study was randomized, and the results showed similar reductions in the use of heroin and benzodiazepines and criminality 6 months after prison release. In conclusion, depot formulations of naltrexone seem to be promising in order to improve outcomes in opioid dependence disorder in less well-integrated subjects with a strong motivation to become total abstinent. Oral naltrexone is a treatment option for patients also with a strong motivation to become total abstinent of all opioid agonists and very well integrated.

28.2.2.5 Opioid Maintenance Treatments

Maintenance treatment with opioid agonist stabilizes brain neurochemistry by replacing short-acting opioids with a long-acting opioid that has relative steady-state pharmacokinetics, such as methadone or buprenorphine.

Opioid agonist maintenance treatment is designed to have a minimal euphoric effect, blocks the euphoria associated with the administration of exogenous opioids, and eliminates the phenomenon of opioid withdrawal (Fiellin et al. 2006). The most frequently studied medications for maintenance treatment are methadone and buprenorphine and, to a lesser extent, (*R*)-methadone, levacetylmethadol (LAAM), sustained-release morphine, and diacetylmorphine (heroin).

28.2.2.6 Methadone Maintenance Treatments

In general, methadone maintenance treatment (MMT) is considered the first-line treatment for opioid dependence. MMT is the most widely used treatment for heroin dependence, and a great body of research exists that supports its effectiveness in the treatment of opioid dependence disorder. MMT has demonstrated its efficacy in retaining patients in treatment and decreasing illicit opioid use (Amato et al. 2005b; Farre et al. 2002), decreasing risk behaviors related to the HIV/sexually transmitted diseases (Marsch 1998), decreasing criminal behavior related with drug use (Dolan et al. 2005), reducing the risk of fatal overdose (Brugal et al. 2005), and improving health-related quality of life (Torrens et al. 1999).

Methadone dosing should be based on clinically guided dose titration. Usual maintenance dosage of methadone is 60–100 mg/day; some patients achieve abstinence or are free of withdrawal symptoms when treated with less than 40 mg/day of methadone. Some studies suggest that methadone doses of 60–100 mg/day or higher are more effective than lower doses for reducing or stopping illegal opiate self-administration in opioid-dependent patients. Regarding the duration of maintenance treatment, there are no clear recommendations; however, the literature shows better improvements with longer treatments, so the advice is to favor indefinite treatments and start the suppression when significant changes in lifestyle have been made (Calsyn et al. 2006; McLellan et al. 1997).

In spite of its well-established therapeutic efficacy, there is a large interindividual variability in outcome; between 30 % and 80 % of patients treated are poor responders to methadone treatment when retention in program and illicit opioid use are considered as the main measures of outcome (Bell et al. 2006; United States General Accounting Office 1990). Classically, the main strategies used to optimize the MMT programs have been focused in the characteristics of the MMT program, mainly in relation to the methadone provided (high vs. low methadone doses, abstinence-oriented programs vs. maintenance-oriented programs, etc.) and psychosocial programs offered (Ward et al. 1998).

The main problem associated with MMT has been described in the first part of this chapter and is related with an increased risk of QTc prolongation, needing a closer cardiological supervision (Fonseca et al. 2009; Krantz et al. 2009).

28.2.2.7 Buprenorphine and Buprenorphine–Naloxone Maintenance Treatments

Buprenorphine is a partial opioid agonist, with a ceiling effect for respiratory depression and with reduced abuse potential (Veilleux et al. 2010). Studies found buprenorphine to be therapeutically superior to naltrexone (Schottenfeld et al. 2008). When compared to placebo, buprenorphine at medium and high doses improved treatment retention and decreased opioid use (verified by urinalysis) (Mattick et al. 2008). However, when compared to methadone maintenance, methadone is more efficacious than buprenorphine in terms of treatment retention (Mattick et al. 2008; Hser et al. 2013).

A major concern with the use of buprenorphine the risk of diversion and misuse. Two strategies have been used to overcome this risk. The commercialization of buprenorphine in combination with naloxone (4:1 ratio, sublingual tablets containing buprenorphine 2 and 8 mg and naloxone 0.5 and 2 mg), and the use of deterrent formulations, as the soluble film, approved by the FDA in 2010 (sublingual film containing buprenorphine 2, 4, 8, or 12 mg and naloxone 0.5, 1, 2, or 3 mg) (Soyka 2012).

To initiate buprenorphine or buprenorphine–naloxone treatment successfully and to avoid a precipitated withdrawal, it is essential to determine that the patient is opiate-free for at least 24 h (in case of short-acting opiates) and observe the presence of opiate withdrawal symptoms. The recommended initial dose is 4 mg sublingually and should be administered at the clinic, and the patient should remain under observation for 2 h. Supplemental doses can be given if withdrawal symptoms persist, with a maximum recommended first-day dose of 8 mg. The dose can be raised in 2 to 4 mg increments over the next 2–3 days. Doses of 8–16 mg buprenorphine are superior to lower doses, and doses of 12–24 mg are preferable for maintenance treatment. Doses should not exceed a maximum single daily dose of 24 mg. Because of the ceiling effect, there is no pharmacological justification for daily doses over 32 mg.

Less than daily dosing can be used in patient using 8 mg/day or less. After a satisfactory stabilization has been achieved, the frequency of dosing may be decreased to dosing of every other day at twice the individually titrated daily dose. For example, a patient stabilized to receive a daily dose of 8 mg may be

given 16 mg on alternate days, with no dose on the intervening days. In some patients, after a satisfactory stabilization has been achieved, the frequency of dosing may be decreased to three times a week (e.g., on Monday, Wednesday, and Friday). The dose on Monday and Wednesday should be twice the individually titrated daily dose, and the dose on Friday should be three times the individually titrated daily dose, with no dose on the intervening days. However, the dose given on any 1 day should not exceed 24 mg.

The main advantages of buprenorphine compared to methadone maintenance treatment are the lower risk of fatal respiratory depression during intoxication, the quick induction to full doses, its cardiac safety because it has no effect on the QTc interval, the lower risk of interactions, and the destigmatization of patients compared to methadone.

28.2.2.8 (*R*)-Methadone Maintenance Treatment

(*R*)-methadone (or L-methadone or Polamidon®) is the active component of the racemic methadone, and it is used in Germany as the maintenance treatment of opioid dependence disorder. As described previously, (*R*)-methadone shows more affinity of the mu receptors and has more analgesic potency than (*R,S*)-methadone (Eap et al. 2002). Efficacy studies show no differences between the (*R*)-enantiomer and the racemate (Judson et al. 1976; de Vos et al. 1998).

As the cardiac side effects of methadone reside in the (*S*)-enantiomer, the substitution of the racemate by the (*R*)-methadone has demonstrated a reduction in the QTc interval (Ansermot et al. 2010), reducing the risk of sudden death in methadone-maintained patients. Unfortunately, the direct costs of the treatment with (*R*)-methadone are much higher than the use of the racemate.

28.2.2.9 LAAM Maintenance Treatments

LAAM, another mu full agonist, is associated with the suppression of heroin use. Its long half-life allows an administration pattern of thrice weekly. Stabilization doses vary from 40 to 140 mg. However, LAAM maintenance treatments present more dropouts, likely due to increased adverse events (Clark et al. 2002). Moreover, LAAM has been excluded from treatments due to the possibility of a fatal ventricular arrhythmia ("torsade de pointes") (Clark et al. 2002; Wedam et al. 2007).

28.2.2.10 Sustained-Release Oral Morphine (SROM) Maintenance Treatment

In the last years, maintenance treatment with SROM for opioid dependence disorder had captured more interest. At this moment, SROM is available as an alternative for methadone in Austria, Slovakia, Slovenia, Bulgaria, Luxembourg, and exceptionally France (Jegu et al. 2011). A systematic review (Jegu et al. 2011) and a Cochrane review (Ferri et al. 2013) have been published in recent years. At this point, the body of evidence is not enough to assess the effectiveness of SROM for opioid maintenance; available data shows that retention rates are similar to those of methadone treatments; most of the studies showed that quality of life, withdrawal symptoms, craving, and additional drug consumption improved with SROM;

however, most of the studies were not controlled with other maintenance treatments. Its main advantage over methadone treatments is the lower risk to induce prolongation of the QTc interval (Fredheim et al. 2006), allowing an easy switch from methadone to SROM in case of detection of a QTc interval above 500 ms.

The major concerns with SROM treatments are the risk of misuse and diversion and the severe adverse events, such as overdose (Beer et al. 2010), described in countries such as Austria.

28.2.2.11 Diacetylmorphine Maintenance Treatments

Diacetylmorphine (diamorphine, heroin) has also been studied in patients with a history of unsuccessful agonist treatment in specific programs in a few countries. Various studies and a Cochrane collaboration study have been published in order to analyze the efficacy and feasibility of diacetylmorphine maintenance treatments (Uchtenhagen 2011; Ferri et al. 2011). In general, heroin treatments have been implemented with good acceptance by patients and public opinion. The treatment has been usually prescribed alongside methadone and has demonstrated an increase in treatment retention and reduced engagement in illegal activities in patients who previously failed in other maintenance programs (Strang et al. 2010; Ferri et al. 2011). Diacetylmorphine has been used in these programs by injectable (intravenous), smoked, and oral route.

The main problem is related with the rate of serious adverse events, mainly the risk of overdose; for that reason, the treatment is only recommended in patients refractory to other substitution treatments and should be provided in settings with proper medical assistance (Ferri et al. 2011).

28.2.2.12 Psychosocial Treatments in Opioid Dependence

Psychosocial treatments are those that use any psychological or social strategy to achieve an improvement or a behavioral change. Interventions at a social level include assistance with basic needs such as food, clothing, accommodation, and employment, as well as basic health care, friendship, community, and the pursuit of happiness.

Opioid treatment guidelines (as the WHO guidelines 2009) recommend the use of psychosocial treatments. Interventions at a psychological level range from unstructured supportive psychotherapy and motivational interviewing techniques to highly structured psychological techniques.

The main psychological strategies in opioid dependence are cognitive behavioral therapy (CBT) and contingency management. Cognitive approaches primarily aim to change addictive behaviors by changing faulty cognitions that serve to maintain behavior or by promoting positive cognitions or motivation to change behavior. Behavioral approaches aim primarily to modify behaviors underpinned by conditioned learning, that is, by classical and operant conditioning.

Contingency management rewards or punishes specific types of behaviors using a structured, transparent approach that increases learning of desired behaviors.

In terms of social interventions, the main interventions used in addiction disorders are as follows: vocational training, which includes a range of programs

designed to help patients find and retain employment; housing services that can vary from group accommodation for the homeless to more stable, affordable, long-term accommodation; the referral to participate in activities, such as enjoying leisure activities of their choice; and self-help groups, which, in the context of opioid dependence, are voluntary, small-group structures formed by peers to assist each other in their struggle with opioid dependence. Usually abstinence oriented, they often provide both material assistance and emotional support and promulgate an ideology or values through which members may attain a greater sense of personal identity. Social skills training refers to methods that use the principles of learning theory to promote the acquisition, generalization, and durability of skills needed in social and interpersonal situations. Training should take place in the context of real everyday life experiences, not in closed, unrealistic settings.

In opioid dependence, the efficacy of psychosocial interventions has little evidence due to the difficulty in the design of controlled trials. Also, there is scarce knowledge about the effectiveness of psychosocial interventions alone or in combination with pharmacological strategies and which intervention is the most effective. There are studies recommending counseling (Grönbladh and Gunne 1989), relapse prevention, and motivational interview techniques (Pollack et al. 2002). Also, family therapy (Stanton and Shadish 1997) and psychoanalytic psychotherapy have been shown to have some benefits in the treatment of opioid dependence disorder (Woody et al. 1987).

A Cochrane collaboration study (Mayet et al. 2010) addressed the issue of the efficacy and acceptability of psychosocial interventions alone for treating opiate use disorders. Only randomized controlled trials comparing psychosocial interventions alone versus pharmacological intervention, placebo, or no intervention were selected. The psychosocial interventions evaluated included the following: contingency management, brief reinforcement-based intensive outpatient therapy coupled with contingency management, cue exposure therapy, alternative program for methadone maintenance treatment program (MMTP) dropouts, and enhanced outreach counseling program. The main findings were that both enhanced outreach counseling and brief reinforcement-based intensive outpatient therapy coupled with contingency management had significantly better outcomes than standard therapy regarding relapse to opioid use, re-enrolment in treatment, and retention in treatment. At 1-month and 3-month follow-up, the effects of reinforcement-based intensive outpatient therapy were not sustained.

A parallel review (Amato et al. 2011) was performed to evaluate the effectiveness of any psychosocial plus any agonist maintenance treatment versus standard agonist treatment for opiate dependence. In this review, 35 studies and 4,319 participants were included, evaluating 13 different psychosocial interventions. Comparing any psychosocial plus any maintenance pharmacological treatment to standard maintenance treatment, results do not show benefit for retention in treatment and outcomes. Surprisingly, there were no differences also for contingency management approaches; the authors stated that the short duration of the trials could interfere in the results.

28.3 Conclusion

In this chapter the authors have presented the main pharmacological characteristics of the most common opioids involved in drug addiction and addiction treatment (both opioid addiction and alcohol addiction) and the present alternatives for the treatment of the opioid dependence disorder. The majority of research until few years ago has been focused on the effects mediated by mu-opioid receptors. However, in recent years most interest has been shifted to the effects on the kappa-opioid receptors. The kappa system including its natural ligand (dynorphin) interacts with dopaminergic pathways and modulates the reward, mood, and stress processes by its effects on the hypothalamic–pituitary–adrenal (HPA) axis. Kappa agonism usually produces aversion and dysphoria; in rats, depressant-like effects after the administration of kappa agonists have been described; on the other hand, the anhedonic symptoms that appear after stress exposure or cocaine withdrawal are ameliorated with kappa antagonists (Shirayama et al. 2004; Chartoff et al. 2012). Researchers postulate that increased endogenous kappa/dynorphin activation could result in neuropsychiatric adverse events (Butelman et al. 2012), explaining in part the high rates of psychiatric comorbidity in the addicted patients (Tejeda et al. 2012). From a therapeutic point of view, the use of kappa partial agonists could provide a stable counter-modulatory tone to dopaminergic urges and cause a relative blockade of excessive or fluctuating kappa/dynorphin tone; both effects may mitigate against relapse and reescalation (Butelman et al. 2012).

Abstract

Buprenorphine provides a number of benefits and was registered as a medication for opiate addiction treatment by the French health authorities as early as 1995. All registered medical doctors may prescribe this treatment without requiring any supplementary educational program or special licensing. The French health organizations enable a substantial care within primary care settings through medical and social support and through the possibility of supervised dispensing through pharmacy services. Overall, 26 % of French physicians prescribe buprenorphine to 75 % of overall patients in buprenorphine maintenance treatment. Buprenorphine maintenance treatment for problem heroin users has been associated in France to consistent public health, social, individual and economic benefits; might be contingent upon characteristics of the French health and social services system; and may not necessarily be generalizable as is to other areas of the world.

29.1 Introduction

It has been argued that the pharmacology of buprenorphine provides a number of benefits (Cowan and Lewis 1995). Like methadone, buprenorphine is a long-acting oral medication used to stabilize patients with opiate addiction and reduce or prevent craving. Unlike methadone its long duration of action is not due to a long plasma half-life but to its high affinity for the mu receptor. Buprenorphine also differs from methadone in that it is a partial agonist at the mu receptor, making overdose less likely. Cessation of the drug is associated with milder levels of withdrawal distress; and the long duration of its action permits more flexible dispensing options such as every other day administration. Based on our experience of using buprenorphine for opioid dependence with dispensing in community pharmacies in France since 1986 (Auriacombe et al. 1992, 1994) and that of others, buprenorphine was registered as a medication for opiate addiction treatment by the French health authorities as early as 1995. All registered medical doctors may prescribe this treatment without requiring any supplementary educational program or special licensing, exactly as for most medications. The French experience since 1995 in using buprenorphine and training and regulating family physicians is informative for worldwide efforts to facilitate opiate problem users' access to treatment (Auriacombe et al. 2004). Many contextual factors contribute to buprenorphine treatment in France and have to be taken in consideration to understand the overall outcomes and possible generalization to other regions of the world. These include the role of buprenorphine's pharmacology vs. that of methadone, the involvement of GPs over specialist practitioners, the importance of office-based settings vs. center-based settings, and issues of funding and health insurance. All these play a role in the overall outcome of "buprenorphine treatment in France" (Fatseas and Auriacombe 2007).

29.2 The French Experience

29.2.1 "Buprenorphine Treatment" in the French Context

29.2.1.1 General Characteristics of the French Health System

The overall organization of the healthcare system is an important possible contributor to buprenorphine treatment in France. The social security system acts as a universal medical insurance that covers over 90 % of the population, regardless of their economic situation, legal status, or nationality (Fielding and Lancry 1993). This facilitates the treatment of marginalized individuals. A general practitioner is paid a fixed price for an office visit, regardless of duration or frequency. Ordinary consultations are reimbursed at a 65 % replacement level. However, if the patient has a chronic illness, reimbursement covers 100 %, and the payment can be made directly from social security to the general practitioner. Because opiate dependence may qualify as a chronic illness in the French healthcare system, payment is fully covered by social security. In addition, there is a dense psychosocial support service funded by local authorities at no charge to those in need. Further, patients with opiate dependence can be treated in special substance abuse treatment centers supported by social security funds. The medication itself can be dispensed and ingested at the pharmacy under the supervision of the pharmacist daily, if prescribed. In this context, pharmacists play a crucial role in dispensing of treatment, in monitoring clinical improvement of patients, and in informing the prescriber about any difficulties. Overall, the French health organizations enable a substantial care within primary care settings through medical and social support and through the possibility of supervised dispensing through pharmacy services.

29.2.1.2 Methadone and Buprenorphine Prescription Regulations in France

The difference in regulation contributes to the specific French increased number of buprenorphine-maintained patients in comparison to methadone-maintained patients in contrast to most other countries worldwide. Only physicians working in state-licensed substance abuse clinics or hospitals can initiate a methadone prescription that is initially dispensed only on-site. Urine testing is compulsory. Once the initial prescriber has determined that the patient is stabilized, clinical management of the patient and methadone prescription may be transferred to any medical doctor. At that point, dispensing may be done from any pharmacy in the same manner as for buprenorphine. In contrast, buprenorphine's regulation is very different. Any physician working in office-based settings can prescribe buprenorphine, and any pharmacy can provide the medication. There is no requirement for any type of specific training. The maximum duration of a buprenorphine prescription is 28 days, and the maximum number of take-home doses is seven. However, a physician can override this rule by requesting that the pharmacist either provide daily supervised dosing of buprenorphine or dispense up to 28 days of take-home doses. There is no regulatory requirement for urine testing.

Overall, 26 % of French physicians prescribe buprenorphine to 75 % of overall patients in buprenorphine maintenance treatment (Cadet-Taïrou and Chollet 2004). These physicians are more often members of a healthcare network, trained for drug maintenance treatments, which may reflect special motivation and involvement in management of opiate-dependent subjects (Feroni et al. 2004). Hence, although there are no regulatory training requirements prior prescribing buprenorphine, the majority of patients are receiving prescriptions from physicians that have had extra training in addiction medicine and are involved in community-based treatment networks.

29.2.2 Main Outcomes of Buprenorphine Treatment in France

Buprenorphine maintenance treatment for problem heroin users has been associated in France to consistent public health, social, individual, and economic benefits (Fédération française d'addictologie 2004).

Studies have reported a significant decrease of heroin use and injection practice and an improvement in the social conditions of those in treatment (Duburcq et al. 2000; Bilal et al. 2003). Data also suggest among those that inject a decrease of risk-taking behavior related to injection, such as needle and paraphernalia sharing (Cadet-Taïrou and Chollet 2004). Similarly, in both retrospective and prospective studies (De Ducla et al. 2000; Duburcq et al. 2000; Fhima et al. 2001) carried out among drug-dependent outpatients treated by general practitioners, results indicate a significant decrease of both heroin and benzodiazepine use over time in treatment and that persistent benzodiazepine use among buprenorphine-treated individuals was related to less supervised dispensing and lower buprenorphine dosage. A study documented particularly the positive impact of buprenorphine on the social conditions of patients (Bilal et al. 2003), indicating that all markers of social vulnerability assessed through standardized questionnaires (employment, housing, social insurance, days of in-patient treatment related to drug consumption, and number of convictions) were improved after a 6-month period with buprenorphine.

Another consistent impact is the dramatic decrease of the reported overdose deaths since the development of buprenorphine treatment. In France, overdose deaths are registered by the police (Office Central pour la Répression du Trafic Illicite des Stupéfiants 1999). The causes of such deaths are determined on the basis of on-site evidence. This source of information is, as in most countries, considered to be an underrepresentation of true overdoses. Since country-specific methodological, legal, and political issues affect this reporting, the data cannot be compared between different countries. But since the monitoring system has been unchanged for many years, it is appropriate to compare the development of overdoses from year to year within France (Auriacombe et al. 2001). In this regard, the French overdose mortality monitoring system shows a consistent decrease in overdose deaths since the introduction of buprenorphine. The number of overdose deaths declined by 79 %, while the overall number of opiate-abusing individuals in either buprenorphine (80 %)

or methadone (20 %) treatment increased by over 95 % (from less than 2,000 per year to over 60,000 per year) within the 5 years following the introduction of buprenorphine and the involvement of general practitioners. Some authors have suggested that the increase in buprenorphine-treated individuals is the major cause for the decline in overdose deaths (Lepere et al. 2001). However, it should be acknowledged that during this same time, there was a development of syringe exchange programs, an increased availability of center-based methadone treatment, and a possible overall change in attitude toward intravenous drug users by health providers (Emmanuelli and Desenclos 2005).

29.2.3 Problems Related to Buprenorphine Treatment in France

29.2.3.1 Mortality Related to Buprenorphine

Deaths due to buprenorphine misuse are very rare, and it is thought that the risk of overdose is lower with buprenorphine than with other opiates because of its agonist–antagonist pharmacological characteristics and because its usual administration is sublingual.

However, some authors have reported deaths in which buprenorphine was considered as a contributing or causal factor (Tracqui et al. 1997, 1998; Reynaud et al. 1998a, b; Kintz 2001). In all of these cases, buprenorphine was found by systematic analytical toxicology regardless of clinical context information very often lacking. Benzodiazepines and other central nervous system respiratory depressants were almost all the time identified in addition to buprenorphine: benzodiazepines, cannabis, neuroleptics, and alcohol. A causal role for buprenorphine in most of these deaths is questionable. It is thought that the risk of overdose is highest with intravenous injection and concomitant use of alcohol and sedatives.

Perhaps what is most relevant is to compare overdoses between buprenorphine treatment and methadone treatment over the same time frame (Auriacombe et al. 2001), as the alternative to buprenorphine is not no treatment but methadone treatment. For the 1995–1998 period, the risk of death attributed to methadone was considerably higher than that attributed to buprenorphine – in fact, over ten times higher during the same 4-year period. Comparing data on the number of deaths related to methadone misuse and the number of deaths related to buprenorphine misuse, buprenorphine appears to be associated with a lower risk than methadone (Observatoire français des drogues et des toxicomanies 2005). Noteworthy, this has now been reported in other countries (Bell et al. 2009; Soyka et al. 2011).

29.2.3.2 Diversion and Abuse Related to Buprenorphine

The diversion of buprenorphine to the black market is likely to concern marginalized populations, who may obtain it from multiple providers. French surveys from medical insurance database indicated that around 10–20 % of patients collect prescription from more than one provider and/or filled prescriptions in several

pharmacies, whereas 80 % of patients in treatment only see one prescriber on a regular basis and go to only one pharmacy (Damon et al. 2001; Vignau et al. 2001; Thirion et al. 2002). Several factors might be involved in the practice of "doctor shopping." First, the French health system and insurance policy make it easier by allowing people whatever the medication to receive care and treatment from different general practitioners. Indeed, the French healthcare system is centered on the patient who determines when, where, and how frequently to attend heath providers. Another factor potentially involved is subtherapeutic buprenorphine dosing as data suggest that doctor shopping is less common when physicians prescribe 8 mg/day of buprenorphine or more (Feroni et al. 2005; Carrieri et al. 2006).

The diversion of buprenorphine via the intravenous route varies widely between studies. Diversion poses the problem of the risk-taking behaviors related to injection, medical complications (particularly an increased risk of liver toxicity), and the association to other substances (with possible increased risk of overdose). Some studies report that 11 % or less of outpatients in treatment have used buprenorphine intravenously (Cadet-Taïrou and Chollet 2004). Studies carried out among specific populations have revealed that the proportion of buprenorphine misusers is higher among patients of low-threshold services (up to 41 %) (EMCDDA 2005). Misuse of buprenorphine is also reported to be quite common among homeless people living in urban regions (Blanchon et al. 2003). Specific risk factors for buprenorphine injection in treatment settings may be as follows: being a polydrug user, being in precarious economic conditions, and having an insufficient dose of buprenorphine (Blanchon et al. 2003). Interestingly, since 2005, a consistent decrease in buprenorphine injection is reported (EMCDDA 2005; Cadet-Taïrou et al. 2010). This seems to be parallel to shared concerns by health regulatory authorities and individual clinicians.

Among regular opiate users, buprenorphine's pharmacology makes it theoretically unlikely to be a substance of abuse, and indeed, from some reports, it appears that out-of-treatment opiate users are not interested in buprenorphine as a recreational drug. Despite the relatively easy access to buprenorphine, it appears that the large majority of French out-of-treatment opiate users are not interested by buprenorphine and prefer heroine when available. One study (Moatti et al. 2001; Obadia et al. 2001) reported on the use of buprenorphine by individuals who were interviewed while they were accessing clean syringes from syringe exchange programs, vending machines, or community pharmacies. In this intravenous drug-using population, 57 % reported that they injected buprenorphine at least once over the past 6 months. However, the majority (60 % of those having used buprenorphine intravenously at least once and 34 % of the total sample) reported being regular injectors of heroin and cocaine but injecting buprenorphine only occasionally. The remaining 40 % of buprenorphine injectors (24 % of the total sample) declared having used only buprenorphine over the past 6 months; interestingly, the majority of those declared being in buprenorphine treatment. This group of in-treatment buprenorphine injectors (compared to occasional out-of-treatment buprenorphine injectors) declared less needle-sharing activities and polydrug use. The confusing factor preventing a clear conclusion from this study's data is the heterogeneity of the studied population.

The majority of patients were out-of-treatment, and they injected primarily heroin and cocaine as well as buprenorphine. A significant minority was in buprenorphine treatment and only injected buprenorphine. On all variables, this latter group had better adjustment: more employment, less needle sharing, and less polydrug use. Thus, the simple prevalence of intravenous diversion may not be the best indication of the overall effectiveness of buprenorphine treatment. This study only documents the existence of buprenorphine abuse, but even this population of regular buprenorphine intravenous abusers appears to be doing better than those that use less or no buprenorphine. Similar results with similarly limited information were found in a study focusing only on syringe exchange programs (Valenciano et al. 2001). Two studies (Fontaa and Bronner 2001; Franques et al. 2003) have compared the use of the intravenous route in both methadone- and buprenorphine-treated individuals. Interestingly, the prevalence of use of the intravenous route was similar in both populations, about 20 %. However, the buprenorphine patients were more likely to inject their own prescribed buprenorphine, whereas those methadone patients who injected were more likely to inject heroin and cocaine but not methadone, which is only available as a difficult-to-inject syrup at the time.

Finally, cases of buprenorphine use as first drug of abuse or dependence have been reported in France (Escot and Fahet 2004) in low-threshold programs. In these settings, buprenorphine as the first opiate used concerned 6 % of the subjects, and buprenorphine as the first opiate used with a diagnosis of dependence, 12 % of the subjects. These buprenorphine-dependent subjects were more likely to have a problematic associated use of alcohol or benzodiazepines and reported more often to use buprenorphine for its anxiolytic or psychotropic effect, in order to relieve social or psychological difficulties than just as a recreational alternative.

29.2.4 What Is Next?

Increasing quality of treatment services and decreasing collateral damage related to such services are important challenges for health authorities and individual clinicians. It is currently an important issue in the French situation for the treatment of opiate-addicted patients with buprenorphine office-based treatment and methadone center-based treatment. From a public health perspective, it is likely difficult to imagine doing any better when comparing with other regions in Europe, North America, and Australia. In a very cost-effective manner (Kopp et al. 2000), more than two-third of the total estimated number of opiate problem users are in either buprenorphine or methadone treatment, and the large majority of these receive treatment from a general practitioner. Since these important changes, over the past 10 years, opiate-related overdose mortality, HIV drug-related prevalence, and drug-related crime have dropped dramatically (Emmanuelli and Desenclos 2005). From this public health and societal perspective, major changes in regulations are not easy to imagine. However, from an individual clinical perspective, cases of misuse of buprenorphine by the intravenous or intranasal routes and associated damage are of legitimate concern as well as issues related to the leaking of

buprenorphine to the black market and possible clinically inappropriate use. Understanding some of the determinants of these individual behaviors, such as patient motivation for use, can give insight as to how to do better (Fatseas et al. 2009).

Within the French treatment system, an important variable that may influence office-based treatment efficacy could be the frequency with which supervised – as opposed to take-home – doses of buprenorphine are administered. In a study, 202 patients were assigned quasi-randomly to daily supervised dosing for either 2 weeks, 3 months, or 6 months, after which dosing was on a weekly schedule (Auriacombe et al. 2002). Results from this study showed that retention in treatment at the 6-month follow-up was highest for those patients in the 6-month daily supervised dosing group (80 %) and lowest for those patients in the 2-week daily supervised dosing group (46 %). Rates of opiate-positive urine samples were lowest for the 6-month daily supervised dosing group, compared to the 3-month daily supervised and 2-week daily supervised groups. Finally, average daily buprenorphine doses at the 6-month assessment were similar for the three groups. These results suggest that initial efficacy for office-based buprenorphine treatment may be enhanced by a more closely supervised dispensing of medication and that this may be acceptable to patients.

Finally, data strongly suggest that prescription practices (single daily and individually titrated dosing) and prescribers' attitudes and beliefs about drug-dependent patients are closely associated to general treatment outcomes and patient compliance and behavior (De Ducla et al. 2000; Feroni et al. 2005).

29.3 Conclusion

As evidenced by the French example, buprenorphine maintenance treatment for problem opiate users can be feasible and safe through office-based prescriptions. This "French experience" is unparalleled in its rapid growth, and even though there is some level of diversion and continued intravenous use, it is also fair to say there are very significant societal and individual benefits. In addition there is evidence that some clinical attitudes of physicians might favor diversion more than patient characteristics. Particularly buprenorphine underdosage, the lack of toxicological monitoring of drug use, and the lack of supervised dispensing in pharmacies have been shown to represent risk factors for diversion and misuse. In the current context of the French experience, strategies to reduce buprenorphine diversion and misuse should focus on quality of treatment provision more than on regulatory changes. Among these strategies, helping health professionals, especially general practitioners, may play a crucial role allowing specific training in addiction treatment and facilitating interactions between primary care settings and specialized facilities. Finally, it is important to keep in mind that some of the public health benefits seen during the time of buprenorphine expansion in France might be contingent upon the characteristics of the French health and social services system and may not necessarily be generalizable as is to other areas of the world.

Buprenorphine Implants: Review of Clinical Studies

30

Martin S. Mumenthaler and Katherine L. Beebe

Contents

Abstract

To address shortcomings that opioid dependence treatment with daily sublingual buprenorphine doses has, such as medication adherence, buprenorphine abuse and diversion, and accidental exposure to children, Buprenorphine Implants (BI) have been developed as a subdermally implantable formulation of buprenorphine with 6-month duration of action. A New Drug Application has been submitted for this novel medication and is currently under review by the FDA. This chapter provides a summary of the clinical studies of BI to describe the formulation and its pharmacokinetics, efficacy, and safety. The data showed superiority of BI to Placebo Implants (PI) and non-inferiority to sublingual

buprenorphine in primary (urine samples negative for opioids) and secondary outcome measures, demonstrating safety and efficacy of BI for the maintenance treatment of opioid dependence.

30.1 Introduction

Addiction to heroin and prescription opioids represents a worldwide health and social crisis. Methadone maintenance has been established as a successful treatment for opioid dependence, reducing morbidity, mortality, and the spread of infectious diseases (Marsh 1998) but is restricted in the USA to specialty clinics and has a risk of mortality with overdose (Luty et al. 2005). The use of buprenorphine, a partial opioid receptor agonist which can be prescribed in office-based physician practice in the USA, has significantly increased in the treatment of opioid dependence in the last decade, and buprenorphine is established as a safe and efficacious treatment. However, the sublingual (SL) route of delivery has several shortcomings. First, it requires strict subject dosing compliance: one missed dose may allow cravings and withdrawal symptoms to increase to the point at which the subject seeks illicit drugs. More specifically, poor medication adherence is the leading cause of relapse, treatment failure, re-involvement in criminal activity, and mortality. Second, in some countries, including the USA, the patient is in control of his/her dosing, and a conscious decision to discontinue buprenorphine treatment for the short term in anticipation of exposure to illicit drugs can easily occur. Third, buprenorphine SL tablets can easily be diverted for illicit use, a growing public health issue in the USA, or accidentally ingested after misidentification (Winstock et al. 2008; Chandler et al. 2009). Fourth, frequent visits to the clinic or pharmacy are required, limiting subject independence and requiring significant medical staff time and cost. And fifth, although the SL formulation is thought to reduce the euphoria-inducing effects of buprenorphine by slowing down its absorption and uptake to the brain, plasma concentrations initially peak steeply with each dose, leading some subjects to experience withdrawal symptoms between doses. These shortcomings represent significant obstacles to realizing the full potential of buprenorphine as an important pharmacotherapy for the opioid-dependent population and for society as a whole, and they provided the rationale to develop Buprenorphine Implants (BI).

Buprenorphine Implants are a subdermally implantable formulation of the active ingredient buprenorphine, intended to provide continuous delivery of buprenorphine for 6 months for maintenance treatment of opioid dependence following outpatient induction with daily SL buprenorphine. It minimizes access to buprenorphine and the potential for diversion and misuse. This novel formulation is not yet FDA approved and a New Drug Application (NDA) is currently under review by the FDA.

The present review will summarize the Buprenorphine Implants clinical program which consisted of six studies designed to evaluate the safety and efficacy of BI for maintenance treatment of opioid dependence.

30.2 Clinical Studies of Buprenorphine Implants

30.2.1 Buprenorphine Implants Formulation

Buprenorphine Implants are subdermal implants containing 80 mg buprenorphine hydrochloride USP in an ethylene vinyl acetate copolymer (EVA) matrix. Each implant measures 26 mm in length, 2.5 mm in diameter, and 112 mg in weight.

BI provide a long-acting (6 months) treatment for opioid dependence that should be used as part of a complete treatment program to include counseling and psychosocial support. Four implants are administered subdermally in the inner side of the patient's upper arm during an in-office procedure, and patients may receive a fifth implant if an increased dose is required. By the end of the sixth month, BI must be removed and may be replaced by new implants in the opposite arm at the time of removal, if continued treatment is desired. The matrix formulation of the implants results in a steady-state delivery of buprenorphine that maintains a stable plasma level of the drug for 6 months.

30.2.2 Buprenorphine Implants Clinical Program

To test the clinical efficacy of BI, two multicenter, double-blind, Placebo Implant-controlled studies (PRO-805 and PRO-806) with one containing an exploratory open-label active comparator arm (PRO-806) and two open-label extension studies (PRO-807, PRO-811) were conducted. Study 806 was partially funded by a grant from NIDA. Two pharmacokinetic studies also provided supportive efficacy and safety information (studies TTP- 400-02-01 and PRO-810). The six studies are summarized in Table 30.1.

30.2.3 Buprenorphine Implants Pharmacokinetics

During all six clinical studies, plasma samples were collected for measurement of buprenorphine concentrations. Figure 30.1 shows the six individual mean plasma concentration-time curves of these studies. The buprenorphine plasma concentration profile after subdermal implantation of BI shows an expected initial peak on the first day followed by a gradual concentration decrease over 4 weeks to a more constant, low plasma level ("steady state") that is then maintained within an efficacious range for the duration of the 6-month treatment. In a 24-week, open-label, sequential dose group study (TTP-400-02-01), steady-state plasma buprenorphine concentrations in the 2- and 4-implant groups were approximately dose linear, and the within-patient variability during the plateau phase was low, with coefficients of variation (CVs) ranging from 11 % to 20 % for patients who received two implants and 9–20 % for patients who received four implants.

In the single crossover, open-label, relative bioavailability PK study (PRO-810), comparing the reference drug Suboxone® SL tablets (16 mg/day) to four 80 mg BI,

Table 30.1 Clinical development program

Study number	Description
TTP-400-02-01	Phase 1/2 PK study of 2 or 4 Buprenorphine Implants in adults with heroin dependence
PRO-805	Randomized (2:1), double-blind, Placebo Implant-controlled[a] phase 3 study of the safety and efficacy of buprenorphine for maintenance treatment of opioid dependence in adults
PRO-806	Randomized (2:1:2), double-blind, Placebo Implant- and active-controlled[a] phase 3 study of the safety and efficacy of buprenorphine for maintenance treatment of opioid dependence in adults
PRO-807	Open-label extension study (PRO-805) to evaluate safety of serial 6-month treatment periods
PRO-810	Relative bioavailability PK study comparing buprenorphine with SL buprenorphine, no rescue medication used
PRO-811	Open-label extension study (PRO-806) to evaluate safety of serial 6-month treatment periods

TTP-400-02-01 was conducted in Australia; all other studies were conducted in the USA
[a]Patients in all treatment groups were allowed to receive SL buprenorphine/naloxone as rescue therapy

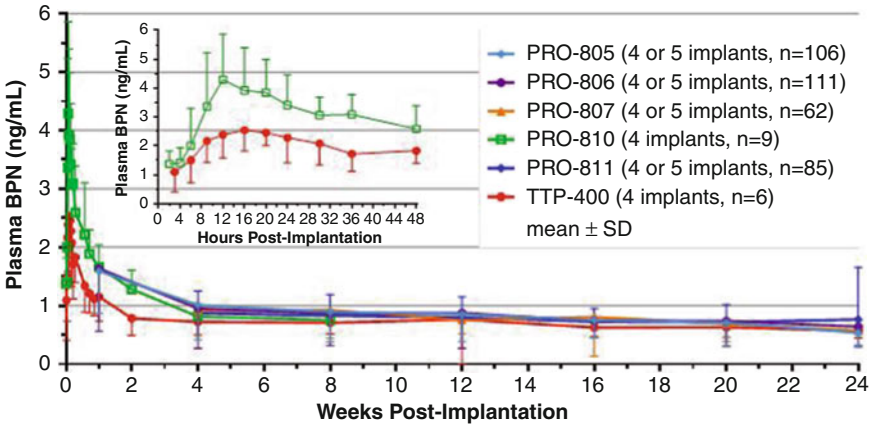

Fig. 30.1 Plasma buprenorphine concentrations over time, individual studies

buprenorphine concentrations in the BI group at steady state were 38–48 % less than trough concentrations during SL buprenorphine dosing on Days 2 and 1 (i.e., 2 days and 1 day before the transition to the four implants). At steady state, daily exposure (area under the plasma concentration-time curve from time 0 to 24 h) in the BI group was approximately 70 % lower than that in the SL buprenorphine group. In all phase 3 efficacy studies, mean steady-state plasma buprenorphine concentrations were similar at approximately 0.5–1 ng/mL.

30.2.4 Clinical Safety of Buprenorphine Implants

The safety evaluation of BI, which included analysis of adverse events (AEs), clinical laboratory assessments, ECG evaluations, and vital signs, showed that BI were well tolerated and posed minimal safety risks through two 24-week periods in adults with opioid dependence. The safety observations in all phase 3 studies were consistent with the known profiles of marketed buprenorphine forms and with the safety of EVA subdermal implants that are in wide clinical use. Further, the non-implant site safety profile observed with BI was unremarkable and fundamentally similar in the BI, Placebo Implant (PI), and SL buprenorphine groups, with discrete events occurring more frequently in one group or another with no systematic pattern. No unexpected systemic AEs occurred, and implant site AEs were generally minor, easily managed, and rarely leading to study discontinuation. The most common non-implant site adverse events (in >5 % of patients) that occurred at a higher incidence in the BI group than in the PI group were headache, nasopharyngitis, nausea, constipation, URI, back pain, toothache, anxiety, upper abdominal pain, vomiting, oropharyngeal pain, fatigue, and cough. The most common implant site adverse events (in >5 % of patients) in the first double-blind study (PRO-805) were pruritus, pain, erythema, hemorrhage, edema, hematoma, and scar. With modified procedures introduced in study PRO-806, the implant site adverse events decreased substantially and only pain and hematoma were reported in more than 5 % of patients. Collectively, the data from the safety program indicate that BI are safe and well tolerated for maintenance treatment of opioid dependence.

30.2.5 Clinical Efficacy of Buprenorphine Implants

All clinical studies evaluated similar patient populations. This chapter will focus on the two multicenter, placebo-controlled 24-week pivotal trials (PRO-805, PRO-806) and will provide only brief descriptions of efficacy measures in the open-label extension. The primary efficacy objective was to determine whether BI reduced illicit opioid use relative to PI, and the primary efficacy measure was the proportion of urine samples negative for opioids collected from weeks 1 to 24 (with missing urines imputed as positive), incorporating patient self-reported opioid use, and examined as a cumulative distribution function (CDF). Additional efficacy measures included study completion, Clinical Opiate Withdrawal Scale (COWS), Subjective Opiate Withdrawal Scale (SOWS), Visual Analog Scale (VAS) for opioid cravings, Clinical Global Impressions scores for self and observer (CGI-self, CGI-observer), and supplemental SL buprenorphine use.

In studies PRO-805 and PRO-806, patients underwent an outpatient induction period with SL buprenorphine or buprenorphine/naloxone tablets (12–16 mg/day) and were then randomized to either receive four BI or four Placebo Implants. All patients could receive supplemental rescue medication (SL buprenorphine/naloxone) if they met one or more of the following pre-specified criteria: (a) withdrawal

symptoms with a score of >12 on the COWS, (b) cravings with a score of >20 mm on the opioid cravings VAS, and (c) patient request for rescue medication deemed appropriate by the investigator. Patients who required supplemental SL buprenorphine/naloxone ≥3 days per week for two consecutive weeks or ≥8 days of supplemental SL buprenorphine/naloxone over four consecutive weeks received one additional implant. Patients returned to the clinic thrice weekly for urine toxicology screening and other data collection and attended twice-weekly manual-guided drug counseling during study weeks 1–12 and weekly counseling during weeks 13–24. A more detailed description of the study methodology can be found in (Ling et al. 2010).

30.2.5.1 Primary Efficacy Measure

To aid interpretation of the primary analysis using CDF, Fig. 30.2. first illustrates the results for the percentage of opioid-negative urine samples from weeks 1 to 24 as mean and median values. In both studies, the BI group had significantly greater mean and median proportions of opioid-negative urines than did the PI group.

The median values displayed in Fig. 30.2 are also illustrated in the CDF display as the "x" values corresponding to 50 % of patients in Fig. 30.3 below.

The primary analysis was a stratified Wilcoxon rank sum test of the CDF of the percentage of urine samples that were negative for illicit opioids from weeks 1 to 24. Figure 30.3 shows that BI were superior to PI in both studies.

To explore whether efficacy varied over the 24-week treatment period, the CDF of opioid-negative urine samples was applied to various time periods (weeks 1–16, 17–24, 5–24, 9–24). For each time period, the differences between the BI and PI groups were nominally statistically significant (P-values ranging from <0.0001 to 0.0347), suggesting that the efficacy of BI is not restricted to either the early or the late part of the 6-month treatment period, that patients treated with BI engage in treatment early, and that the treatment effect is sustained throughout the 24-week period.

30.2.5.2 Additional Efficacy Measures and Data

Study completion was assessed as a marker of treatment duration. A greater proportion of patients assigned to BI (65 % in PRO-805 and 64 % in PRO-806) compared with PI (28 % and 26 %, respectively) completed the studies. This analysis was prospectively defined and protected in the fixed testing sequence. In addition, a supportive, exploratory survival analysis (Kaplan-Meier) showed that the group difference in time to study discontinuation was nominally statistically significant in both studies ($P < 0.0001$), favoring BI over PI. In the open-label SL buprenorphine arm of PRO-806, the completion rate was 64 %.

Opioid withdrawal symptoms and cravings were assessed by the Subjective Opioid Withdrawal Scale (SOWS) (Dijkstra et al. 2007), the Clinical Opioid Withdrawal Scale (COWS) (Tompkins et al. 2009), and the Opioid Craving Visual Analog Scale (VAS, patient-rated assessment of cravings on a scale of 0 (no craving) to 100-mm (maximum possible)). Mean scores for withdrawal

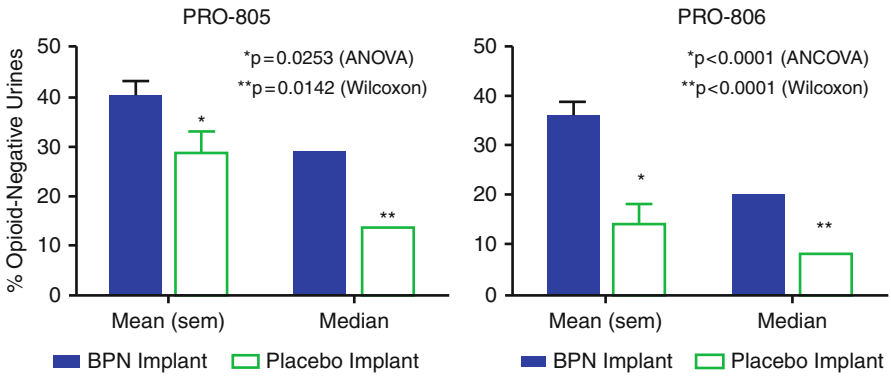

Fig. 30.2 Mean, median percentage of opioid-negative urine samples, weeks 1–24

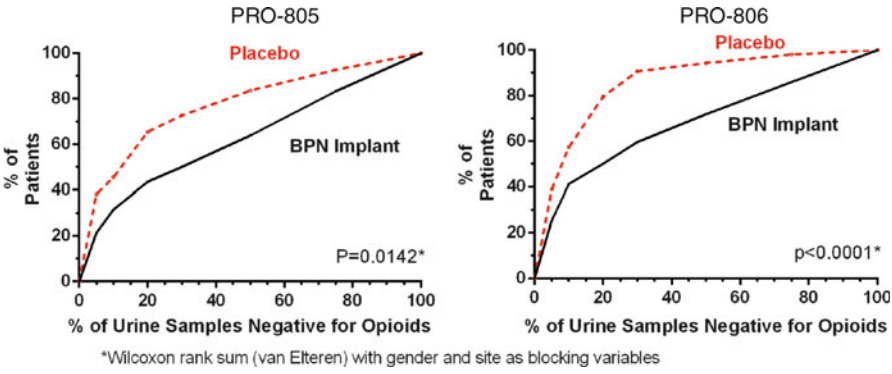

Fig. 30.3 CDF of the percentage of opioid-negative urine samples, weeks 1–24

symptoms and cravings as assessed by these measures were similar in the BI and PI groups at baseline (immediately following SL buprenorphine induction) but were significantly higher (reflecting more withdrawal symptoms and craving) in the PI groups compared to the BI groups ($P < .0001$ for all scores) across 24 weeks of treatment. These results support that opioid withdrawal symptoms and cravings (both self- and observer-assessed) were better controlled, in a clinically and nominally statistically significant sense, in the BI group than in the PI group.

Clinician-rated Clinical Global Impressions-Severity (CGI-S) (of opioid dependence) and Improvement scales (CGI-I) (Guy 1976) were obtained at weeks 16 and 24. At week 16 the proportion of "responder" patients was higher in the BI groups than in the PI groups for both the CGI-self and CGI-observer scores, although the differences were not nominally statistically significant. At week 24, the differences between the two treatment groups had increased and were nominally statistically significant on both scores in study PRO-805 and for

observer-rated status in PRO-806. Overall, the majority of the BI groups was considered responders at study end, while only a minority of the PI groups was self- or observer-rated responders.

Supplemental SL buprenorphine use was allowed by design as rescue medication in the placebo-controlled trials for subjects in all treatment groups when clinically indicated. This allowed for adequate treatment of patients who were not responsive to the starting dose of four BI or were assigned to the PI arms. In the double-blind studies, the majority of patients in the BI group were treated with four implants and did not require a dose increase. More specifically, 63 % of patients who were treated with four BI and 45 % of patients, after receiving a fifth Buprenorphine Implant, took no sublingual rescue medication. In the open-label studies, 79 % of the four BI groups and 67 % of the five BI groups took no supplemental rescue medication. Of 83 patients who completed both double-blind and open-label studies, 41 (or 49 %) took no supplemental rescue medication over two sequential 24-week treatment periods.

Open-label extension studies PRO-807 and PRO-811 supported the efficacy results of the double-blind Placebo Implant-controlled preceding studies. For example, during the second 6-month treatment period, plasma buprenorphine exposure and study completion rates (74.2 % in study PRO-807 and 78.8 % in study PRO-811) were comparable to those achieved in the BI group in the first 6-month treatment period.

30.2.5.3 Exploratory Comparison of Buprenorphine Implants to Active Comparator SL Buprenorphine

Study PRO-806 included an exploratory open-label active comparator arm, in which patients received SL buprenorphine/naloxone (Suboxone®) at doses up to 12–16 mg/day. The protocol pre-specified comparison relevant to the active control was an analysis of the difference in proportions of urine samples negative for illicit opioids from week 1 to week 24 with a pre-specified non-inferiority margin of –15 %. Buprenorphine Implants met the non-inferiority criterion with similar proportions of opioid-negative urine samples in the BI group (31.3 %, $N = 114$) and the SL buprenorphine/naloxone group (33.5 %, $N = 119$) and the lower bound of the 95 % confidence interval for the difference in proportions greater than –15 % (95 % CI –10.7, 6.2). In additional exploratory analysis, the CDFs of the percentage opioid-negative urines over weeks 1–24 in the BI and SL buprenorphine/naloxone groups did not differ significantly. Study completion rates were similar in the BI arms of study PRO-805 (65 %) and PRO-806 (64 %) and the open-label SL buprenorphine/naloxone arm of PRO-806, (64 %). Finally, a post hoc analysis of the proportions of patients with at least 4 weeks of continuous abstinence defined as no positive urine tests (three per week) combined with patient self-reported opioid use showed comparable rates of 4-week abstinence between the BI ($n = 69$) and SL buprenorphine ($n = 119$) groups of 29 % in each group compared to PI ($n = 54$) of 3.7 %. The BI and PI group comparison was performed using a Cochran-Mantel-Haenszel test stratified on gender and pooled site, $p = 0.0002$. This post hoc analysis excluded any BI patient who was treated with rescue SL buprenorphine/naloxone.

30.3 Conclusion

Collectively, the data of six clinical studies indicate that Buprenorphine Implants are a safe and efficacious maintenance treatment for opioid dependence. BI was superior to PI in both double-blind studies for the primary outcome measure, the proportion of urine samples negative for opioids. Secondary and exploratory endpoints supported the conclusion that BI was more efficacious than PI. These included analyses of opioid-negative urines during various segments of the treatment period, the proportion of patients completing each study, measures of opioid withdrawal symptoms and cravings, patient- and observer-rated improvement in opioid dependence, and use of supplemental buprenorphine. In secondary and exploratory comparisons, BI and open-label SL buprenorphine resulted in similar proportions of opioid-negative urine samples over 24 weeks, documenting the overall comparability of 4–5 Buprenorphine Implants to sublingual buprenorphine (12–16 mg/day) in a 6-month treatment for opioid dependence. The Buprenorphine Implants clinical program demonstrated safety and efficacy of Buprenorphine Implants for the maintenance treatment of opioid dependence.

Abstract

Opioid addiction is one of the most severe drug problems due to its high level of morbidity, mortality, and psychosocial consequences. Naltrexone completely blocks the effects of opioids and, when administered to detoxified opioid addicts and taken as directed, prevents relapse and reduces the chances for a wide range of adverse effects associated with untreated addiction. It has been available as a 50 mg tablet since the mid-1970s, and early studies showed very limited efficacy due to lack of interest by patients, high dropout rates, and a preference for methadone maintenance. In addition, patients must be detoxified and free of physiologic opioid dependence prior to starting naltrexone because it

will precipitate withdrawal if given to a person who is currently dependent, and such services are not always available or prohibitively expensive. In Russia, the law prohibits use of methadone, buprenorphine, and other opioid agonist therapies, and naltrexone is the only effective pharmacotherapy available for treating opioid addiction. Inpatient detoxification followed by 1–3 months of residential treatment is the standard treatment for opioid addiction. A number of randomized, placebo-controlled trials have been conducted in Russia that have demonstrated efficacy of the oral formulation with younger patients who are living with their families; that combining oral naltrexone with an antidepressant (fluoxetine) or an α-*adrenergic agonist* (guanfacine) does not increase the proportion of patients who remain in treatment without relapsing and that sustained-release formulations (injectable and implantable) are more effective compared with oral formulations and placebo. The implant that has been studied (Prodetoxone®) prevents relapse for 2–3 months and the injectable formulation (Vivitrol®) prevents relapse for a month. This chapter will summarize the results of these studies, all conducted in Russia during the past 13 years.

31.1 Introduction

Naltrexone, an opioid antagonist, was approved by the US Food and Drug Administration to treat opioid dependence in 1984. Approval was based primarily on its pharmacologic profile, as it blocks opioid effects by antagonism at the μ-opioid receptors (Kleber 2007). Naltrexone is a perfect antagonist for treating heroin dependence, as 50 mg (one tablet) blocks the effects of heroin for 24-36 h; it is easy to administer (one tablet per day or two tablets every other day), safe (no common serious adverse events if used in recommended doses), and well tolerated (a relatively small number of side effects) and does not have addictive potential; and tolerance does not develop to the opioid antagonism.

However, one problem markedly reduces naltrexone's efficacy and has limited its use for treating heroin and other forms of opioid dependence worldwide: patients often do not like it and do not take it on a daily basis. The dropout rate with oral naltrexone has been better in the limited number of patients in whom there is substantial external motivation to remain abstinent, such as physicians who are in monitoring programs and could lose their license if they relapse, those involved in the criminal justice system who could go to prison if they relapse, and those facing loss of employment (O'Brien and Cornish 2006; Kleber 2007).

Recent World Health Organization guidelines for the pharmacologic treatment of opioid dependence suggest that the limited evidence available demonstrates that in dependent opioid users who have withdrawn from opioids, those treated with naltrexone are less likely to use heroin or engage in criminal activity than those who do not take naltrexone, but the proportion who continue taking naltrexone has been very low (World Health Organization 2009). However, our recent studies of naltrexone for treating opioid dependence in St. Petersburg, Russia, have shown that in some cultural settings, naltrexone may be much more effective. In particular,

Russian law forbids substitution therapy for opioid dependence with methadone or buprenorphine, and the national health-care system supports over 25,000 inpatient detoxification and rehabilitation treatment beds, thus making it easy to start patients on naltrexone. Naltrexone is the only specific pharmacotherapy that is currently approved for use in the Russian Federation and is available as an oral tablet and two extended-release formulations: implantable and injectable. The results of studies using these formulations are summarized below.

31.2 Naltrexone Studies - Russian Context

31.2.1 Studies of Oral Naltrexone

31.2.1.1 Naltrexone Only

Our first relatively small ($n = 52$ patients), double-blind, placebo-controlled, randomized trial of naltrexone for opioid dependence began in the late 1990s (Krupitsky et al. 2004). At that time, Russia faced a dual epidemic of HIV and heroin addiction that had been spreading rapidly. Treatment of opioid dependence consisted of detoxification and drug-free rehabilitation, but relapse rates were high. We hypothesized that naltrexone may be an effective treatment in Russia for several reasons: (1) heroin addicts are mostly young people living with their parents, who are usually the initiators of treatment and can control the daily process of taking naltrexone; (2) heroin addiction is generally not accompanied by use of other drugs; and (3) use of agonists for addiction treatment is illegal, thus naltrexone is the only pharmacotherapy available for treating this disorder. That pilot study evaluated the efficacy of naltrexone for preventing relapse to heroin addiction in a Russian cultural setting. A total of 52 heroin addicts who completed detoxification at addiction treatment hospitals in St. Petersburg and provided informed consent (mean age, 22 years; dependent on heroin for 2.5 years on average) were randomly assigned to a double-blind, 6-month course of biweekly manualized drug counseling and oral naltrexone, 50 mg/day, or counseling and identical-looking placebo. A close family member (e.g., mother, spouse) agreed to supervise daily dosing. Drug testing and brief evaluations were done at each biweekly visit. Medication compliance was evaluated using a riboflavin marker; more extensive psychometric evaluations were done at 3–6 months. A total of 81 patients were asked if they would be interested in participating: 62 gave informed consent and 52 met study entrance criteria and were randomly assigned. Significant differences in retention and relapse favoring naltrexone were seen beginning at 1 month and continuing throughout the study. At the end of 6 months, 12 of the 27 naltrexone patients (44.4 %) remained in the study and had not relapsed, compared with four of 25 placebo patients (16 %; ($P < 0.05$). Among patients who remained in the study, compliance with medication measured by riboflavin in the urine was high (85–95 %), probably a result of the family involvement. Reductions in HIV risk, alcohol use, anxiety, depression, and anhedonia and improvement in overall function were substantial and about equal in both groups among those who were

retained in treatment. However, the proportion of those retained in treatment was significantly higher in the naltrexone group. Thus, the study demonstrated that cultural factors unique to Russia are associated with greater interest and compliance with naltrexone than in the United States and that oral naltrexone was significantly more effective than detoxification and counseling alone.

Thus, although our first study showed a clear advantage for naltrexone, the number of patients was relatively small, dropout continued to be a problem, and naltrexone did not reduce protracted withdrawal-related psychiatric symptoms. Because an earlier study showed that a selective serotonin reuptake inhibitor (SSRI; citalopram) reduced anxiety, depression, and other protracted withdrawal-related symptoms but did not prevent relapse (Krupitsky et al. 2002), we hypothesized that combining naltrexone with an SSRI might be additive, with the antidepressant alleviating protracted withdrawal-related symptoms and improving adherence to naltrexone and treatment outcome.

31.2.1.2 Naltrexone in Combination with Other Psychoactive Medications

Naltrexone and a Selective Serotonin Reuptake Inhibitor

Although our first double-blind pilot study demonstrated that naltrexone was more effective than placebo for relapse prevention in heroin addicts in Russia, it provided no data to indicate that naltrexone itself reduced the depression, anxiety, and anhedonia that are typically associated with heroin dependence and withdrawal following detoxification. It is possible that psychiatric symptoms increase the risk for dropout and relapse, and, therefore, antidepressants might alleviate these symptoms and thus improve results of naltrexone therapy. Our next study aimed to test this hypothesis using fluoxetine with and without naltrexone (Krupitsky et al. 2006). We chose fluoxetine, as it is approved for use in Russia and was offered at reduced cost by Gideon Richter (Budapest, Hungary). This second study was much larger: 280 heroin addicts who completed detoxification at addiction treatment hospitals in St. Petersburg and provided informed consent were included in a 6-month course of biweekly drug counseling and randomly assigned under double-dummy and double-blind conditions to one of four medication groups of 70 participants each: naltrexone (N, 50 mg daily) plus fluoxetine (F, 20 mg daily), naltrexone plus fluoxetine placebo (FP), naltrexone placebo (NP) plus fluoxetine, or naltrexone placebo plus fluoxetine placebo. The primary outcome was relapse to opioid (heroin) dependence. Urine drug testing and brief psychiatric evaluations were conducted at each biweekly visit, and medication compliance was evaluated biweekly using a riboflavin marker; more extensive psychiatric evaluations were done at 3 and 6 months. Results showed that 414 patients were asked if they would be interested in participating, 343 agreed, and 280 met study entrance criteria and were randomly assigned. At the end of 6 months, 43 % of participants in the N plus F group remained in the study and had not relapsed, as compared with 36 % in the N plus FP group, 21 % in the NP plus F group, and 10 % in the NP plus FP group. Based on the survival analysis and retention rate in 6 months, N plus F and N plus FP were more effective than NP plus FP ($P < 0.001$) and NP plus F ($P < 0.01$).

Fluoxetine (NP + F) did not differ significantly from NP plus FP, and N plus F did not differ from naltrexone alone (N + FP; $P = 0.2$). However, women in the N plus F group showed a trend toward an advantage when compared with women receiving naltrexone and fluoxetine placebo (N + FP; $P = 0.08$), probably due to a higher level of depression, anxiety, and anhedonia in women at study intake compared with men. Thus, it was confirmed in this larger study that naltrexone was more effective than placebo for relapse prevention in opioid addicts in Russia. In addition, naltrexone and fluoxetine, or naltrexone alone, were both more effective than fluoxetine alone, although the combination of naltrexone and fluoxetine had a tendency to be more effective than naltrexone alone in women (Krupitsky et al. 2006). Overall, the antidepressant did not dramatically improve the naltrexone treatment outcome. It should be added that oral naltrexone was generally well tolerated, the number of side effects was limited, and neither serious adverse events nor lethal overdose occurred.

Naltrexone and Presynaptic, α-Adrenergic Agonists

A small pilot study of opioid-dependent patients ($n = 18$) found that a combination of naltrexone and lofexidine (a presynaptic α-adrenergic agonist that has antihypertensive and stress protective properties and reduces opioid withdrawal) may improve naltrexone outcome (Sinha et al. 2007). Lofexidine is used commonly in the United Kingdom for treatment of hypertension and opioid withdrawal and has been studied in the United States to treat opioid withdrawal but is not FDA approved for this indication. A small pilot study by Sinha and colleagues (2007) at Yale University School of Medicine suggested that lofexidine may enhance success rates among patients taking maintenance naltrexone and help them avoid relapse to opioids. However, these results were very preliminary because of the small sample size.

We recently completed a large ($n = 301$ opioid-dependent patients), randomized, double-blind, double-dummy, placebo-controlled, four-cell study of naltrexone and guanfacine (another presynaptic α-adrenergic ligand used to treat hypertension) in collaboration with Dr. T. Kosten of Baylor College of Medicine. Three hundred and one opioid-dependent patients met inclusion criteria, gave informed consent, and were randomized (mean age ± SD = 28.3 ± 4.4 – older than in our previous naltrexone trials) into four treatment groups: naltrexone (N) 50 mg/day + guanfacine (G) 1 mg/day (N/G) ($n = 75$), naltrexone (50 mg/day) + guanfacine placebo (N/GP) ($n = 76$), naltrexone placebo + guanfacine (1 mg/day) (NP/G) ($n = 75$), and double placebo (NP/GP) ($n = 75$). All patients received drug counseling with parental or significant other involvement to encourage adherence. At 6 months (end of treatment) retention in N/G group was 26.7 %, in N/GP group 19.7 % ($p = 0.258$ to N/G), in NP/G group 6.7 % ($p < 0.05$ to both naltrexone groups, Fisher exact test), and in NP/GP 10.7 % ($p = 0.013$ to N + G group, Fisher exact test). Overall, adding guanfacine to naltrexone did not improve outcomes significantly (retention in treatment and number of opioid-free urines). During the 6-month treatment period, HIV risk, depression, anxiety, anhedonia, and craving for opioids gradually reduced among all patients who remained

in treatment and did not relapse, regardless of group assignment; however, guanfacine reduced severity of stress. The frequency of adverse events (AE) was low (4.7 %) with no significant differences between the groups; most common AEs were headache, poor appetite, insomnia, and dizziness.

In summary, combining naltrexone with fluoxetine (an SSRI) or an α-adrenergic agonist has not demonstrated a significant improvement in treatment outcome (with the opioid addicts getting older, the efficacy of oral naltrexone slightly decreased), and we have decided to change the direction of our naltrexone research and study long-acting, sustained-release formulations, as they may improve the adherence problem.

31.2.2 Studies with Long-Acting, Sustained-Release Formulations

31.2.2.1 Implantable Naltrexone

The first long-acting, sustained-release naltrexone formulation available in Russia was an implant (Prodetoxone®; Fidelity Capital, Moscow, Russia). It contains 1,000 mg of naltrexone that is slowly released after being inserted subcutaneously in the abdominal wall via a small incision. It was registered in Russia in 2005 and shown to block opioids for 2 months, but this time frame was extended to 3 months during the past year, based on clinical experience. As of this writing, it is the only officially registered naltrexone implant in the world, and we recently completed a double-blind, double-dummy, placebo-controlled, randomized study of this naltrexone formulation (Krupitsky et al. 2012). In this study, 306 recently detoxified opioid addicts were randomized to a 6-month course of biweekly drug counseling and one of three medication groups (102 patients in each one): naltrexone implant (1,000 mg, three times – every other month) + oral placebo daily (NI+OP), placebo implant + oral naltrexone (PI+ON) (50 mg/day), and double placebo (implant and oral) (PI+OP). Medications were administered under double-dummy/double-blind conditions. Urine drug testing and brief psychiatric evaluations were done at each biweekly visit. Oral medication compliance was evaluated using a urine riboflavin marker. By month 6 (end of treatment), 54/102 (53 %) of NI+OP patients remained in treatment without relapsing compared to 16/102 (16 %) in PI+ON (survival analysis, log rank test $p < 0.001$) and 11/102 (11 %) in PI+OP ($p < 0.001$). The PI+ON vs. PI+OP comparison showed a nonsignificant trend favoring PI+ON ($p = 0.069$) but was significant ($p < 0.024$) when limited to those with proven relapse. Counting missing tests positive, the proportion of opiate negative urines was 63.6 % (CI: 60–66 %) for NI+OP, 42.7 % (CI: 40–45 %) for PI+ON, and 34.1 % (CI: 32–37 %) for PI+OP ($p < 0.0001$, Fisher exact test to NI+OP group). There were 12 wound infections among 244 implantations (5 %) in the NI+OP group, two among 181 implantations (1 %) in PI+ON, and one among 148 implantations (1 %) in PI+OP ($p < 0.01$, Fisher exact test). All were in the first 2 weeks after implantation and resolved with antibiotic treatment. There were four local site reactions (redness and swelling), all in the 2nd month after implantation in the NI+OP group ($p = 0.12$, Fisher exact test); all resolved with anti-allergy medication.

Using the number of visits as the denominator, nonlocal site AEs were reported by 8/886 (1 %) in the NI+OP group, 4/522 (1 %) in the PI+ON group, and 3/394 (1 %) in the PI+ON group; none were serious and all resolved without medication. There was no evidence of increased overdose death after naltrexone treatment ended. Thus, the implant was more effective than ON or placebo. More patients in NI+OP than in the other groups developed wound infections or local irritation at the implant site, but none were serious and all resolved with treatment (Krupitsky et al. 2012).

No significant differences were detected between groups in physical and social anhedonia, thus implying that the long-acting naltrexone did not interfere with normal pleasurable stimuli. Similar to our studies with oral naltrexone, psychiatric symptoms (anxiety, depression, opioid craving) were markedly reduced in patients who remained in treatment and did not relapse, and no differences were noted between groups for those who remained in treatment and did not relapse. The efficacy of oral naltrexone was lower in this implant study compared with our previous oral naltrexone studies (Krupitsky et al. 2004, 2006), which may be related to the age of opioid addicts and the degree to which family members could supervise compliance. For example, the mean age of patients in the implant study was 28-29 years, significantly higher than previous studies, in which the average was 21-23 years. These older patients were less likely to be living with relatives, which made it more difficult for the relatives to supervise compliance.

Results of two recent randomized trials of another naltrexone implant developed in Australia also demonstrated its advantages over oral naltrexone (Hulse et al. 2009) and usual-treatment aftercare (Kunoe et al. 2009); however, these studies did not have a placebo control group. Other long-acting, slow-release naltrexone formulations (implantable and injectable) for opioid dependence are being developed and tested (Krupitsky and Blokhina 2010).

Implantable naltrexone formulations have several limitations. First, they require a minor surgical procedure that carries with it the risk of wound infections and cosmetic defects. Second, it is possible for the patient to remove the implant within the first few weeks, as Prodetoxone slowly dissolves and can be removed reasonably intact within the first few weeks. Third, in some patients (<10 %), the implant appeared to block opioids for less than 2 months. Therefore, a long-acting, slow-release formulation that is injectable and simple to use and does not require surgery might have some advantages over an implant formulation.

31.2.2.2 Injectable Naltrexone

Three sustained-release, injectable naltrexone formulations have been developed in the past 10-15 years: Vivitrol® (Alkermes, Waltham, MA), Depotrex® (Biotech, Bethesda, MD), and Naltrel® (Drug Abuse Sciences, Hayward, CA). Only Vivitrol® has US Food and Drug Administration approval. It is administered via a monthly intramuscular injection and blocks the subjective effects of opioids for 1 month (Dunbar et al. 2007).

The effectiveness of Vivitrol® for preventing relapse to opioid dependence was recently studied in a phase 3, double-blind, placebo-controlled, randomized,

multicenter trial (Krupitsky et al. 2011). The study, conducted at 13 sites in Russia, recruited males and females (≥18 years) meeting DSM-IV criteria for opioid dependence disorder, who had completed inpatient opioid detoxification (≤30 days) and who were off opioids for ≥7 days. Patients were voluntarily seeking treatment and were excluded if they were under justice system coercion, i.e., parole or probation, or pending legal proceedings with potential for incarceration. Patients were randomized to either injectable naltrexone 380 mg (Vivitrol®) or placebo in a 1:1 ratio, stratifying by site and gender in a centralized, permuted-block method. Vivitrol® was injected within 1 week following detoxification and then every 4 weeks, for a total of six injections over 24 weeks. Participants were also offered 12 biweekly sessions of manualized individual drug counseling (IDC), adapted for opioid dependence. The primary outcome was the response profile for confirmed abstinence, based on opioid-negative urine drug tests and self-report of nonuse during weeks 5–24. Patients were predominantly young, male, white, and addicted to heroin for ~10 years and had high rates of HIV and hepatitis C infection. In the 30 days prior to the first injection, heroin was used by 221 (88.4 %) of participants, methadone by 29 (11.6 %), and other opioids/analgesics by 33 (13.2 %). Baseline characteristics showed no significant intergroup differences. Vivitrol® yielded a median of 90 % confirmed abstinent weeks vs. 35 % for placebo ($p = 0.0002$); total abstinence occurred in 36 % of Vivitrol® patients vs. 23 % ($p = 0.0224$). An anti-craving effect was observed; at baseline (scale 0–100), there was no group difference (21.8 vs. 18.2); however, during treatment Vivitrol® showed a mean reduction of −10.1 (vs. +0.7 for placebo; $p < 0.0001$). Median retention was >168 days with Vivitrol® vs. 96 days with placebo ($p = 0.0042$). Naloxone challenge confirmed relapse to physiologic opioid dependence in 17 placebo patients vs. one Vivitrol® patient, a 94 % difference ($p < 0.0001$). Reduced HIV risk behavior and improved mental health function were observed with Vivitrol® vs. placebo. Adverse events were reported by 50 % on Vivitrol® vs. 32.3 % on placebo. Mean increases, for Vivitrol® vs. placebo, were similar for ALT (6.9 vs. 5.6 IU/L) and AST (3.8 vs. 6.7 IU/L), but hepatic enzyme abnormalities were more common with Vivitrol®. All nonserious adverse events were rated mild or moderate and included nasopharyngitis, insomnia, injection site pain, and toothache. No patients died or overdosed. Thus, in opioid-dependent patients, Vivitrol® with counseling demonstrated efficacy vs. placebo across multiple recovery goals including prevention of relapse, showing that it represents a new approach that is distinct from opioid maintenance treatment through once-monthly, injectable, opioid blockade.

31.3 Conclusion

Studies conducted in St. Petersburg, Russia, for more than a decade have demonstrated the efficacy and safety of different naltrexone formulations (oral, implantable, injectable) for relapse prevention and maintenance of abstinence in detoxified opioid addicts. The positive results from different formulations seem related to two

cultural factors. One is that detoxification is widely available and relatives can be recruited to supervise daily dosing of the oral formulation; however, this advantage appears to decrease as the population ages. The second is that substitution therapy is not available; thus, naltrexone is the only effective medication, which makes it easier to motivate patients to use it. Findings from studies of long-acting, extended-release formulations (implantable and injectable) show that they are more effective than oral formulations and likely to be important additions to current treatment options not only in Russia but also for patients in other settings who do not want or do not have ready access to agonist or long-term residential treatment. How extended-release naltrexone formulations compare with maintenance treatment using methadone or buprenorphine in settings in which all three treatment options are available is a topic for future studies.

Acknowledgment The studies of oral naltrexone with or without fluoxetine were supported by NIDA grants P60-DA05186l (Dr. O'Brien) and DA017317 and K05-DA 17009 (Dr. Woody) and the Department of Veterans Affairs. Alkermes (USA) supported the study of injectable naltrexone (Vivitrol®) in Russia.

Disclosure DuPont Pharmaceutical provided naltrexone, and Gideon Richter provided fluoxetine for the studies of oral naltrexone with or without fluoxetine. Fidelity Capital (Russia) provided Prodetoxone at reduced cost.

Dr. Krupitsky had been serving a consultant for Alkermes in 2007–2010. No other potential conflicts of interest relevant to this article were reported.

The Response to HIV/AIDS Epidemics Among Drug Users

Min Zhao

Contents

Abstract

China has a long history of opium abuse problems and currently faces the challenge of a dual epidemic of drug use and HIV/AIDS. China has adopted methadone maintenance therapy (MMT) as a primary strategy to combat this dual epidemic. The results from the studies have shown that most of the interventions MMT programs were successful and had positive effects in reducing drug-related risk behaviors among drug users. It is expected that the

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment: International Perspectives*, DOI 10.1007/978-88-470-5322-9_24,

coverage and quality of the MMT programs will improve and they will fully achieve their goals in the near future.

32.1 Introduction

China is the largest populated country in the world and suffered from a long history of opium abuse problems. As for economic development and modern socialization, like other Western countries, China faces the challenge of dual epidemics of drug use and HIV/AIDS. The former has fuelled the latter and in the last 30 years, both the number of drug users and cases of HIV/AIDS have increased dramatically. This has prompted the government to consider employing harm reduction strategies to control the spread of HIV/AIDS among drug users. Following the success of the proven "substitution" pharmacotherapy approach that has been tested extensively in the Western nations, China has adopted methadone maintenance therapy (MMT) as a primary strategy to combat the combination threat of drug use and HIV/AIDS. MMT program has been implemented in China for nearly 10 years and achieved remarkable progress with the support of central government.

32.2 The Epidemic of Drug Use and HIV/AIDS in China

China has had a long history of drug use, especially opium abuse. The country enjoyed a relatively drug-free period between the 1950s and 1980s due to a successful antidrug campaign. Shortly after the new Chinese government established in 1949, under Mao's leadership, the government launched a national level antidrug campaign, which included compulsory detoxification of drug abusers, severe punishment for drug dealers, and the replacement of opium with other crops, and was greatly assisted by closing the borders (McCoy et al. 2001). However, in the late 1970s, China introduced its "open door" and economic development policy. China is close to the "Golden Triangle" and "Golden Crescent," two of the three biggest opiate suppler areas in the world. Concurrent with increased trade of licit goods, the trade in illicit goods, including narcotics, reemerged (Zhao et al. 2004). When drug use reemerged in the late 1970s, it was concentrated in Yunnan and Guangxi provinces which border with Myanmar and Vietnam. At that time, Chinese authorities were under the impression that China only served as a trafficking route for drug smugglers to traffic drugs to other countries and that there was no or little drug consumption. Efforts were exclusively focused on seizures of smuggled drugs, with little attention given to prevention and treatment of drug use among the Chinese. Along drug traffic routes, more and more youths and young adults became drug users, and later, drug use spread very quickly from border areas to inner regions of the country (Zhao et al. 2004). It was not until the mid-1990s that Chinese officials and scholars recognized that drug use was a severe social problem. China's Public Security Bureaus (PSB) started to register drug users in 1990. The registered number of drug users in 1990 was 70,000 and this

figure rose to 1.79 million in 2011 (National Narcotic Control Commission 2012), representing a rapid epidemic of drug use problems in China.

With the drug use problem increasing rapidly, the drug use-related family, social, and public health problems become more and more oblivious. One of the severe public health consequences is HIV/AIDS transmission among drug users. Needle sharing to inject heroin is believed to have been the principal entry route of HIV into China. Indeed, first HIV outbreak was identified among 146 injecting drug users in Yunnan province in 1989 (Wang 2007). Since then, China has observed an ever-growing HIV/AIDS epidemic. In 2001, up to 66.5 % of newly diagnosed HIV infections were related to drug use. The prevalence of HIV is highest in those provinces located closest to the borders of Myanmar (Yunnan Province), Vietnam (Guangxi Autonomous Region), and Central Asia (Xinjiang Uygur Autonomous Region). The HIV/AIDS has spread rapidly through the injecting drug user (IDU) population and had reached IDUs in all 31 provinces by 2002. By the end of 2005, HIV was estimated to have infected 288,000 drug users, accounting for 44.3 % of China's 650,000 HIV infections (Bao and Liu 2009). The prevalence of HIV in China is roughly 0.05 %, but among drug users it is much higher and surveys among drug users have found the prevalence to be 12.5 % among drug users (Bao and Liu 2009). Facing the threats of HIV/AIDS epidemics among drug users, harm reduction efforts began in 2003 and have slowed the pace of HIV infection among drug users has stabilized and reduced, particularly since 2005, with the overall growth rate of newly reported cases having decreased from 9.0 % in 2006 to 5.8 % in 2009. By the end of Oct. 2012, 492,000 HIV-infected cases were reported and 25.8 % of the cases were injecting drug users (IDUs). It was thought that IDU is no longer the major HIV/AIDS transmission mode in China. Among the harm reduction strategies, methadone maintenance treatment was the most successfully implemented program in China.

32.3 The Development of Methadone Maintenance Treatment Program

In the early 1990s, government officials began the lengthy process of understanding how best to constrain the dual epidemic of HIV and drug use. This included learning from other countries, developing policies and plans suitable to China, piloting harm reduction strategies, and ultimately implementing a multifaceted program to slow the HIV epidemic among drug users. When first introduced, harm reduction was controversial because it conflicted with laws and regulations on narcotics control. Thus, despite a large body of evidence supporting the effectiveness of MMT, it was initially difficult to convince government officials, especially those in law enforcement, to try this strategy (Yin et al. 2010). But finally the National Center of AIDS/STD Control and Prevention (NCAIDS) make great effort to develop MMT program as a strategy to control HIV transmission by several phases.

32.3.1 Preparation Phase

In order to advocate for implementation of MMT program to control HIV/AIDS epidemics, public health professionals from the National Center of AIDS/STD Control and Prevention (NCAIDS) took the bold step to explore the feasibility and effectiveness of MMT by conducting pilot interventions to advocate for evidence-based policy. Prior to 2001, efforts focused on policy advocacy and preparation. The Medium-and Long-Term Strategic Plan for HIV/AIDS (1998–2010) issued in 1998 was China's first HIV-specific policy document with clear targets. It resolved to contain the rapid spread of HIV among injecting drug users and mandated HIV/STD education in drug rehabilitation centers and prisons, as well as in schools. Thus, harm reduction as a control strategy was formally introduced (Li et al. 2010). The plan called for a pilot of Maintenance Treatment for Opiate Users in therapeutic institutions. The National Working Group for Community-based Maintenance Treatment for Opiate Users (hereafter referred to as the National Working Group) was established in August 2002, consisting of members of the Ministries of Health, Public Security, and the State Food and Drug Administration and experts on addiction and HIV/AIDS. The national guidelines were drafted by the secretariat and reviewed by National Working Group members, and further consultation was sought from stakeholders (Wu et al. 2007). In February 2003, the Ministry of Health, the Ministry of Public Security, and the State Food and Drug Administration jointly issued the Temporary Scheme for Community-Based Drug Maintenance Treatment for Heroin Dependents.

32.3.2 The Pilot Phase

The temporary scheme prioritized MMT implementation in those areas most severely affected (more than 500 drug users) and outlined eligibility criteria for participation. The eligibility criteria to participate in MMT were (1) opiate users who had failed more than one attempt to quit, (2) at least two terms in a detoxification center or once in a reeducation-through-labor detoxification facility, (3) at least 20 years of age, (4) a local resident and settled in the local area where the clinic was located, and (5) capable of complete civil liability. Drug users testing HIV positive needed only to fulfill requirements (4) and (5) to qualify. The temporary scheme also outlined the safety and security protocol to guide methadone production, transport, and distribution under the supervision of the State Food and Drug Administration. Methadone powder was purchased centrally and distributed to participating provinces, which have each assigned one pharmaceutical body to produce methadone liquid according to the Chinese pharmacopoeia. In addition, it was stipulated that the maximum daily cost for a drug user receiving MMT services is 10 Chinese Yuan per day (US $1.20) irrespective of dosage. Patients had to appear in person to collect their daily dose. Between March and June 2004, the first eight MMT clinics were established: two in Sichuan, one in Yunnan, two in Guizhou, one in Guangxi, and two in Zhejiang (Wu et al. 2007). The locations of

the clinics were based on need and the local government agencies' willingness to participate. A total of 1,029 clients were enrolled during the first calendar year of the pilot. To estimate the effectiveness of these first eight clinics, the national secretariat established a monitoring and evaluation system.

32.3.3 The Scale-Up Stage

In 2004, the first national meeting on piloting MMT was convened among experts and government officials from Ministry of Health and National Narcotics Bureau. The meeting served to share the experiences and to promote rapid scale-up throughout the country. With growing political and technical support, the MMT program began to steadily expand. By the end of 2005, there were 58 MMT clinics opened in 11 provinces. Thus, the pilot period ended and the MMT program moved to national scale. In 2006, the adjoining Five-Year Action Plan to Control HIV/AIDS (2006–2010) set specific targets for scaling up MMT; by the end of 2007 and 2010, MMT would be made available for no fewer than 40 % and 70 % of opiate users, respectively, in counties and districts with more than 500 registered drug users (State Council of P. R. China 2006). Also, in July 2006, the National Working Group revised the temporary scheme to improve MMT services. Several crucial improvements were made to benefit and cover more target groups. Notably, the enrolment and exclusion criteria were relaxed. For example, (1) clients are no longer required to have a history of detoxification or several failed attempts to quit using drugs to enter the program, (2) clients are no longer required to be registered as local residents and a transfer system has been set up to meet the needs of those who are relocating either permanently or temporarily, and (3) relapse is no longer a strong reason for expulsion. Furthermore, a detailed clinical guideline for methadone treatment was added to the protocol to support clinical practice, and comprehensive interventions are highlighted in the new protocol that suggests clinics offer ancillary services. These include counseling, psychosocial support, testing for HIV, syphilis, hepatitis C and tuberculosis, referrals for antiretroviral treatment, peer education, health education, group activities, and skills training for employment. The treatment fee for MMT services was not specified, as in some areas where heroin is easily obtained at low cost, the fee is reduced or even waived. In 2007, central government funding was also allocated to the program, enabling those places with less than 500 registered drug users to establish MMT clinics. Another target of 500 MMT clinics was set and 503 MMT clinics were cumulatively accomplished by the end of 2007, in 23 provinces serving 97,554 clients.

32.3.4 The Quality Improving Phase

There were 680 clinics by the end of 2009, in 27 provinces with some 242,000 clients ever enrolled, roughly half of whom remain in treatment. Areas of greatest need have MMT clinics and the expansion has thus slowed down and then the focus

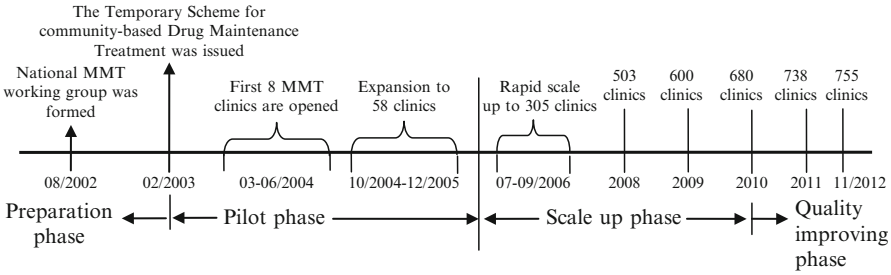

Fig. 32.1 The development process of MMT program in China

of the National Working Group is focused on improving the service quality. It was emphasized to improve the retention rates and a series of intensive training was carried out to improve the service quality. Clinic services have been extended to offer clients a range of ancillary services, including HIV, syphilis, and hepatitis C testing; information, education, and communication; psychosocial support services; and referrals for treatment of HIV, tuberculosis, and sexually transmitted diseases. Regular evaluation and professional supervise were organized to identify problems and provide technical support. By the end of Nov. 2012, there were 755 clinics in 28 provinces with 381,900 clients ever enrolled, roughly 78.2 % of whom remain in treatment within 1 year. The development process of MMT program in China is illustrated in Fig. 32.1.

32.3.5 MMT Mobile Service

China is a vast country with many rural areas where the density of population is varied largely. In order to provide MMT services to drug users in remote, rural areas to access to methadone, the first MMT mobile service vehicle was established in Nov. 2006 in Yunnan province. The mobile MMT service vehicle serves as a small MMT clinic, equipped with necessary medical equipment, medicine, and qualified professionals and securities. Every day the mobile MMT service vehicle travels decades of miles with several fix stops where the patients are concentrated. Following the success experiences in Yunnan, the mobile services were available later in other provinces, with a total of 30 MMT vehicles by the end of Nov. 2012.

32.3.6 Extension MMT Service Site

In recent 2 years, in order to improve the accessibility and service coverage of MMT, it was encouraged to set up MMT extension service site based on the existing MMT clinics (fixed MMT clinics) in the area. The extension MMT service site can be established in countryside or community health service center where patients are relatively concentrated resided but no fixed MMT clinics available. The fixed MMT

clinics are responsible for the technique support such as staff training and clinical supervision for the extension sites. The fixed MMT clinics are also in charge of the everyday clinical management such as patients recruit, data collection, laboratory test, and methadone delivery in the extension MMT service sites. There are 308 extension MMT service sites available by the end of November 2012 since it was first opened in Yunnan province.

32.4 The Governance and Technical Support for MMT

The National Working Group was given an overall responsibility for managing the MMT program, supervising the operation, and overseeing its expansion. At the provincial and county level, working groups have also been established to take on these duties locally. The National Working Group members meet regularly to identify potential gaps, resolve emerging issues, and refine the management of the program. The NCAIDS serves as the secretariat for the National Working Group, which is tasked with executing the national plan, coordinating the implementation, providing technical support to the clinics, and conducting routine monitoring and evaluation. The national training center was established in the Yunnan Institute of Drug Abuse to provide clinical and administrative training for key staff working in MMT clinics. Two specific training programs are provided to trainees. The first is a 10-day intensive training course covering addiction theory, clinical practice, and administrative skills for delivery of MMT services. The second is on-site training provided by clinical addiction experts to assist local staff for the first 7 days after a clinic has opened, to guide them in the practice of addiction treatment and data management. The MMT clinics in China are nonprofit medical facilities assigned by local public security and public health departments to be established and operated by local Centers for Disease Control and Prevention (CDC), primary health hospitals, mental health hospitals, or voluntary detoxification centers in areas with a concentration of drug users. Typically, an MMT clinic is required to have eight to ten staff members including qualified doctors, pharmacist, security personnel, etc. Doctors are primarily responsible for prescribing methadone, providing physical examination, and psychological counseling, and they are required to be certified physicians authorized to prescribe analgesic and psychotropic drugs. Nurses are responsible for dispensing methadone to the clients and observing them taking the methadone. Other clinic staff members are responsible for data entry, management, report, and other logistical issues. One or two security personnel are required for each of the MMT clinic. Patients meet with the doctor every day and pay not more than 10 Yuan (or US $1.25) for the daily dosage. Urine testing is routinely required. The services offered at methadone clinics have been broadened and provide access to other services, including HIV and hepatitis testing, antiretroviral therapy for eligible AIDS patients, group activities, peer education, and skills training for employment. Regular monitoring and evaluation need to be carried out to quality control. A national MMT program database was developed in 2004 to monitor the pilot and was later upgraded to a web-based management

database in 2008. The database enables regular reporting on the implementation of the program. Such information can be used to identify gaps in the delivery of services in a timely manner. Each of the clinics uploads its daily services records to the database in real time. This includes clients' demographic information at the start of treatment, as well as their daily dose record and the results of any tests performed for opiate use, HIV, hepatitis C, syphilis, and tuberculosis. The information is collected at entry, 6 months after entry, and 12 months after and then at 12-month intervals thereafter, allowing the secretariat to measure the relative change in clients staying in the program in order to evaluate the effectives of MMT.

32.5 The Outcomes of MMT Programs in China

The results of the empirical studies in China revealed that most of the interventions of MMT program were successful and had positive effects in reducing drug-related risk behaviors among drug users. A 2007 evaluation survey conducted in the first phase of eight MMT clinics found a positive change in the self-reported rate of injecting drug use, drug-related illegal offenses, employment opportunities, and family relations. Only eight HIV seroconversions were found among 1,153 sero-negative clients during the 12-month follow-up (Pang et al. 2007). Another two MMT intervention studies showed that the use of MMT decreased the frequency of IDU and criminal behaviors. The sentinel surveillance data showed that HIV infection prevalence among drug users has been leveled off and has a tendency to decrease after the MMT program was implemented in China (Yin et al. 2010, Fig. 32.2).

These positive results are consistent with the large body of empirical evidence on effectiveness of harm reduction programs in other countries. One study in Yunnan province analyzed the cost and cost-effectiveness of methadone maintenance treatment (MMT) program, and it demonstrates that MMT is a cost-effective

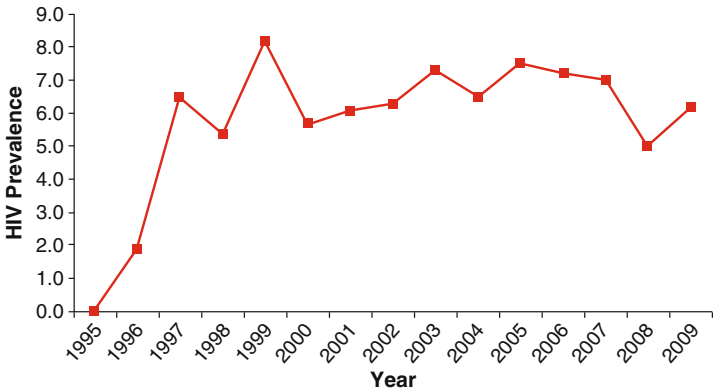

Fig. 32.2 HIV sentinel surveillance data for drug users, 1995–2009

intervention for reducing HIV transmission among injecting drug users (Xing et al. 2012). In summary, the MMT program not only decreased the drug use and HIV transmission; it was also a cost-effective intervention.

32.6 Challenges and Future Direction in MMT

China has made substantial progress in the development and implementation of MMT programs and many positive outcomes from the program have been shown within just less than 10 years since it started in 2004. However, program planners, researchers, and policy makers of MMT programs are facing several special challenges that need to be addressed in future (Lin et al. 2010).

32.6.1 The Service Coverage and Utilization Needs to Be Increased

First, despite a high number of registered opiate addicts in the country, the number of clients in the MMT program is very limited, with low coverage of the total drug-using population (Li et al. 2007). There is great variation in the numbers of clients in each MMT clinic, some with more than 200, whereas others have fewer than 20. According to the newest data from the National Working Group's report recently, there are 755 MMT clinics, and only 209,400 clients (less than 20 % of the registered number of drug users) are currently in the treatment. The majority (63.8 %) of the MMT clinics only had less than 200 clients. Clearly the program does not reach the majority of opiate addicts, although there is adequate capacity to handle more clients.

Given human resources constraints and the size of the country, it is not feasible to offer MMT services in all areas with drug use. It is pragmatic to provide the service in the worst affected areas first, and only areas with more than 500 drug addicts had MMT clinics. The denominator used to calculate the targeted clients is currently registered drug users, which may be significantly less than the actual number. Although mobile MMT service vehicles and extension MMT service site have been implemented to increase the service coverage in some areas, it may be a long time before services are more widely accessible. The existing MMT clinics can serve much more clients than the actual number of clients in MMT programs now; therefore, a very important strategy should focus on how to increase the service utilization. In-depth research are needed to find out the barriers for service utilization, and related adjustment on policy and operation of the MMT programs should be taken to address these barriers.

32.6.2 The Retention of the Clients Need to Be Increased

Second, the client dropout rate is high in most sites (Qian et al. 2006) and a considerable proportion of clients continue illicit drug use while participating in MMT.

The MMT program has suffered from a high relapse rate, especially in its initial phases. In 2009, the overall retention of MMT in China was about 50 % and most of the clients who dropped out relapsed to drug use.

Previous studies have documented that both treatment and individual level characteristics are associated with treatment retention. Treatment characteristics are crucial predictors of retention and drug use. For example, methadone dosage is strongly positively associated with retention and other favorable treatment outcomes. MMT clients in China receive lower dosages of methadone compared with patients treated in other countries. The average daily dosage of methadone given to Chinese clients in eight pilot MMT clinics was 44.9 ± 21.9 mg (Pang et al. 2007). One qualitative study showed that the average dosage prescribed in the 28 clinics was 35 mg per day (Lin and Detels 2011). Therefore, it is necessary to formulate clear guidelines concerning individualized dosage management and to improve training among service providers in MMT clinics in China. The National Working Group has realized the abovementioned problems and challenges and is making a great effort to solve these problems. The scale-up pace of MMT program has been slowed down and the focus of the National Working Group has been shifted to improve service quality to increase the retention and drug use.

32.6.3 MMT Programs Should Serve as a Comprehensive Service Platform

Drug dependence is a chronic disease with problems in many aspects, only provide methadone is not enough for client's rehabilitation. Psychosocial intervention and other medical interventions should be available to meet client's individual need. Due to shortage of professionals and other facilities, and not shortage of methadone, the MMT clinics cannot provide other services such as counseling, linkage to aftercare, and other treatments. This may be one of the important reasons for clients to drop out and use drugs during the treatment. Unlike MMT clinics in other Western countries, other pharmacotherapies such as buprenorphine, Suboxone, and naltrexone are also available as alternative choices. Methadone is the only choice for patients in China; no medications are available for patients who do not want to use methadone in China. Despite demonstrating the efficacy of buprenorphine and naltrexone, these trials have had a minimal influence on policy. A study of Suboxone has been conducted in Guangxi Zhuang Autonomous Region and Xinjiang Uygur Autonomous Region by the China CDC and local CDCs in collaboration with Johns Hopkins University. However, Suboxone produced by domestic or international company is still at clinical trial stage and is not available in Chinese market. It is predictable that Suboxone will serve as an alternative medication for opiate dependents within few years. Further research that examines the reasons for attrition and how the delivery of services can be improved is needed, and MMT program should serve as a platform of comprehensive intervention and offer more choices to meet individual needs of each patient.

32.6.4 Collaboration Among Multi-sectors

Drug addiction behavior is defined as illegal and can be sent to compulsory drug rehabilitation institution by public security system. The conflicting approach between "zero tolerance" policies toward drug use and harm reduction programs including MMT and a lack of cooperation among related departments may make it difficult for the effective implementation of MMT programs. Entry into the MMT program requires registration as a drug user with the public security system, and this may be a big barrier for patients since they do not want to be marked as "drug addicts" which is highly stigmatized in China. MMT clinics are required to report to the police patients who are drug positive for the third time. Clinics operated by law enforcement are likely to be stricter and less able to deviate from official guidelines than facilities that are operated by the public health system. Some patients who relapse in the MMT clinics were sent to compulsory drug rehabilitation center; therefore, many patients are scared to go to MMT clinics.

Significant progress has recently been made in this area and the public security system are being ever more supportive, especially of MMT, paving the way for faster scale-up of MMT programs. Health workers cannot expect law enforcers to ignore illegal behaviors, but they can work with them to find mutually agreeable strategies for achieving their respective goals. Synchronized drug use control approach, open communication, and strong cooperation among involved governmental departments are needed to ensure the effective implementation of MMT program in China. As a substantial number of drug users are incarcerated and a proportion of them are HIV positive, MMT program should be considered in incarceration centers to prevent further spread of HIV and drug use in the future.

32.6.5 Capacity Building for Staffs in MMT Clinics

Evidence-based treatment approaches for addiction are effective only when properly implemented and conducted. Compared with Western nations, MMT programs in China are still at an early stage of development. Staffs working in MMT have different backgrounds with different levels of professional capacity. The majority of MMT clinicians only received minimum professional trainings and lack sufficient expertise in managing pharmacotherapy treatment or in delivering psychosocial interventions. Drug addiction is a very complicated condition with multidrug use and complex comorbid physical or mental health problems, and well-trained treatment staffs are needed to deal with these problems. Studies have consistently indicated that methadone maintenance combined with psychosocial services is more effective in retaining patients, decreasing relapse rates, and reducing costs than maintenance treatment alone. But no standardized comprehensive psychosocial service or counseling is available for patients due to the shortage of professional capacity in China. Therefore, sustained and intensive professional trainings are needed to enhance the capacity of staffs in MMT programs. Institutional capacity building to deliver sustainable and standardized services will ultimately improve retention rates in China.

Despite the abovementioned challenges, the MMT programs in China have achieved tremendous progress. The evaluation of the ongoing MMT program has suggested reductions in heroin use, risky injection practices, and, importantly, criminal behaviors among clients and resulted in other positive outcomes. With the great determination and effort to control drug use and HIV transmission from the government, it is hoped that the coverage and quality of MMT program will be improved further and its treatment goal in the near future will be achieved.

Contents

Abstract

The opioid addiction rate in Iran is among the highest in the world. One contributing factor is Iran's long border with the world's main opium producer, Afghanistan, with consequent extensive availability of opium and heroin. Following the 1979 Islamic revolution, drug policy employed in Iran was primarily based on a supply reduction rationale, with an aggressive criminal justice/

incarceration response. This began to change as harm reduction programs in Iran were initiated in 2003. After an alarming increase in HIV infection among injection drug users and following a pilot study in 2002, methadone maintenance treatment became an accepted health policy and has been extensively implemented in Iran. Success of the Iranian harm reduction approach is based on attitudinal changes by policy makers, a rapid dissemination throughout the country, and implementation of programs by private sector people and NGOs. After successful implementation of methadone maintenance program in the country, buprenorphine maintenance was started since 2006. In 2011, opium tincture maintenance was initiated for those who are dependent to opium. Iran also has one of the most extensive methadone maintenance treatment programs within the prisons throughout the country. Currently, there are more than 2,500 agonist maintenance treatment units available in almost all large cities, providing treatment to more than 300,000 patients. In addition to the agonist maintenance centers and prisons, agonist therapy is available in drop-in centers and triangular clinics which are health centers run by public sector, where drug users have a free, voluntary HIV consulting and testing, free antiretroviral treatment, and needle syringe exchange program.

33.1 Introduction

Since centuries ago until the present time, psychoactive substances have influences on personal, sociocultural, religious, and even political aspects of Iranians' life. Wine, according to mythical stories and archeological excavations from 5400 BC, may have originated in Iran (McGovern 2003). It was a drink of choice for the upper class patricians in premodern times. Its use diminished temporarily after the introduction of Islam in the seventh century, but after a short period of time, people started drinking wine and its use continued to be popular but hidden until the present-day Islamic Republic (Matthee 2005). In ancient Iran (Persia), Mei (the Persian word wine) has been a central theme of poetry more than a thousand years, although alcohol is strictly forbidden in Islam. Shiraz, a very old city in Iran (1 h far from Persepolis), continued to be a center of wine production in Islamic era, and today, its name is on a very famous dry red table wine (Robinson 2006). Safavid dynasty permitted producing and exporting wine and also drinking it but not in public. It is interesting that Safavid kings were the most religious Iranian kings after Islam, but some of them died from alcoholism (Matthee 2005) (Fig. 33.1).

The eleventh century Persian poet Farrokhi has said: Although wine is forbidden, I believe that it becomes licit for lovers when spring arrives, God gives us his blessing as we drink. Come and don't regret it.

Opium was also a popular drug since Safavid dynasty (1502–1736) and became more popular during Qajar period (1785–1925).

Dr. Jacob Eduard Polak (1818–1891) – a Jewish Austrian physician who worked in Iran between 1851 and 1860 as a teacher of the first Iranian medical school – has

Fig. 33.1 Serving Wine in a Royal Ceremony in a Painting form Safavid Era

written in his book with the original title "Persien, das land und seine bewohner": "opium use is a very popular habit and it has no negative social stigma or shame for users. It is not forbidden and every Iranian who can afford its cost uses it daily... most people only took up the habit only in old age and stick to the same amount, so that effects tended to be minimal." Iranians began to develop a noticeable addiction to opium in the mid-ninetieth century. Although opium has existed in Iran in some form or another for centuries, widespread addiction was not known in the country until about 1860 (McLaughlin 1976).

33.2 Drug policy and Drug Treatment in Iran

33.2.1 From Over-Criminalization to Harm Reduction

The first treatment centers specialized for addiction and first outpatient methadone program in Iran initiated in the early 1970s. The first program was launched in 1974 in Shiraz city which used opioid agonist medication for assisted withdrawal of opioid-dependent clients. Before that there are reports of methadone use for

inpatient medically supervised assisted withdrawal for opioid treatment in Tehran. There was limited number of clients in this program which received methadone on maintenance basis.

All programs changed again to criminalization, moralization, and supply reduction after Islamic revolution in 1979. The situation continued in the same way until 1990s. By that time, the country political and health official realized that supply reduction and criminalization policy is not working. Drug offenders made up more than 50 % on the country prisoners, and drug flow from eastern borders was unchanged even with long border blockade. On the other hand, continuing conflicts in Afghanistan, the eastern neighbor of Iran, made it the main producer of opium which produces more than 90 % of global opium, and opium became cheaper and more easily accessible. At this time, Iranian Welfare Organization started first addiction treatment program after the revolution and launched outpatient addiction treatment centers in many cities across the country.

33.2.2 First National Epidemiological Studies

In order to have a real picture of substance abuse in the nation, the Iranian Welfare Organization in collaboration with the United Nation's International Drug Control Program (UNDCP) office performed a rapid situation assessment in a study from 1998 to 1999. According to the data of this study and other studies, authorities in Iran Drug Control Headquarters (DCHQ) and other officials believe that around 1,200,000–2,000,000 individuals living in Iran would have a diagnosis of drug abuse or drug dependence according to the DSM-IV criteria. The average Iranian addict is very likely male, married, and employed. Data from various provinces and within different groups show that more than 90 % of the drug-abusing population is male. In fact, the RSA study claimed that on average, 93 % of drug abusers in the nation are male, whether imprisoned, in treatment, or on the streets. The lowest preponderance of males belonged to Tehran, with 87 %. Around two-thirds of the addict population is married. This figure is lowest in Tehran, where only half seem to be married. Even in the incarcerated group, the majority (51 %) was married. In fact, less than 10 % of the addicts live alone; a spouse, parent, or sibling is usually present. Employment is also the rule in this group. Unemployed drug abusers comprise only a fifth of the population. According to study, a quarter of Iranian narcotic abusers have a history of intravenous (IV) injection of opioids, mainly heroin. Appearance of heroin injection dates back to 1960s. A study performed on 318 narcotic abusers with a lifetime history of IV drug abuse has shown that the average Iranian IV drug user (IDU) is 31.4 ($\pm$8.7) years of age, significantly 2 years younger than non-IDU; has started drug use around 3.5 years before non-IDUs (19.6 year vs 23.1 year); and has started injecting while 26.2 ($\pm$6.7) years old. Thus, injection of illicit drugs begins on average 7 years after its non-IV consumption. While the male-to-female ratio for non-IDU is 12:1, it is 31.3:1 for IDUs. More than half of the IDUs are single (Mokri 2002).

As opium production in neighboring Afghanistan has dramatically increased over the past decade, Iran has been impacted more than any other country (International Narcotics Control Board 2009; UNODC 2009a).

Although the vast majority of global opium seizures (83 %) take place in Iran, every year tons of opium flow from Afghanistan to the rest of the world, and the biggest share – 40 % – is through Iran. Iran faces many problems along its eastern border, and much of the country's supply reduction efforts are focused in this area. Global consumption of opium is estimated at 1,100 t per year, used by four million users; over 42 % is estimated to be used in Iran. It is estimated also that Iran consumes 17 t of heroin annually; this is 5 % of global consumption. Iran has the highest rate of abuse of opiates in the world (UNODC 2009b). Many adolescents in Iran, age of drug use onset, are under age 18 (Momtazi and Rawson 2010).

33.2.3 Methadone Maintenance Treatment (MMT) Programs

With the aim of adopting more effective strategies to address opioid use and HIV-related drug-using behavior among opioid-dependent population, the first methadone maintenance treatment (MMT) pilot project was conducted in Roozbeh psychiatric hospital, in August 2002 (UNODC 2005). It was a double-blind randomized, controlled trial comparing fixed doses of 40 and 70 mg daily oral methadone to treat opioid dependency. The result of the study indicated that MMT effectively reduced illicit opioid use and criminal and violent behavior and helps patient save a reasonable sum of money formerly spent on drug consumption. Three-month treatment retention among 40 mg, 70 mg, and total sample were 44, 74, and 54 %, respectively. Another multicenter, open-label study of individualized dose of methadone maintenance treatment showed dramatic improvement of illegal opioid use, injection, and mood and social and personal functioning indicators of opioid-dependent clients seeking help from Roozbeh hospital (Iranian National Center for Addiction Studies, since October 2003), West Triangular Clinic, and Persepolis drop-in center measuring by Opioid Treatment Index (Razzaghi et al. 2005).

The finding of abovementioned studies supporting feasibility, acceptability, and effectiveness of MMT led to adoption of MMT as a building block of drug treatment and HIV prevention programs for people who inject opioids by Ministry of Health (MoH) and DCHQ. By 2004, Substance Abuse Prevention and Treatment Office (SAPTO) of MoH developed the first protocol for MMT which included clinical guideline to provide the treatment, as well as regulations for establishment of opioid agonist treatment program referred as "agonist units" within substance abuse treatment centers. Certified drug treatment programs affiliated to public-owned, private, or nongovernmental organizations (NGOs) were allowed to establish MMT programs for 50 clients providing one multidisciplinary treatment team consisted of one trained general physician, one clinical psychologist, and two nurses. The opioid agonist treatment units could increase their MMT slots to 100 after 1 year of activity without any violation of regulations and providing

two multidisciplinary treatment teams. They also allowed increasing their MMT treatment slots to 200 after another year of activity and providing four multidisciplinary treatment teams and one social worker. For each 100,000 general population, one opioid agonist unit was allowed to establish, and they must have at least 1 km distance with each other.

Addiction treatment practitioners in Iran have had many decades of experiences with short-term assisted withdrawal of opioid dependents with clonidine or opioid medications before introduction of MMT at 2002. Initially some practitioner, clients, and their families preferred short-term withdrawal with methadone over long-term maintenance programs; however, gradually both practitioner and the clients realized that the methadone treatment should be long term to be successful. Newly established agonist units' slots were filled very soon, and waiting lists for entering to methadone maintenance programs were developed. At the end of 2004, 93 public-owned and 201 private agonist units were reported in 4,091 and 3,701 clients on MMT, respectively (Razzaghi et al. 2009).

To increase accessibility of methadone maintenance treatment, requirements for establishment of opioid agonist treatment were eased by second edition of the protocol which released in 2006 (SAPTO 2006) and other regulations issued by MoH in 2007. Currently certified outpatient drug treatment programs could establish an agonist unit for 100 MMT clients providing one multidisciplinary treatment team consisted of one trained general physician, one trained bachelor level psychologist or counselor, and one nurse as well as enough physical environments to deliver the program including one prescribing room, one counseling room, one distribution unit, and one waiting room. Agonist units could increase their MMT slots, if they provide enough staff and physical. The limitation of establishment of new agonist units in terms of the area population and distance from other agonist units has been removed for private sector.

The first methadone protocol devised the following inclusion criteria for MMT program: (1) diagnosis of opioid dependence according to DSM-IV-TR criteria, (2) using drugs through injection, (3) above 18 years old, and (4) written informed consent for treatment. Non-IV drug users were allowed to enter MMT only after psychiatrist visit verifying existence of at least one of following conditions: (1) chronic psychiatric comorbidity, (2) history of three documented failed treatment attempt in a client above 30 years old and at least 10 years of drug use history, (3) diagnosis of cluster B personality disorder, (4) female gender, or (5) history of imprisonment (SAPTO 2004). These criteria were aimed to increase availability of MMT for people who inject opioids who needed it more, but limited access to psychiatrist in some setting led to revision of them in the second methadone protocol (SAPTO 2006) as follows: (1) diagnosis of opioid dependence according to DSM-IV-TR criteria, (2) above 18 years old, (3) written informed consent for treatment, and (4) one of the conditions – (a) IV drug use, (b) heroin or crack heroin use, (c) opium users with history of three previous failed treatment attempt in a client with at least 10 years of drug use history, (d) HIV positive, (e) history of imprisonment, or (f) female gender.

Table 33.1 No. of MMT clients in community programs

Year	No. of clients on MMT in the community
2002	160
2003	1,133
2004	1,551
2005	7,792
2006	35,139
2007	66,126
2008	111,699
2009	158,975
2010	237,688
2011	283,019

The criteria for MMT programs aimed to increase treatment access for people who inject drugs or use heavier opioids such as heroin or crack heroin, but there has been a high demand for this program from people who use opium through swallowing or smoking. This shows that on one hand, MMT has been an acceptable intervention for Iranian opium users, but on the other hand, it has been a challenge for opioid treatment system in the country because opium users compete with heroin or injecting drug users to fill MMT slots which mainly provide by private sector without any insurance coverage (Mokri and Schottenfeld 2008). To address this issue, DCHQ supported MoH and Social Welfare Organization (SWO) to scale up public-funded, low-cost MMT programs provided for socially disadvantaged and homeless opioid users across the country in 2007. At the end of 2007, 173 public-owned and 587 private agonist units were reported in 15,983 and 50,191 clients on MMT, respectively (Noroozi et al. 2011). Table 33.1 presented number of MMT clients in community programs at the end of each year from 2002 to 2011.

There is no limitation on methadone dose or length of treatment in Iranian national protocol. MMT programs delivered through outpatient clinics must provide regular assessments and psychosocial interventions, although low-threshold MMT programs delivering through drop-in centers do not need to provide intensive psychosocial services and drug testing. Drop-in centers initially established to provide harm reduction services including needle, syringe programs (NSPs), wound care, HIV prevention, psycho-education, and support services including bath and warm meals for hard-to-reach homeless injecting drug users in suburb areas of Tehran and few large metropolitan areas in 2003. Treatment team in low-threshold MMT programs consisted of one trained general practitioner and one nurse which could provide services to 100 MMT clients. The low-threshold MMT clients do not benefit from privilege of take-home methadone doses. The number of MoH-funded drop-in centers and outreach teams established by NGOs increased from 12 and 12 in 2004 to 79 and 126 in 2007, respectively. The number of clients who received MMT in MoH-funded DICs during this time period increased from 886 to 4,114 (Razzaghi et al. 2009). Effectiveness of MMT provided

in DIC setting is documented in a multicenter open-label individualized dose of methadone among clients of one drop-in center in south of Tehran (Razzaghi et al. 2005). The total sum of drop-in centers funded by MoH and SWO reached to 150 in 2007 and has been stable since then.

An Iranian site – Iranian National Center for Addiction Studies (INCAS) – was among the study sites of World Health Organization (WHO) multi-country study which tested effectiveness of opioid substitution treatments (OSTs) in eight countries with very diverse availability of resources including China, Indonesia, Thailand, Lithuania, Poland, Ukraine, Australia, and Iran (Lawrinson et al. 2008). Two interesting findings of the study were as follows: (1) MMT can be effective consistently in a diverse range of settings in terms of cultural background and resources and (2) MMT not only can reduce illicit opioid use and HIV-related high-risk behavior associated with injection but also can significantly improve quality of life of the clients.

Data regarding the coverage of MMT program for people who inject drugs is not available. A cross-sectional study of 810 clients (95 % male; mean age, 40.5 year) on MMT in eight randomly selected private clinics in Tehran indicated that only 5 % of participants admitted injection drug use as their drug administration route (Shekarchizadeh et al. 2012). The first biobehavioral survey among people who inject drugs reported that 33 % of participants were on MMT (MoHME 2010). The second biobehavioral survey in people who inject drugs in 2010 indicated that 43 % of drug users with a history of drug injection during last 12 months were under MMT and had not injected during last month (Haghdoost et al. unpublished report; Ministry of Health and Medical Education 2012). A recent modeling study projected a shift in highest trend of HIV from people who inject drugs to female sex workers. It was estimated that new infected cases via unsafe sex will increase in the future, while over time, the trend with respect to transmission via unsafe injection will decrease, which could be attributed to implementation of evidence-based harm reduction programs particularly MMT among injecting drug users (Haghdoost et al. 2011).

A more recent study on injecting drug users recruited from referrals of seven drop-in centers in three provinces of Iran including Golestan, Alborz, and Isfahan showed that 63 % of participants "know somewhere to get low cost or free MMT," 42.2 % "received MMT in their lifetime," and 35.3 % "have been on MMT during last year" (Noroozi et al. 2012).

Despite these promising preliminary findings, there are limited data regarding the quality of MMT program at national level, and development of a monitoring and evaluation system to develop necessary data and provide timely feedback to the system is crucial for the future of the program.

33.2.4 Methadone Maintenance Treatment Program in Prisons

Although the frequency of drug use might decrease after imprisonment, the high-risk drug-using behavior including injecting drug use and shared injection will increase (Center for Education and Research of Prison Organization 2002). Methadone maintenance program has showed its efficacy in a randomized controlled

Table 33.2 No. of MMT clients in Prisons

Year	No. of clients on MMT in correctional settings
2002	100
2003	300
2004	1,423
2005	2,814
2006	8,048
2007	19,500
2008	25,400
2009	25,000
2010	28,826
2011	38,256

trial comparing individualized dose methadone plus counseling and psychiatric visits with counseling and psychiatric visits alone in an Iranian prison (Bayanzadeh et al. 2007). The study indicated that MMT significantly reduced drug use, injection, suicidal thoughts, and suicidal attempts as compared to baseline assessment, while no significant change in control group was detected. The methadone maintenance program was scaled up rapidly in the country, and currently, almost all medium- and large-size correctional setting in the country has methadone maintenance programs (Farnia et al. 2010). Table 33.2 presented number of MMT clients in correctional settings at the end of each year from 2002 to 2011.

Insufficient recourses to implement the program and limited access to continuation of MMT after release are among major problems of Iran MMT programs (Zamani et al. 2010). Discontinuation of treatment after release will negatively affect post-release treatment outcomes. The Prison Organization lunched some after care MMT program, but many prisoners might move to other cities after release and need continuation of the program in their place.

33.2.5 Buprenorphine

Ahmadi and his colleagues were the first who compared efficacy of different doses of sublingual buprenorphine for maintenance treatment of opioid dependence in Shiraz, Iran. They showed sublingual buprenorphine is safe and effective for maintenance treatment of opioid dependence in outpatient settings, and the treatment group which received higher daily buprenorphine dose (8 mg) had significantly higher retention rate as compared to lower doses groups (Ahmadi and Bahrami 2002; Ahmadi et al. 2004).

Buprenorphine has been approved to use for assisted withdrawal or maintenance treatment of opioid dependence since summer 2006. The previously certified "agonist units" were allowed to use buprenorphine without limitation for treatment slots. Although there is no insurance coverage or governmental support for buprenorphine program, there is a demand for it particularly from opioid users with less severe opioid dependence.

33.2.6 Tincture of Opium

To first pilot project of Tincture of Opium – an oral water/alcohol extract of opium containing 1 % morphine – for treatment of opium dependence was conducted in INCAS clinic in 2006 (Mokri et al. 2007). Twenty-two opium-using clients with history of an average daily opium use of 4.33 g stabilized on an average dose of 31.6 ml Tincture of Opium and followed for 6 months. Six-month retention rate was 71 % for all sample and 87 % excluding first-week dropouts. Improvement in familial and social scales but to a lesser extent was also noticed. Further studies showed safety and efficacy of Tincture of Opium as compared to methadone and effectiveness of it in two treatment models including maintenance treatment and gradual dose reduction combined with self-help programs including peer counseling and recreational activities initiated by Congress 60, an NGO for opium abusers. Since 2011, Tincture of Opium is also available for "agonist units" with at least 2 years of experiences with methadone and or buprenorphine and without history of violation of regulations. The half-life of the medication is about 8 h, and clients need to receive it in two divided dose, so agonist units were allowed to dispense afternoon take-home doses from the beginning of the treatment. The maintenance model of the program has not been accepted largely because there is no take-home dose for that and clients have to come to clinic for all of their morning doses. The program works best where the medication dispensed through clinic and peer counseling, and recreational activities developed by NGO for opium abuser, namely, Congress 60, are available.

Opioid Agonist Diversion in Opioid-Dependence Treatment

34

Hannu Alho

Contents

Abstract

Diversion is defined in this publication as unauthorized rerouting or use of a substance, and abuse is defined as any use of a prescription drug that deviates from medical practice. This refers to the manner in which medication is used such as snorting, injecting, taking excessive quantities, or combining it with other substances for intoxicative purposes.

Diversion and abuse of pharmacotherapy used in opioid-dependence treatment can have a serious negative impact on public health at the individual and societal level. Diversion can lower the credits of treatment services through increased morbidity and mortality and economic burden through lost productivity and unemployment. Diversion is a global problem, but most studies and concerns arise from the USA, Australia, and Northern Europe. While existing

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment: International Perspectives*, DOI 10.1007/978-88-470-5322-9_26,

evidence confirms the occurrence of this issue, standardized indicators are missing and the phenomenon is not uniformly appreciated by prescribers and policy makers.

Most publications of diversion and abuse report the mortality rates associated with the diversion and abuse of methadone and prescription opioid analgesics. The reports of fewer buprenorphine-related deaths compared with deaths associated with methadone can be attributed to buprenorphine's pharmacology and ceiling effect on respiratory depression. However, deaths due to asphyxia as well as following acute poisoning with severe respiratory depression have recently been attributed to buprenorphine in opioid abusers. The abuse prevalence and injection of buprenorphine tablets are reported in worldwide publications addressing the harms associated with it. Several studies indicate that inability to enter opioid maintenance or substitution treatment could be a significant contributor to diversion. In addition, studies are challenging the often-held view that regulation and restricted access are necessary to ensure the safety of individuals using opioid agonists' medications.

To lower the diversion and develop strategies to avoid abuse, it is important therefore to examine and understand the reasons of it. One of the most important strategies to avoid diversion is good quality of the treatment and treatment outcomes. Some pharmacotherapies may have lover diversion potentiality, but the key factor is patient confidentiality and good quality of treatment.

34.1 Introduction

Opioid dependence is widely recognized to be a chronic relapsing condition (Goldstein and Herrera 1995; Fiellin and O'Connor 2002; O'Brien 1996; Cami and Farre 2003) that requires long-term treatment to achieve positive clinical outcomes. Untreated opioid dependence harms the individual and society through increased mortality (Kimber et al. 2010; World Drug Report 2012), increased risk of blood-borne virus (BBV) transmission associated with injection drug use (Kimber et al. 2010; Altice et al. 2011), poor social functioning (De Maeyer et al. 2010), loss of economic productivity (Hansen et al. 2011), and criminal justice expenditure (Hansen et al. 2011).

Most common substances (though not exclusively) related to diversion and abuse of opioid pharmacotherapies and opioid-based formulations in the treatment of opioid dependence are methadone, Polamidone (trade name of R-methadone), buprenorphine, buprenorphine/naloxone, codeine, slow-release oral methadone, and slow-release oral morphine. However, significant diversion/abuse related to other divertible prescription medications including benzodiazepines and opioid-based painkillers is not included in this paper.

Definition for diversion can be defined as the unauthorized rerouting or appropriation of a substance (Merriam–Webster's Dictionary of Law 1996). Abuse is defined as any use of a prescription drug that deviates from medical practice. This refers to the manner in which medication is ingested such as snorting,

injecting, taking excessive quantities, or combining it with other substances for intoxicative purposes (American Psychiatric Association 2004).

34.2 Features of Diversion

34.2.1 Consequences of Diversion

Though strong evidence indicates that diversion and abuse is occurring, a global understanding of the consequences is missing or the issue is varied. The impact of consequences on public health can be used to raise awareness of this issue, identify regional epidemiological trends across globe, and drive management strategies in opiate maintenance area. The most well-known consequences include:

- Increased patient morbidity and mortality (Centers for Disease Control and Prevention 2010) through an increased risk of:
  - Overdose/fatal respiratory depression (Laberke and Bartsch 2010; Perret et al. 2000)
  - Nonfatal overdose and related emergency admissions (Centers for Disease Control and Prevention 2010)
  - Contracting blood-borne viruses such as HIV and hepatitis C (HCV) (Center for Disease Control and Prevention 2011; Berson et al. 2001)
  - Complications associated with injection drug use including limb ischemia, tissue necrosis, and endocarditis (Ho et al. 2009a)
- A negative impact on prescribers' practice (Noroozi and Mianji 2008)
- Threatened reputation of treatment services and compromised public acceptance of long-term treatment of opioid-dependent individuals (Noroozi and Mianji 2008).

34.2.2 Indicators of Diversion

In the absence of standardized indicators of diversion and abuse of opioid pharmacotherapy, the following impact measures should be considered:

- Mortality associated with abuse and diversion
- Incidence of injection complications (site reactions, amputations)
- Contribution of injecting drug use to HIV transmission
- Contribution of injecting drug use to HCV transmission
- Role of methadone and buprenorphine injection in hepatic complications
- Patterns of abuse (including injection drug use) in relation to drug availability

34.2.3 Strategies to Limit Diversion

A 2010 survey of European physicians found that despite acknowledging that diversion and abuse was their responsibility, it was the most difficult area of

opioid-dependence treatment to manage (Bacha et al. 2010). To limit the diversion of pharmacotherapy used in opioid-dependence treatment, several countries have implemented regulations stipulating administration of doses under direct supervision in specialized clinics or pharmacies. However, such policies may restrict access to treatment, which in turn may fuel the demand for diverted opioid pharmacotherapy and increase the harms and financial burden of untreated opioid dependence (Bell 2010). While the use of abuse-deterrent formulations including volume-expanded methadone and buprenorphine-naloxone has been introduced to reduce diversion and abuse while maintaining treatment access, large-scale studies are needed to confirm its efficacy for this purpose.

34.2.4 "A Better Approach", Defining Treatment Outcomes in Opioid Dependence (OD)

Mitigation of diversion and abuse of opioid pharmacotherapy by the treatment community is of key importance, as it can pose significant risks to patients, physicians, and the availability of treatment in the future. However, treatment outcomes may play a key factor in management of diversion (Subata et al. 2013). There are currently two major limitations in the way outcomes data for opioid-dependence treatments are collected. Firstly, there is no standardized set of outcomes measures, so the quality of outcomes measurement will vary by country, region, and on an individual center basis. Secondly, this lack of outcomes standards means that collecting comparative information to compare outcomes between countries is difficult. These difficulties are highlighted by the situation in Europe. The European Monitoring Centre for Drugs and Drug Addiction (EMCDDA) currently collates and reports data collected by individual countries; however, the variability in the outcomes measured and irregularity in country reporting can create issues.

In order to identify appropriate outcomes measure, it is important to look at various aspects of the treatment including the patient population, treatment goals, and setting. One single metric cannot quantify the range of outcomes of opioid-dependence treatment. Instead, a set of metrics are needed to capture mortality in treatment, individual and societal benefits, as well as harm-related outcomes. In addition, because opioid-dependent populations are highly variable in terms of their clinical presentation and their personal goals for therapy, there needs to be some flexibility in scoring success. Therefore, population or system-wide outcomes measurement in OD management should be based on a scorecard of a number of metrics.

Increasing access to OD treatments calls for better understanding of the impact of treatment outcomes to diversion. A range of measures describe effectiveness and long-term safety of buprenorphine and methadone in opioid-dependence management; however, there is a need for a universal or at least European system, to allow comparison at the "above-individual-patient" level.

34.2.5 Patterns and Prevalence of Diversion

Despite evidence demonstrating that abuse and diversion does happen, there is increasing consensus that considers diversion to be noncompliance and a sign of suboptimal treatment. The majority of studies related to diversion relate to patterns and rates of injection drug use and injection drug use-associated mortality. Methadone has been the most researched opioid pharmacotherapy for both lead impact measures, followed by buprenorphine, hydrocodone, and oxycodone. However, despite association with potential hepatic complications in clinical studies, few studies can be identified suggesting a role for methadone or buprenorphine in hepatic complications. The majority of diversion studies per product derived from the USA, followed by Australia. Data from the USA largely focused on the diversion and abuse of prescription opioid analgesics, in addition to opioid-dependence pharmacotherapy. In regions demonstrating a paucity of research/publications such as southern Europe, Asia (excluding Singapore), and Pacific countries, those identified focused on the diversion and abuse of methadone and buprenorphine. Reports from South Asia indicate that prescribing for pain is inadequate. There is a paucity of data across South Asia regarding the extent of diversion and abuse, although the problem is widely acknowledged. There is also a significant lack of treatment facilities across the region, as well as HIV awareness and needle-syringe programs (Larance et al. 2011).

In general, studies have shown that around 70 % of those injecting medication are self-treating, either due to inability to access treatment or suboptimal therapeutic dosing (Alho et al. 2007; Courty 2009). A post marketing surveillance study (2003–2007) from the USA indicated that there were steady increases in the rates of abuse, misuse, and diversion of both methadone and buprenorphine. Rate ratios (per 100,000 population quarter) of abuse, misuse, and diversion were consistently higher for methadone than buprenorphine (Dasgupta et al. 2010). A global literature review (Degenhardt et al. 2011) on mortality among dependent or regular opioid users across regions, according to specific causes, and related to a number of demographic and clinical variables demonstrated that overdose was the most common cause of death, with a crude overdose mortality rate 1.71 times higher in men than women. Out-of-treatment periods had 2.38 times higher mortality risk than in-treatment periods ($p < 0.0005$). Higher prevalence of opioid injection was associated with higher mortality rates. Retrospective data analysis (Laberke and Bartsch 2010) of methadone-associated deaths in Zurich, Switzerland, showed that most of the detected deaths occurred during illicit intake of methadone and high percentage of cases involved polydrug intoxication (76 %). An epidemiological review from the USA indicates that deaths from unintentional drug overdoses in the USA have risen steeply since the early 1990s and are the second leading cause of accidental death, with 27,658 such deaths recorded in 2007. The increase has been propelled by a rising number of overdoses of opioids, which caused more deaths than heroin and cocaine combined in 2007 alone (Okie 2010).

In Europe, diversion is a common problem, and a 2010 European survey of 300 physicians who treat opioid dependence found that diversion was a significant problem for 72 % of respondents (Bacha et al. 2010). Indeed, a wealth of data demonstrates that many opioid pharmacotherapies, particularly those used in the treatment of opioid dependence, are diverted and abused. For instance, in 2006, up to 25 % of French buprenorphine doses were diverted onto the black market (International Narcotics Control Board 2011); in Finland, over 70 % of the street drug users (IDUs), the primary drug was buprenorphine (Simojoki and Alho 2008); in Germany, 80–85 % of injecting drug users reported finding it easy to access methadone and buprenorphine on the black market (Simojoki and Alho 2008); and in Austria, according to a 2010 publication, diverted slow-release oral morphine was dominating the Austrian black market (Wickert et al. 2009).

A prospective cross-sectional study (Beer et al. 2010) from Australia demonstrates that on currently injecting drug users (IDUs), more than 10 % of participants reported buprenorphine as the drug they had most often injected, and 32 % had injected buprenorphine at least once in the 3 months before the interview. Frequency of sharing a used needle was also associated with buprenorphine injection, but HCV exposure was not (Beer et al. 2010; Aitken et al. 2008). In Australia, opioid diversion to the black market occurs in proportion to the amount of nonsupervised consumption, and inversely to heroin availability. Adverse consequences of diversion include opioid overdose fatalities, increased incidence of addiction (particularly in jurisdictions where heroin is scarce), and compromised public acceptance of long-term opioid prescribing (Bell 2010). Retrospective data analysis from Singapore with patients presenting with medical complications of buprenorphine abuse showed that since the introduction of buprenorphine for opioid-dependence treatment in 2002, there was a significant increase in IV abuse that led to life-threatening medical complications including infective endocarditis and cardiac failure. This study identified pulmonary hypertension as a potential comorbidity among IV buprenorphine users (Jenkinson et al. 2005; Chong et al. 2009). Nearly half of patients died as a result of their complications (Jenkinson et al. 2005).

To address the increased incidence of buprenorphine diversion and abuse, buprenorphine was combined with naloxone in sublingual tablet formulation (buprenorphine-naloxone combination). Injection of the combined product was planned to cause withdrawal symptoms and thus acting as a deterrent to abuse. Data is controversial, research from Australia indicates that patients receiving medication-assisted therapy (MAT) buprenorphine-naloxone combination product were injected less frequently than buprenorphine, especially when corrected for medication availability; injection of buprenorphine was more likely in those injecting other prescription opioids (Ho et al. 2009b). Data from Canada shows that among treatment-seeking opioid-dependent individuals characterized with buprenorphine-naloxone diversion practices, 100 % had diverted buprenorphine-naloxone to modulate opiate withdrawal symptoms arising from attempted "self-detoxification," with insufficient funds to purchase preferred illicit opioids, or inability to find a preferred source of drugs. A small study in Italy (Degenhardt et al. 2009)

evaluating the use of buprenorphine-naloxone for treatment of opioid-dependent patients after therapeutic switch from buprenorphine alone showed that only 2 % of patients attempted the intravenous abuse of the combined product, none of whom experienced any gratifying effects. A recent long-term follow-up study from Finland indicates that the street value of buprenorphine-naloxone product is 30–40 % less than the corresponding amount of mono-buprenorphine (Montesano et al. 2010).

34.2.6 Discussion

Diversion and abuse poses a significant risk to opioid-dependent individuals including increased overdose mortality, risk of blood-borne viral transmission, and medical complications associated with intravenous drug use. Diversion has very likely a negative impact on society through influence on prescribers, compromised integrity of treatment services, and a potential increase in societal aversion to the treatment of opioid dependence. While these well-known consequences often describe diversion and abuse, there is increasing consensus that diversion can be a sign of noncompliance and a sign of suboptimal treatment. A paucity of qualitative information and assessment of standardized indicators of diversion and abuse was noted. This may be due to the illicit nature of practices associated with this issue, making quantitative or qualitative data gathering difficult. In addition, geographical distribution of the publications per impact area and per product was uneven, with the majority originating from the USA and Australia. Research into diversion and abuse of prescription opioids has been based mainly in Central and Northern Europe, although an uneven geographical distribution within these regions was also identified.

Legal and regulatory measures to counter diversion and abuse by restricting availability of opioid pharmacotherapy can often serve to decrease treatment access. This can put opioid-dependent individuals at risk of further harm because drug users often buy diverted pharmacotherapies in an effort to self-treat their condition. However, treatment outcomes may play a key factor in management of diversion.

An alternative strategy is the use of opioid pharmacotherapy formulated to deter abuse. However, the impact of abuse-deterrent formulations on the extent of diversion and abuse is not fully clear. The overall number of prevalence of diversion and abuse of buprenorphine was greater than those relating to methadone diversion. Reported prevalence of buprenorphine diversion was higher (15.3–73 %) compared with methadone diversion (4.3–55 %). In addition, the lifetime prevalence of buprenorphine diversion and abuse was higher than that for methadone. This supports previous observations that buprenorphine is abused in many countries and may be more widely diverted than methadone.

Comparison of the numbers of publications relating to this issue in the USA, Australia, and all European regions suggests buprenorphine is more significant issue in European markets. The majority of publications identified are based on

studies which were conducted in the USA and Australia. This could be due to that in the USA, the Drug Abuse Warning Network (DAWN) (Drug Abuse Warning Network 2011) monitors drug-related visits to hospital emergency departments and drug-related deaths investigated by medical examiners and coroners. Emergency department data is published biannually. Mortality data is published annually, and additional analyses are available during the year. DAWN collects detailed drug data including that for illicit substances, prescription medication, and over-the-counter remedies. The Australian Illicit Drug Reporting System (2009) and the Ecstasy and Related Drugs Reporting System have operated in all jurisdictions since 2000 and publish annual reports of trends associated with illicit drug use (including heroin, amphetamines, cocaine, and cannabis). Trends are extrapolated from three data sources: interviews with injecting drug users, interviews with key experts who regularly encounter illicit drug users, and existing indicator data sources relating to illicit drug use.

Large proportion of publications per impact area is related to methadone-associated mortality (Perret et al. 2000). Evidence shows that methadone diversion is associated with a high risk of mortality due (Reynaud et al. 1998) to its full opioid agonist profile, effect on respiratory depression, and multiple drug interactions leading to increased plasma levels of methadone and toxicity. In addition, a long elimination half-life (24–36 h) may increase the risk of fatal overdose due to excessive intake and dose accumulation in the body. The high mortality risk attributed to methadone is supported by the high numbers of emergency calls for overdose or accidental exposure of children to methadone and the numbers of deaths in which methadone has been implicated, either alone or in combination with other substances (Rainey 1986; Gibson and Degenhardt 2007). It has been thought that the increase in methadone mortality may result from inappropriate prescribing to patients who have risk factors or indicators for abuse and increasing use of methadone as a low-cost analgesic by inexperienced prescribers. Even when buprenorphine may be more widely diverted than methadone (Ho et al. 2009b; Reynaud et al. 1998), buprenorphine-based treatment seems to be associated with fewer fatalities than methadone (Rainey 1986; Kim et al. 2012; Winstock et al. 2008).

However, there is clear and increasing evidence of harm associated with the diversion of prescription opioid analgesia. This phenomenon appears to be somewhat specific to the USA as the greatest number of publications relating to oxycodone, and hydrocodone in particular, originate from this region and are second only to methadone. In addition, the prevalence of prescription opioid analgesic abuse reported by publications from this region ranged from 72 % to 75 % (Gibson and Degenhardt 2007). In accordance with the trends in prescription opioid mortality, data shows an increasing prevalence of opioid analgesic abuse in rural and urbanized regions in the USA (Gibson and Degenhardt 2007).

Although buprenorphine maintenance therapy is associated with significant benefits including decreased HIV risk behavior and lower risk of fatal overdose (Rainey 1986) compared with methadone (Kim et al. 2012), injection of buprenorphine is associated with potentially fatal harms, as cutaneous

complications (Ho et al. 2009a), infective endocarditis (Jenkinson et al. 2005), and by mixing buprenorphine with other drugs including alcohol and benzodiazepines can be dangerous and may lead to fatal overdose (Bell et al. 2009). The injection of the combined buprenorphine-naloxone product was designed to cause precipitated withdrawal in opioid-dependent individuals, thereby acting as a deterrent to abuse. Although data suggest that injection rates of buprenorphine-naloxone are significantly lower than rates of mono-buprenorphine injection (Ho et al. 2009b), and the street value of the combination product is significantly less than corresponding mono-product (Montesano et al. 2010), further epidemiological studies are needed to determine whether the combination product is effective in deterring diversion and abuse. Buprenorphine has been considered being less fatal in overdosing because of its ceiling effect; however, recent studies show that buprenorphine's metabolite, norbuprenorphine, is assessed as being a potent respiratory depressor in rodents. Recently, norbuprenorphine, in contrast to buprenorphine, was shown in mice and in vitro to be a substrate of human P-glycoprotein, a drug-transporter involved in all steps of pharmacokinetics including transport at the blood-brain barrier (Havens et al. 2007). Even a major role for drug-drug interactions that can lead to P-glycoprotein inhibition in buprenorphine-associated fatalities and respiratory depression, there is no proof that buprenorphine can cause fatal poisoning except on children (Alhaddad and Cisternino 2013).

34.2.7 Key Messages

- Diversion and abuse of opioid-dependence pharmacotherapy is a significant worldwide public health issue.
- Adverse consequences include overdose fatalities, increased incidence of dependence, and compromised public acceptance of long-term opioid prescribing.
- Monitoring is essential to assessing prevalence and practices associated with diversion and abuse in order to direct national strategies aimed at neutralizing the problem.
- Treatment outcomes and good quality of treatment are key factors preventing diversion.
- Treatment restrictions policies may restrict access to treatment, which in turn may fuel the demand for diverted opioid.
- While additional large-scale epidemiological studies are required to confirm efficacy in reducing diversion and abuse, existing data is promising.
- The main observations on diversion of pharmacotherapies used for treatment of opiate dependence include:
  - Methadone abuse is widespread and is injected and diverted for recreational use.
  - Diverted methadone contributes significantly to the methadone-related death toll.
  - Diversion of slow-release oral morphine has begun dominating the Austrian black market.

- Buprenorphine alone is widely abused in many countries.
- Buprenorphine may be more widely diverted than methadone.
- Buprenorphine-based treatment is associated with fewer fatalities than methadone.
- Buprenorphine is associated with a lower risk of mortality compared with full agonist opioid treatments like methadone and morphine and may less unlikely to cause fatal overdose when ingested by opioid-naive individuals.
- Mixing buprenorphine with other drugs including alcohol and benzodiazepines can be dangerous and may lead to fatal overdose.
- Combination buprenorphine/naloxone product may have a lower abuse potential than other opioid pharmacotherapies.
- There is no research yet on the diversion of film or long release formula of buprenorphine.

Contents

Abstract

Hallucinogenic drugs have as their primary effect the production of disturbances of perception. Hallucinogens can be classified according their chemical structure as: indoleamines (similar to serotonin), phenethylamines (similar to catecholamines), dissociatives (phencyclidines) and others (including salvinorin, dextromethorphan, muscarinic antagonists and cannabinoids). The hallucinogenic effects appear to be related to the agonistic action on 5-HT2A receptors in the cortex. Ketanserin, a 5-HT2 antagonist, blocks some of the specific effects of LSD and other hallucinogens. It also activates the dopaminergic receptors and

causes a glutamatergic activation. All these actions seem to cause a functional imbalance at various levels (cortical areas, the limbic system, which is a group of brain structures involved in emotional regulation), contributing to distortion of the integrative action. The novel psychoactive substances (NPS) can induce substance use disorder, intoxication and in some cases withdrawal syndrome (for those with psychostimulant properties). Depending on the substance and pharmacological effects, the DSM-V diagnostic criteria for hallucinogens or stimulants can be applied (American Psychiatric Association 2013).

The therapeutic aim in these cases is to reduce consumption and achieve abstinence. In some cases of NPS cessation can be easy because there is no physical dependence; in other cases (with more of a psychostimulant profile) some symptoms of withdrawal syndrome can be observed. There are no specific drugs for treating the disorders caused by these substances.

35.1 Introduction

This chapter is a review of the different families of hallucinogenic, dissociative and novel psychoactive substances. It provides a brief historical introduction, the origins, chemistry and mechanism of action, the pharmacological and adverse effects, and the relevant psychiatric clinical aspects.

35.2 Hallucinogens, Dissociatives and New Psychoactive Substances

35.2.1 Classical Hallucinogens

Hallucinogenic drugs have as their primary effect the production of disturbances of perception, thought, or mood at low doses, with minimal effects on memory and orientation. A hallucination is defined as a sensory perception without objective reality. An illusion is a perceptual distortion of an actual stimulus in the environment; it is a distortion of what is perceived. Hallucinations can develop in any sensory modality, but are most commonly visual or auditory in nature.

Subjects with hallucinations induced by acute consumption of a hallucinogenic are aware that the experience is caused by the substance, and are able to maintain a sense of reality. There are a variety of widely accepted synonyms for the hallucinogens, including the term psychedelic, and psychotomimetic.

Hallucinogens include a diverse group of substances with different chemical structures. Hallucinogens can be classified (Table 35.1) according their chemical structure as: indoleamines (similar to serotonin), phenethylamines (similar to catecholamines), dissociatives (phencyclidines) and others (including salvinorin, dextromethorphan, muscarinic antagonists and cannabinoids). Hallucinogens can be found naturally in some plants, animals, and can be synthesised in the laboratory. Some hallucinogenic drugs are included in the category of designer drugs, legal highs and new psychoactive substances (Camí and Farré 2003).

Table 35.1 Classification of hallucinogens

Indole amides	**LSD derivatives**	Lysergic acid amides: ergine, isoergine
		Lysergic acid diethylamide (LSD-25 or lysergide)
	Substituted tryptamines	Psilocybin
		Psilocin
		O-Acetylpsilocin (4-acetoxy-DMT)
		Diethyltryptamine (DET)
		Bufotenine (cebilcin, 5-OH-DMT) Dimethyltryptamine (DMT)
		5-bromo-*N*,*N*-dimethyltryptamine (5-Bromo-DMT)
		5-methoxy-*N*,*N*-dimethyltryptamine (5-methoxy-DMT)
		5-methoxy-dimethyltryptamine (5-MeO-DMT)
		Ibogaine
		Ayahuasca (contain DMT)
Phenethylamines	**Methoxyamphetamines "hallucinogenic amphetamines"**	Mescaline (3,4,5-trimethoxyphenethylamine)
		4-bromo-2,5-dimethoxyamphetamine (DOB)
		4-methyl-2,5-dimethoxyamphetamine (DOM, serenity-tranquillity-peace or STP)
		2,4,5-trimethoxyamphetamine (TMA-2)
		Paramethoxyamphetamine (PMA)
		4-bromo-2,5-dimethoxyphenylamphetamine (2CB-MFT)
		2,5-dimethoxy-4-bromo-phenethylamine (2-CB, nexus)
		2,5-dimethoxy-4-iodophenethylamine (2-C-I)
		2,5-dimethoxy-4-ethylthiophenethylamine (2C-T-2)
		2,5-dimethoxy-4-(n)-propylthiophenethylamine (2C-T-7)
		8-bromo-2,3,6,7-benzo-dihydrodifuran-ethylamine (2-CB-Fly)
		Bromo-benzodifuranyl-isopropylamine (bromo-dragonfly)

(*continued*)

Table 35.1 (continued)

	Methylenedioxyamphetamines "entactogen amphetamines"	3,4-methylenedioxymethamphetamine (MDMA, "ecstasy", "Adam")
		3,4-methylenedioxyamphetamine (MDA, "love pill"),
		3,4-methylenedioxyethylamphetamine (MDEA or MDE, "Eve")
		N-methyl-1-(3,4-methylenedioxyphenyl)-2 butamine (MBDB)
		3,4-methylenedioxymethcathinone (methylone, "explosion")
		3,4-methylenedioxyethylcathinone (ethylone)
		β-keto-*N*-methylbenzodioxolylpropylamine (bk-MBDB, butylone)
Dissociatives (Phencyclidines)	Phencyclidine (PCP)	
	Ketamine	
	Methoxetamine	
	3-methoxy-phencyclidine (3-MeO-PCP)	
Others	Opioid derivatives	Dextromethorphan
	Anticholinergics	Atropine, scopolamine, trihexyphenidyl
	Salvinorin A	
	Thujone	
	Muscimol and ibotenic acid	
	Cannabinoids (natural and synthetics)	

35.2.1.1 Origin and Synthesis

Hallucinogens are as old as civilisation. Many cultures recorded eating certain plants specifically to induce visions or to alter the perception of reality. Often these hallucinations were part of a religious or initiation experience. In this context they are referred to as entheogens. Shamans in Siberia were known to eat the hallucinogenic mushroom *Amanita muscaria*. The ancient Greeks also used naturally occurring plant hallucinogens. Peyote, a cactus found in the southwestern United States and Mexico was used by native peoples, including the Aztecs, to produce visions.

The modern synthetic drug era began in the late 1930s with the synthesis of lysergic acid diethylamide (LSD) by the Swiss chemist, Albert Hoffman. While working at Sandoz Laboratories, Hoffman synthesised LSD as part of an effort to develop ergot derivatives capable of reducing post-partum bleeding. Some years later, after accidentally absorbing a small amount, he experienced its psychoactive effects while bicycling home. After World War II there was an explosion of interest in hallucinogenic drugs in psychiatry, either in their potential for psychotherapeutic applications or in their use in producing a "controlled psychosis", in order to understand psychotic disorders. It was marketed by Sandoz laboratories under the trade name Delysid® as a potential tool for psychotherapy in the 1950s. The growing

popularity of LSD in the 1960s associated with the hippie movement resulted in its ban in the United States in 1967. In recent years, there has been new interest in the investigation of the therapeutic use of hallucinogens (Hill and Thomas 2011).

35.2.1.2 Epidemiology and Pattern of Consumption

Hallucinogen use has declined since the 1970s, with the annual prevalence remaining below 10 % (Johnston et al. 2008). The types of hallucinogens used have also changed. LSD, which was the most widely used hallucinogen, has been surpassed by psilocybin and newer synthetic drugs. Today, the majority of LSD is synthetic. However, it can be derived from two naturally occurring substances, morning glory seeds (*Rivea corymbosa*) and *Claviceps purpurea* (a parasitic fungus), which contains some alkaloids, called ergot, as ergine and ergonovine. Synthetic LSD is crystalline. It is a white, odourless, tasteless powder that is dissolved and administered orally, sublingually, intramuscularly or intravenously. Sublingual formulations include postage stamps, chewing gum or sugar cubes, often decorated with new age symbols. Other hallucinogens are usually taken orally (mescaline, psilocybin, ayahuasca), smoked (DMT, salvia) or snorted (DMT).

European data show that among young adults (aged 15–24 years), the prevalence of LSD use at some point of life in Europe ranges from 0 % to 5.2 %, and is more common in the Czech Republic and Scotland, with prevalence of use in the past 12 months of 2.2 %. The prevalence of drug use in the past month was 1.2 %. The overall prevalence levels of hallucinogenic mushroom use in Europe have been generally low and stable for a number of years. Among young adults (aged 15–34), national surveys report last-year prevalence estimates for the use of hallucinogenic mushrooms to range from 0 % to 2.2 % (European Monitoring Centre for Drugs and Drug Addiction 2013b).

The lifetime prevalence of LSD use in the United States in students in the 12th grade is between 3.8 % and 4 % in the past 3 years (Johnston et al. 2013a). The trend in annual prevalence in young adults (30 years) is lower, between 0.2 % and 0.9 % in the last 3 years (Johnston et al. 2013b).

In the United States, of all substance use disorders, other hallucinogen use disorder (excluding dissociatives) is one of the rarest. The 12-month prevalence is estimated to be 0.5 % among 12- to 17-year-olds and 0.1 % among adults aged 18 and older in the United States. Rates are higher in individuals younger than 30 years, with the peak occurring in individuals aged 18–29 years (0.6 %) and decreasing to virtually 0.0 % among individuals aged 45 and older (Johnston et al. 2013a). A higher trend in lifetime prevalence of other hallucinogens in young adults (12.6–11.1 % over the past 3 years) (Johnston et al. 2013b).

Past-year prevalence is higher in clinical samples (19 % in adolescents in treatment). Among individuals currently using hallucinogens in the general population, 7.8 % (adult) to 17 % (adolescent) had a problematic pattern of use that met criteria for past-year other hallucinogen use disorder.

Among select groups of individuals who use hallucinogens (e.g. recent heavy ecstasy use), 73.5 % of adults and 77 % of adolescents have a problematic pattern of use that may meet other hallucinogen use disorder criteria. There are no prevalence

estimates of hallucinogen persisting perception disorder. Initial prevalence estimates of the disorder among individuals who use hallucinogens are approximately 4.2 % (American Psychiatric Association 2013).

35.2.1.3 Mechanism of Action

The reported similarity of psychic experiences elicited by the phenethylamines and the indolealkylamines, as well as cross-tolerance between the two classes (Winter 1971), suggested a shared mechanism of action. With advances in molecular biology, 14 distinct serotonergic receptors comprising seven families (serotonin-1–7) were discovered. Determining which receptors mediate the psychoactive effects, however, presented a challenge (Barnes and Sharp 1999). LSD is an extremely potent substance; active doses are between 0.5 and 2 μg/kg (100–150 μg per dose). Its activity is predominantly on serotonin (5-HT), but also on dopamine receptors. LSD, like other classical hallucinogens, is a partial agonist at serotonin 5-HT2 receptors, and also at the 5-HT1A/1C receptors, both presynaptic and postsynaptic. There is a good correlation between the relative affinity of these compounds for 5-HT2 receptors and their potency as hallucinogens in humans (Abanades et al. 2004; Sharp et al. 2007).

The hallucinogenic effects appear to be related to the agonistic action on 5-HT2A receptors in the cortex. Ketanserin, a 5-HT2 antagonist, blocks some of the specific effects of LSD and other hallucinogens. It also activates the dopaminergic receptors and causes a glutamatergic activation. All these actions seem to cause a functional imbalance at various levels (cortical areas, limbic system, which is a group of brain structures involved in emotional regulation); contributing to distortion of the integrative action. At a peripheral level ketanserin acts as a serotonergic antagonist and also in the dopaminergic system (D1 and D2 at least), and in the alpha adrenergic system. Most classical hallucinogens share the actions of LSD, but dissociative anaesthetics and dextromethorphan are NMDA receptor antagonists (*N*-methyl-D-aspartate or NMDA) (Vollenweider and Kometer 2010; O'Brian 2011; Sanders-Bush and Hazelwood 2011) and salvinorin A is a potent kappa-opioid receptor agonist. Some anticholinergic derivatives (*Amanita muscaria* mushroom, plants containing atropine derivatives) at high doses can induce intoxication with hallucinations owing to their action as antagonists of the muscarinic receptor in the CNS.

35.2.1.4 Acute Effects

Lysergic acid diethylamide(LSD) is well absorbed by the gastrointestinal tract. It is rapidly metabolised and only 1 % of the dose is excreted in urine without being biotransformed. It undergoes hydroxylation (with the addition of a group OH) and conjugation with glucuronic acid in the liver. Its half-life is about 3 h (range 2–5 h), but its effects last longer. The most sensitive analytical methods for detecting the use of LSD through the urine can be used up to 24 h after its consumption (Passie et al. 2008; Jones 2009).

Psychoactive effects peak at 2–4 h and can last for up to 12 h depending on the dose, tolerance, body weight and age. Users of LSD typically experience autonomic symptoms within a few minutes and psychoactive effects approximately 10 min later. The autonomic symptoms are mainly sympathomimetic, such as elevated

blood pressure and pulse, diaphoresis, piloerection, nausea, hyperreflexia and tremor. Anisocoria (unequal pupils) and hippus (rhythmically dilating pupils) are not uncommon (Schiff 2006).

Sensory effects generally appear 1 h after administration. Initially, there are fluctuations or changes in brightness or illumination, shapes are distorted, the colours are more intense and bright and constantly vary in pitch and intensity (Passie et al. 2008; Jones 2009; Sanders-Bush and Hazelwood 2011; O'Brian 2011). Auditory distortions are less common. At higher doses, synaesthesia may occur (perceiving a sensation in a different modality such as hearing colours). Distortions regarding the perception of time include time halting, stretching, repeating and ceasing to exist. The sense of self can change dramatically, even to depersonalisation. It feels as if the mind has left the body and as if there were a union of the self with the Universe. There are frequent religious, philosophical or mystical experiences. Psychological symptoms include multiple mood alterations, ranging from happy to sad. When the overall experience is perceived as enlightening or emotionally stimulating, it is referred to as a "good trip". Other times, the experience might be nightmarish, with fears of insanity or losing control, and anxiety. Such negative experiences are referred to as "bad trips". The cause of good trips versus bad trips is not known. The psychic experience generally lasts 8–12 h and is often followed by a pleasant "psychic numbness".

35.2.1.5 Clinical and Diagnostic Aspects

Tolerance to the psychological effects of lysergic acid diethylamide, but not the physiological effects, develops quickly (Blaho et al. 1997). In contrast to highly addictive drugs, such as cocaine and heroin, they do not produce physical dependence or withdrawal syndrome upon cessation of consumption. There is a clear and accurate memory of what happened during the hallucinogenic experience.

Intoxication

Patients come to have symptoms of sympathetic activation, perceptual changes and psychiatric symptoms (agitation, anxiety, panic, psychosis). There are also frequent "bad trips" that present with psychiatric symptoms (anxiety or significant panic reaction). Intoxications are occasionally accompanied by delirium (a separate diagnostic category). The elimination of the substance gradually improves the symptoms. There are no documented fatalities from LSD use, but fatal accidents and suicides have occurred during intoxication.

Hallucinogen Persisting Perception Disorder

Flashbacks are referred to as hallucinogen persisting perception disorder by the DSM-V when they cause significant distress. They are defined as "the transient recurrence of disturbances in perception that are reminiscent of those experienced during one or more earlier Hallucinogen Intoxications" (American Psychiatric Association 2013).

The most common phenomena are visual distortions, such as colour confusion, geometric hallucinations and trailing, but the content of the flashback may involve

any of the senses. It is not known what causes flashbacks. Theories include persisting damage to visual processing systems, dysfunction of inhibitory cortical interneurons, reverse tolerance, and that they comprise an atypical dissociative state (Garratt et al. 1993). Flashbacks may occur several days to several years after the antecedent use of lysergic acid diethylamide and have been reported with mescaline, phencyclidine and marijuana. Some users find these episodes pleasant and even refer to them as "free trips". For others they can be terrifying and recur frequently (hallucinogen persisting perception disorder). An antecedent good trip does not predict a good flashback. It is unclear what determines who will experience flashbacks and whether or not the experience will be pleasant (McGee 1984).

Flashbacks have reportedly been induced by a myriad of situations, including stress, exercise, pregnancy, sexual intercourse, dark environments, flashing lights, monotony, and use of other psychoactive drugs. It is estimated that anywhere from 15 % to 60 % of LSD users experience flashbacks. The flashback experience is often precipitated by psychiatric illness, as with the use of other drugs (Lerner et al. 2002). It is possible that the success of the medications listed above is related to the treatment of concurrent illness. Regardless of treatment, the frequency of flashbacks tends to decrease with time.

Persistent Psychosis Related to Mental Illness

Occasionally, LSD appears to precipitate a "persistent psychosis", characterised by visual hallucinations, mania, grandiosity, and religiosity. It is estimated to occur in 0.08–4.6 % of people who have used lysergic acid diethylamide (Meyerhoefer 2011).

Chronic effects include descriptions of permanent schizoid disorders, and subsequent or prior ingestion associated with LSD. Although the association between the occurrence of permanent psychosis and LSD is well established in various publications, it is not known precisely what the actual risk is. It seems that LSD would not be the direct cause of the development of permanent disorders, but LSD intake would act as a trigger of a pre-existing disease state (Passie et al. 2008; Jones 2009; O'Brian 2011; Sanders-Bush and Hazelwood 2011; Krebs and Johansen 2013).

Affective Disorders

While feelings of being overwhelmed, scared and afraid of losing control occur in a panic attack, lysergic acid diethylamide intoxication is further characterised by dramatic and persistent perceptual distortions. As with any altered mental state, the clinician should have a low threshold for suspecting delirium. Unlike delirium, there is no fluctuation level of consciousness with LSD intoxication. There is no specific pharmacological treatment for this disorder. When the patients stop consumption anxious-depressive syndrome may occur, requiring symptomatic treatment (Passie et al. 2008; Jones 2009; O'Brian 2011).

Somatic Complications

Although LSD is considered relatively safe compared with other drugs of abuse, there are case reports of respiratory failure, hyperthermia and coagulopathies

associated with massive doses. Early on, a relationship between lysergic acid diethylamide and chromosomal damage was suspected, but this has been consistently refuted and lysergic acid diethylamide does not appear to be teratogenic. LSD, however, does induce uterine contractions, which could disrupt pregnancy.

35.2.1.6 Therapeutic Aspects

The aim is to reduce consumption and achieve abstinence. Although initially is easy to stop consuming, because there is no physical dependence, it is more complex in the medium term. Often, bad trips facilitate abstinence or not wanting to repeat the experience. As in other drug addiction programmes, psychiatric and psychological support components are used.

There are no specific drugs for treating disorders caused by these substances. Psychotropic drugs will be used according to the patient's symptoms (benzodiazepines, antipsychotics, antidepressants). The "bad trip" generally does not require inpatient hospitalisation because of the limited time course and quick recovery. The patient should be placed in a quiet, non-stimulating environment and provided with continuous reassurance that his or her state of mind is drug-induced and will not result in permanent brain damage.

Given that most emergency rooms are chaotic and understaffed, this may not be a realistic option. Furthermore, the patient may be too disorganized or combative to be "talked down". When medications are needed, benzodiazepines are probably the best choice, as long as delirium has been ruled out. The use of neuroleptics should be reserved for instances where none of the aforementioned efforts have succeeded. High-potency (less anticholinergic) neuroleptics should be used because anticholinergics have been associated with paradoxical reactions, such as hypotension, and anticholinergic crises. The use of haloperidol and chlorpromazine carries a high potential risk of seizures.

Mescaline

Mescaline, or 3,4,5-trimethoxyphenylethylamine is a phenethylamine hallucinogen found in several species of North and South American cacti, including Peyote (*Lophophora williamsii)* and San Pedro. Mescaline was first isolated from peyote cacti in 1896 and was synthesised approximately 20 years later.

Natural peyote has a bitter taste. It is dried and chewed, soaked in water and drank or injected. The hallucinogenic dose is approximately 5 mg/kg (0.3–0.5 g). Each button contains about 50–100 mg of mescaline, and users typically ingest 3–8 buttons. Within the first 30 min, before the onset of psychological symptoms, users may experience nausea, vomiting, restlessness and headaches. By 1–2 h, however, these unpleasant physiological symptoms dissipate and the psychic phase, characterised by euphoria, sensory distortions, and feelings of confidence, begins. The entire experience lasts up to 14 h. As is the case with LSD and the other serotonergic hallucinogens, tolerance develops rapidly and physical dependence does not occur. Treatment of acute intoxication and adverse consequences, as with LSD and psilocybin, involves reassurance and use of benzodiazepines if necessary (Jones 2009).

Tryptamines

There are a number of non-controlled tryptamines that are used for their psychedelic properties. They have effects similar to the tryptamines already controlled such as psilocybin (found in *Psylocybes* mushrooms or "magic mushrooms") or dimethyltryptamine (DMT). Tryptamines can be synthesised, although they also exist in plants, fungi and animals.

Albert Hoffman isolated and then synthesised psilocybin. It was marketed by Sandoz laboratories under the trade name Indocybin® as a potential tool for psychotherapy in the 1960s. The mushrooms can be eaten fresh, dried, or brewed. They are usually ingested orally. Psilocybin is a prodrug that is converted in the body into the pharmacologically active compound psilocin by a dephosphorylation reaction. Typical doses of psilocybin range from 4 to 20 mg (40 μg/kg) corresponding to 1–2 g of dried mushrooms. Sympathomimetic symptoms occur at lower doses (3–5 mg), and psychological effects are elicited by doses above 8 mg. Psychological effects begin within 30 min of ingestion, peak at 2–3 h, and dissipate by 12 h (Passie et al. 2002). Psilocybin occasioned sustained experiences similar to spontaneously occurring mystical experiences. Only one third of "magic mushrooms" bought on the street actually contain psilocybin (many are simply store-bought mushrooms laced with phencyclidine) and there are many wild poisonous mushrooms. Adulteration and misidentification are the most common causes of serious adverse outcomes. As with the other serotonergic hallucinogens, tolerance develops quickly, but physical dependence does not occur (Griffiths et al. 2006, 2011).

Dextromethorphan

Dextromethorphan is the dextro isomer of levorphanol, a codeine derivative. It is a substance commonly used as a cough suppressant at doses between 15 and 30 mg orally every 6–8 h. It is marketed in single or in multicomponent medicines for the treatment of symptoms associated with the common cold or flu. In some countries dextromethorphan is used as an adjunct to morphine in the treatment of pain. It is a hallucinogen when administered orally at doses of 240–480 mg.

The hallucinogenic effects of dextromethorphan are due to its antagonistic action on NMDA glutamate receptors. It has no opioid activity.

Readily absorbed orally, it is metabolised to dextrorphan, which is the active ingredient in cough medicine, by cytochrome P-4502D6. Up to 5–10 % of Caucasians have a deficiency of this isoenzyme and therefore cannot metabolise dextromethorphan to dextrorphan (poor metabolisers). This drug is commonly used to determine the phenotype of said cytochrome. The elimination half-life is 1.5–4 h for dextromethorphan and somewhat higher for its major metabolite, dextrorphan, in extensive metabolisers. It is a minority use substance, commonly used as ketamine to provoke feelings of mind–body separation and pictures of so-called near-death experiences. Poisoning presents with light-headedness, fatigue, nausea and vomiting, and ataxia. Also described are euphoria, nystagmus, mydriasis or even coma and death, plus cases of psychosis, dystonia and serotonin syndrome. In the event of poisoning, supportive measures and symptomatic treatment are recommended (Abanades et al. 2004, 2007a, b).

Salvia divinorum

Salvinorin A is the psychoactive substance in the plant *Salvia divinorum*. It can induce dissociative effects and is a potent producer of visual and other hallucinatory experiences. Salvinorin A, appears to be the most potent naturally occurring hallucinogen. Its native habitat is the cloud forests in Mexico. It has been consumed for hundreds of years by local Mazatec shamans, who use it to facilitate visionary states of consciousness during spiritual healing sessions. It is also used in traditional medicine at lower doses as a diuretic to treat ailments including diarrhoea, anaemia, headaches and rheumatism.

In Canada, a national school survey in 2011 reported the widespread use of novel psychoactive substances (NPS) among tenth-grade students (aged 15–16), including *Salvia divinorum* (lifetime prevalence of 5.8 %), jimson weed, or *Datura* (2.6 %), a hallucinogenic plant. The general household survey for 2011 lists only *Salvia divinorum* (lifetime prevalence of 1.6 %) among NPS. According to the 2011 Eurobarometer survey (Gallup Organization 2011), Latvia is the country with the highest lifetime prevalence the use of *Salvia divinorum* in the European Union. In the USA the use of *Salvia divinorum* in youths (aged 17–18) has an annual prevalence of 5.9 % (United Nations Office on Drug and Crime Drug 2013).

Salvinorin A is present in the dried plant (about 0.18 %). It is a potent and selective kappa-opioid receptor agonist; in addition, it is a potent D2 receptor partial agonist, and it is likely that this action plays a significant role in its effects as well. *Salvia divinorum* is usually smoked and produces rapid and intense effects with a short action (15–30 min). Its effects include various psychedelic experiences, including past memories (such as revisiting places from childhood memory), merging objects and overlapping realities (such as the perception of being in several locations at the same time). In contrast to other drugs, its use often prompts dysphoria, i.e. feelings of sadness and depression, as well as fear. In addition, it may prompt a decreased heart rate, slurred speech, lack of coordination and possibly loss of consciousness.

Differing studies suggest no overall consensus so far with regard to the long-term effects of *Salvia* on mood. It is well-established that some kappa-opioid agonists can cause dysphoria in humans, and research using rats in forced-swim tests has been used to suggest that *Salvia* might have "depressive-like" effects.

Ayahuasca

Ayahuasca, also commonly called yagé, is a hallucinogenic brew of various psychoactive infusions or decoctions prepared with the *Banisteriopsis caapi* vine (which contains the beta-carboline alkaloids harmaline and harmine). It is mixed with the leaves from the genus *Psychotria* (*Psychotria viridis*) that contain dimethyltryptamine (DMT). DMT itself is not active orally because it is normally destroyed by deamination enzymes in the gut, but when the two plants are ingested together the beta-carboline alkaloids inhibit the deamination enzymes that ordinarily destroy DMT (monoamine oxidase, MAO). Ayahuasca is used largely as a religious sacrament. The psychedelic effects of ayahuasca include visual and auditory stimulation, the mixing of sensory modalities, and psychological

introspection that may lead to great elation, fear, or illumination. Its purgative properties are important, producing intense vomiting and occasional diarrhoea. In native or religious communities using ayahuasca, there is no evidence of psychological maladjustment, mental health deterioration or cognitive impairment (Bouso et al. 2012).

Ibogaine

Ibogaine is an indole alkaloid found in plants such as *Tabernanthe iboga*. The plant originates in Africa and is traditionally used in sacramental initiation ceremonies. Ibogaine is a hallucinogen at the 400-mg dose range. Ibogaine is a tryptamine that acts as an agonist (for the 5-HT2A receptor). In addition, it acts as an antagonist of the NMDA receptor set and an agonist for the kappa-opioid receptor. Ibogaine is metabolised in the human body by cytochrome P4502D6, and the major metabolite is noribogaine (12-hydroxyibogamine). Noribogaine is most potent as a serotonin reuptake inhibitor and acts as a moderate kappa-opioid receptor antagonist and weak mu-opioid receptor full agonist. In recent years, ibogaine has been studied, and even patented as a pharmacotherapy for opiate and other addictions, involving doses that range as high as 1,500 mg orally. There are no well controlled studies in humans assessing its efficacy at opiate detoxification. The ingested material is taken from the plant or pure powder (Brown 2013). Ibogaine can produce a QT interval prolongation and induce ventricular tachycardia after initial use. Fatalities following ibogaine ingestion are documented in the medical literature (Alper et al. 2012).

35.2.2 Dissociatives

Dissociatives include phencyclidine (PCP, angel dust), ketamine (Special K) and esketamine, and other recent derivatives that sometimes are classified in the novel psychoactive substances category (such as methoxetamine, methoxydine or 4-MeO-PCP, among others). Chemically, dissociatives are arylcyclohexylamine derivatives. These substances were developed as anaesthetics. Phencyclidine was quickly discarded because of a high frequency of postoperative delirium with hallucinations. It was classified as a dissociative anaesthetic because, in the anaesthetised state, the patient remains conscious with analgesia, staring gaze, flat facies and rigid muscles. The use of ketamine persists, especially in animals and humans, as an analgesic and anaesthetic.

35.2.2.1 Phencyclidine

Phencyclidine is rarely consumed in Europe, but is very common in the USA. Approximately 2.5 % of the US population reports having ever used phencyclidine. The proportion of users increases with age, from 0.3 % of 12- to 17-year-olds, to 1.3 % of 18- to 25-year-olds, to 2.9 % of those aged 26 years and older reporting ever having used phencyclidine. There appears to have been an increase among 12th graders in ever used (1.6–2.3 % over the past 3 years) (Johnston et al. 2013a).

Phencyclidine is injected intravenously, smoked, snorted or ingested orally. It is a substance that causes medical complications, resulting often in a more toxic effect than that of LSD. It is estimated that up to 3 % of deaths in drug users in the USA are due to phencyclidine.

Phencyclidine is an antagonist of NMDA glutamate receptors. It also activates the dopaminergic ventral tegmental area, the area starting in the reward pathway. There is tolerance to the effects, but not physical dependence. It tends to be used infrequently, although there is a small percentage of daily users. The elimination half-life is 21 h. At low doses (less than 5 mg) ataxia, dysarthria, blurred vision, nystagmus and weakness were produced. At higher doses (5–10 mg) hypertonia, hyperreflexia, hypertension, tachycardia, sweating, fever, vomiting, stereotyped movements and muscle stiffness appear. Often, aggressive and transient confusional episodes emerge (with psychomotor agitation, belligerence and impulsivity). Also, phencyclidine induces changes in perception, disorganised thinking and a feeling of unreality. At even higher doses, analgesia, amnesia and coma can occur.

The intoxication is a medical emergency because it can be severe and life-threatening. Hyperpyrexia, muscle stiffness, seizures, severe hypertension, intracerebral bleeding and respiratory depression can be observed. Patients go to the emergency room with high levels of hostility, aggressiveness, agitation, anxiety and self-injurious behaviour. It is the substance that produces more pictures of psychosis than any other. It is treated symptomatically with the administration of anxiolytics (diazepam) and antipsychotics (haloperidol) (O'Brian 2011).

35.2.2.2 Ketamine

Ketamine exists as two optical isomers, S and R-., the S-(+) isomer is more potent that the R(−) isomer. The S-isomer, or esketamine, has been recently marketed in some countries. Ketamine is used via an intramuscular or intravenous route as an analgesic and anaesthetic. Recently, ketamine has been used experimentally for the therapy of treatment-resistant depression (Aan Het Rot et al. 2012).

In the case of ketamine, in the UK, 1.8 % of 16- to 24-year-olds reported last-year ketamine use, with levels remaining stable between 2008 and 2012, although they increased from 0.8 % in 2006. Targeted surveys in nightlife settings report higher levels of lifetime prevalence, for example, in Danish clubbers 10 % had tried ketamine. Among UK respondents to an Internet survey who were identified as regular clubbers, 40 % reported last-year use of ketamine and 2 % last-year use of GHB (European Monitoring Centre for Drugs and Drug Addiction 2013a). In the United States the past-year use of ketamine appears to be relatively stable among 12th graders (1.5–1.7 % over the past 3 years) (Johnston et al. 2013a). In Canada, among tenth-grade students (aged 15–16) lifetime prevalence of ketamine use was 1.6 %. Given the strong decline in ketamine use in the United States since the beginning of the millennium, its use among tenth-grade students in Canada is now slightly higher than in the United States (1.2 % in 2011). In Australia, a small

decline occurred in the annual prevalence of ketamine use among the population aged 14 and above, from 0.3 % in 2004 to 0.2 % in 2010 (United Nations Office on Drug and Crime 2013).

Although the pharmaceutical presentation is injectable solution, it is transformed and crystallised in powder to consume. The illegal use of ketamine (Special K, Super K, kit-kat, K) has been increasing in recent years and is one of the so-called club drugs, drugs used at electronic music parties. Another type of consumption is related to the search for new sensations. Consumers also use ecstasy and gamma hydroxybutyrate (GHB). Like PCP, ketamine is an antagonist of the NMDA glutamate receptors. It is administered by injection intramuscular or intravenous), orally, by smoking and by inhalation. The elimination half-life of ketamine is 2–3 h. The effects are fast, short-lasting and dose-dependent, and can cause perceptual changes (from dissociation body sensation to near-death experiences) and psychopathological reactions similar to those of phencyclidine (Morgan and Curran 2012).

Appealing effects described by users include visual hallucinations and out-of-body experiences; undesirable effects include memory loss and decreased sociability. General central nervous system depressant effects include poor concentration and poor recollection similar to alcohol intoxication, which is not unexpected for an anaesthetic drug. Effects of ketamine include profound changes in consciousness and psychotomimetic effects, such as changes in body image (feeling that the body is made of wood, plastic, or rubber) and possible feelings of spiritual separation from the body, including out-of-body experiences. At low doses, users describe mild dissociative effects, distortion of time and space, and hallucinations. At large doses, users experience severe dissociation with intense detachment such that their perceptions seem to be located deep within their consciousness and reality is far off in the distance; this is called the "K-hole". The analgesic and dissociative effects may result in injury or even death.

Tolerance to the desired effects develops rapidly, resulting in reduced length of the subjective experience and requiring an increase in dose to maintain the expected effects. Users escalate the amount used to achieve the full hallucinogenic experience, up to seven times the original amount. Use of higher recreational doses can result in more adverse effects, especially physiological side effects. Use of very high doses can result in the onset of full anaesthetic effects, which may result in an overdose situation for a recreational user. Continued use of ketamine or phencyclidine, despite experiencing these consequences, constitutes addiction (using the phencyclidine use disorder criteria). Some people develop compulsive consumption, which is more reminiscent of the use of cocaine or psychostimulants.

The clinical symptoms of intoxication from ketamine are tachycardia, altered consciousness, disorganised speech and nystagmus. Treatment consists of supportive measures. Some ketamine users suffer urinary symptoms such as urinary frequency, urgency, dysuria and haematuria, which improve or disappear after cessation of use (Abanades et al. 2004, 2007a, b; O'Brian 2011).

35.2.3 Designer Drugs and "Legal Highs": MDMA and New Psychoactive Substances

35.2.3.1 Definitions

The emergence of new psychoactive substances that are not controlled under existing drug laws is not a new phenomenon. Over the last 20 years, a variety of terms and definitions have been used for new psychoactive substances that emerge on the market and are not under international control. The use of different terms to define the same substance can create confusion, because it can be found in different categories. Currently, the preferred term is new/novel psychoactive substances (NPS).

The emergence started in the 1970s with the so-called "designer drugs". They were defined as psychoactive substances produced from chemical precursors in a clandestine laboratory, which, by slight modification of the chemical structure, have been intentionally designed to mimic the properties of known psychoactive substances, and which are not under international control (Buchanan and Brown 1988). Over the past few years, the globalisation and the widespread use of the internet have allowed the unprecedented growth in both the number and availability of these substances. In the European Union (EU), 24 novel psychoactive substances were identified for the first time in 2009, 41 in 2010, 49 in 2011 and 73 in 2012 (European Monitoring Centre for Drugs and Drug Addiction 2013b).

"Designer drugs" have been defined by the International Narcotics Control Board as follows: "Substances that have been developed especially to avoid existing drug control measures and are manufactured by making a minor modification to the molecular structure of controlled substances, resulting in new substances with pharmacological effects similar to those of the controlled substances" (United Nations Office on Drug and Crime 2013). According to the European Monitoring Centre for Drugs and Drug Addiction (EMCDDA) and the European Police Office (Europol), designer drugs can be best defined as substances designed to mimic the effects of known drugs by slightly altering their chemical structure in order to circumvent existing controls.

More recently, "legal highs" has been used as an umbrella term for unregulated novel psychoactive substances, or products claiming to contain them, which are intended to mimic the effects of controlled drugs. The term includes a wide range of synthetic and/or plant-derived substances and products. These may be marketed as "legal highs" (emphasising "legality"), "herbal highs" (stressing the natural/plant origin), as well as "research chemicals" and "party pills"." Legal highs" are usually sold via the internet or in bricks and "head shops" or" smart shops". In most cases they are intentionally mislabelled with regard to their intended use (e.g. labelled as "not for human consumption", "plant food", "bath salts", "room odourisers", "incenses") and the active substances that they contain. This "legal highs" market can be distinguished from other drug markets by the speed at which suppliers circumvent drug controls by offering new alternatives to restricted products (Deluca et al. 2012).

Currently in the European Union a new psychoactive substance is defined as a new narcotic drug or a new psychotropic drug in pure form or in a preparation that has not been scheduled under:

1. The 1961 United Nations Single Convention on Narcotic Drugs, and that may pose a threat to public health comparable to the substances listed in Schedule I, II or IV; or,
2. The 1971 United Nations Convention on Psychotropic Substances, and that may pose a threat to public health comparable to the substances listed in Schedules I, II, III or IV. In this context, the term "new" is not intended to refer to newly invented, but rather to a "'newly available" or a "newly misused" substance. In practice, most "new" drugs were first described in the scientific and patent literature many years ago as part of legitimate research and development, but have not been widely available or used (Sedefov et al. 2013). Novel psychoactive substances are defined by the United Nations Office for Drug and Crime as "substances of abuse, either in a pure form or a preparation, that are not controlled by the 1961 Convention on Narcotic Drugs or the 1971 Convention on Psychotropic Substances, but which may pose a public health threat".

35.2.3.2 Origin and Synthesis

As mentioned above, the term "designer drug" was coined in the 1980s. It originally referred to various synthetic opioids, mostly based on modifications of fentanyl (alfa-methyl-fentanyl) and pethidine. The term entered widespread use when 3,4-methylenedioxymethamphetamine (MDMA, "ecstasy") experienced a boom in the mid-1980s, first in the USA, followed by Europe in the 1990s and then other parts of the world. Another term that emerged in the late 1990s and early 2000s is "research chemicals" (RC). The term was coined by some marketers of designer drugs, specifically, psychedelic drugs of the tryptamine and phenethylamine families. The idea was that by selling the chemicals for so-called "scientific research" rather than for human consumption (they included the advice "not for human use or consumption"), the drug laws could be circumvented. The same strategy was behind the marketing of some of the cathinone-related substances as "bath salts" not intended for human consumption (Camí and Farré 2003).

Substances sold as "legal highs" are mainly manufactured in chemical laboratories in Asia, according to the International Narcotics Control Board and the Europol, although some manufacture also takes place in Europe, the Americas and other regions. They are legally imported, either as chemicals or as packaged products. The "legal highs" market is characterised by the speed with which suppliers circumvent drug controls by offering new alternatives to restricted products and advertise them with aggressive and sophisticated marketing strategies (as air fresheners, herbal incenses, bath salts, plant fertilisers, collectors' items etc. (European Monitoring Centre for Drugs and Drug Addiction 2012).

New psychoactive substances can be classified as shown in Table 35.2.

Phenethylamine, including MDMA, and tryptamine derivatives are shown in Table 35.1 above.

Table 35.2 Classification of substances categorised as novel psychoactive substances (NPS) based on the systems used by United Nations Office on Drugs and Crime (UNODC) and European Monitoring Centre for Drugs and Drug Addiction (EMCDDA). Some of the substances of each class are included as examples

Group	Substances
Synthetic cannabinoids	JWH-018
	JWH-073
	JWH-200
	JWH-250
	AM-694
	CP 47,497
	Cannabicyclohexanol
	CP 55,940
	HU-210
	THC-O-acetate
Synthetic cathinones	Cathinone
	Methcathinone (ephedrone)
	Methylmethcathinone (mephedrone)
	Methylenedioxypyrovalerone (MDPV)
	Pyrovalerone
	Naphyrone (naphthylpyrovalerone, NRG-1)
	Ethylone (see Table 35.1, entactogens)
	Methylone (see Table 35.1, entactogens)
	Butylone (see Table 35.1, entactogens)
Phenethylamines	See Table 35.1
	Paramethoxymethamphetamine (PMMA)
	2,5-dimethoxy-4-iodophenethylamine (2C-I)
	2,5-dimethoxy-4-methyl-phenethylamine (2C-D)
	2,5-dimethoxy-4-iodoamphetamine (DOI)
	2,5-dimethoxy-4-bromo-phenethylamine (2-CB)
	4-methylthioamfetamine (4-MTA)
Piperazines	1-benzylpiperazine (BZP)
	1-(3,4-methylenedioxybenzyl) piperazine (MDBP)
	1-(3-chlorophenyl) piperazine (mCPP)
	1-(3-trifluoromethylphenyl)piperazine(TFMPP)
	1-(4-methoxyphenyl)piperazine (MeOPP)

(*continued*)

Table 35.2 (continued)

Group	Substances
Ketamine and phencyclidine-type substances	See Table 35.1
	Ketamine
	N-ethylnorketamine
	3-methoxy-phencyclidine (3-MeO-PCP)
	4-methoxy-phencyclidine (4-MeO-PCP)
	Eticyclidine (PCE, CI-400, *N*-ethyl-1-phenylcyclohexylamine)
	2-(3-methoxyphenyl-2-(ethylamino)cyclohexanone) (methoxetamine)
	Rolicyclidine (PCPy; 1-(1-phenylcyclohexyl)pyrrolidine)
	Tenocyclidine (TCP; 1-(1-(2-thienyl)cyclohexyl)piperidine)
	2-(3-methoxyphenyl-2-(ethylamino)cyclohexane) (3-MeO-PCE)
Tryptamines	See Table 35.1
Plant-based psychoactive substances	Kratom (*Mitragyna speciosa*)
	Salvia divinorum
	Khat (*Catha edulis*)
Other	
Aminoindanes	2-Aminoindane (2-AI)
	5,6-Methylenedioxy-*N*-methyl-2-aminoindane (MDMAI)
	5,6-Methylenedioxy-2-aminoindane (MDAI)
	5-Methoxy-6-methyl-2-aminoindane (MMAI)
Benzofuranes	5-(2-Aminopropyl)-2,3-dihydrobenzofuran (5-APDB, 3-Desoxy-MDA, EMA-4)
	6-(2-Aminopropyl)-2,3-dihydrobenzofuran (6-APDB, 4-Desoxy-MDA, EMA-3)
Piperidines	Pipradrol
	Desoxypipradrol (2-diphenylmethylpiperidine, 2-DPMP)
Synthetic cocaine	Dimethocaine
	4-fluorotropacocaine
Medicines	Phenazepam
	Etizolam
	Ethylphenidate
	Phenibut
	4-methylphendimetrazine

35.2.3.3 Epidemiology and Pattern of Consumption

During 2012, 73 NPS were notified by the European Member States for the first time through the EU Early Warning System. Reflecting consumer demand for cannabis-like products, 30 of these substances were synthetic cannabinoid receptor agonists. Nineteen compounds did not conform to the readily recognised chemical groups (including plants and medicines), while 14 new substituted phenethylamines were reported, the highest number since 2005 (European Monitoring Centre for

Drugs and Drug Addiction 2013b). As the internet is an important marketplace for NPS, the EMCDDA undertakes a regular snapshot exercise to monitor the number of online shops offering products to European consumers. This number of shops continues to grow, with 693 online shops identified in January 2012.

The use of NPS has grown rapidly over the past decade, in contrast to the prevalence of the use of internationally controlled drugs, which generally seems to have stabilised in the same time period. Producing and marketing such substances holds the promise of high profits without penalty. When brought under control in one country, production and/or the distribution centres of these substances are shifted to another country so that the sales, often conducted via the internet, can continue.

In other cases, the substances are modified slightly so that they are not covered by the respective country's legislation. The number of NPS reported by Member States to the United Nations Office on Drugs and Crime (UNODC) rose from 166 at the end of 2009 to 251 by mid-2012. This exceeds the total number of psychoactive substances currently controlled by the international drug conventions (234 substances) (United Nations Office on Drug and Crime 2013).

Well-known examples of NPS include substances such as synthetic cannabinoids contained in various herbal mixtures, piperazines, products sold as "bath salts" (i.e. cathinone-type substances, such as mephedrone and methylenedioxypyrovalerone [MDPV]) and various phenethylamines. Ketamine was among the first NPS to appear. Its abuse was first recognised in North America at the beginning of the 1980s. It became a noticeable phenomenon in Europe in the 1990s, before spreading extensively throughout Asia and, to a lesser extent, throughout South America and Southern Africa. NPS belonging to the phenethylamine family appeared on the market in the 1990s and substances belonging to the piperazine family at the beginning of the 2000s. From 2004 onwards, synthetic cannabinoids, such as Spice, appeared on the market, followed by synthetic cathinones and other emerging groups of NPS.

According to the Eurobarometer, 5 % of young people reported having used these NPS in the past (Gallup Organization 2011). The national survey on drug use in students aged 14–18 years in 2010, conducted by the Spanish Drug Observatory (OED), assessed the use of ketamine, Spice drugs, piperazines, mephedrone, nexus (2-CB), methamphetamine, magic mushrooms, "research chemicals" and other LH. Reported prevalence of use was 3.5 %, 2.5 % and 0.5 % for lifetime, last year and last month respectively for any of these substances (Clinical Committee Report 2011).

The lifetime prevalence of legal substances that imitate the effects of illicit drugs rises with age, from 3.6 % among the European Union population aged 15–18 to 5.6 % among those aged 19–21 and 22–24. The lifetime prevalence for the use of legal substances that imitate the effects of illicit drugs in individual European Union countries ranged from 0.3 % in Malta to more than 16 % in Ireland. Levels above the European Union average (4.8 %) have been reported—in descending order—from Ireland, Poland, Latvia and the UK, followed by Luxembourg, Slovenia, Estonia, Portugal, Lithuania, France and Spain (United Nations Office on Drug and Crime 2013).

MDMA (Ecstasy) and Derivatives

The consumption of ecstasy is associated with attending electronic dance music events or raves. It is estimated that 1.8 million young adults used ecstasy in the last year, with national estimates ranging from under 0.1 % to 3.1 %. Consumption of the drug typically peaked in the early to mid-2000s, before declining. Between 2006 and 2011, most countries have reported stable or declining trends in ecstasy use. With the exception of Poland, this decline continues to be seen in data from countries reporting surveys since 2010. Few users entered treatment for problems relating to ecstasy in 2011: ecstasy was mentioned as the primary drug by less than 1 % (around 600 clients) of reported first-time treatment entrants in Europe. In young adults aged between 15 and 24, the (lifetime) prevalence in Europe of ecstasy use is between 0.4 % and 16.6 %, with the higher rates seen in the Czech Republic (European Monitoring Centre for Drugs and Drug Addiction 2013b).

In the United States the lifetime prevalence of ecstasy (MDMA) use in students in 12th grade was between 7.2 % and 8 % over the past 3 years. For amphetamines it was 11.1–12.2 %, and for methamphetamines 1.7–2.3 % (Johnston et al. 2013a).

Cathinones

There are signs that synthetic cathinones, including mephedrone, may have carved a space in the illicit stimulants market in some countries. At present, however, only the UK has repeat surveys that include these drugs. In the most recent data, 1.1 % of adults (16–59) in England and Wales reported using mephedrone in the last year, making it the fourth most commonly used illicit drug. Among 16- to 24-year-olds, last-year prevalence was the same as that of ecstasy (3.3 %), the third most prevalent drug among this age group. A decrease in levels of use, however, was noted for all groups compared with the 2010/2011 survey.

More generally, mephedrone-related mortality and morbidity continue to be reported in Europe, although at relatively low levels. Some countries also report the injection of mephedrone, MDPV and other synthetic cathinones among groups of problem drug users and drug treatment clients (Hungary, Austria, Romania, UK) (European Monitoring Centre for Drugs and Drug Addiction 2013b).

In the USA data on changes in the prevalence of the use of MDPV are not available. However, data show that the number of calls to poison control centres concerning “bath salts” (often linked to MDPV) rose from 304 in 2010 to 6,134 in 2011, a 20-fold increase in 1 year (United Nations Office on Drug and Crime 2013).

Piperazines

The British Crime Survey found in 2011 that the annual prevalence of BZP was 0.1 %. The Mixmag Global Drug Survey, in 2011, reported a lifetime prevalence of 17.2 % and last-year prevalence of 5 % and a prevalence in the last month of 0.5 % (United Nations Office on Drug and Crime 2013). In New Zealand, the market for NPS has been associated with piperazines. The national household survey there revealed that 5.6 % of the population aged 15–64 had used BZP in the past year (United Nations Office on Drug and Crime 2013).

35.2.3.4 Pharmacological Proprieties and Consequences of the Use of MDMA (Ecstasy)

The 3,4 methylenedioxymethamphetamine (MDMA) is a ring-substituted amphetamine that is structurally similar to methamphetamine and mescaline. MDMA has become widely known as "ecstasy" (shortened to "E", "X", or "XTC"). MDMA acts as a potent releaser and/or reuptake inhibitor of presynaptic serotonin (5-HT), dopamine (DA) and norepinephrine (NE). These actions result from the interaction of MDMA with the membrane transporters involved in neurotransmitter reuptake and vesicular storage systems. Globally, this results in the increased activation of postsynaptic receptors. In comparison to methamphetamine, MDMA is more potent and active on serotonergic neurons. MDMA is also a mild inhibitor of monoamine oxidase (MAO) and also has some direct action in several types of receptors including the 5-HT2 receptor, the M1 muscarinic receptor, the 2-adrenergic receptor and the histamine H1 receptor. MDMA inhibits the activity of the rate-limiting enzymes of serotonin synthesis (tryptophan hydroxylase), decreasing the formation of serotonin (de la Torre et al. 2013).

Ecstasy is presented for use as tablets/pills, capsules or powder (ice). It is usually taken orally, but some users snort the contents. The MDMA content of pills or tablets varies widely between regions and different brands of pills, and fluctuates. Pills may contain other active substances meant to stimulate in a way similar to MDMA, such as amphetamine, mephedrone, methamphetamine, ephedrine or caffeine. In some cases, tablets sold as ecstasy do not even contain any MDMA.

In general, users begin reporting subjective effects within 30–60 min of consumption, a peak appears at about 75–120 min, reaching a plateau that lasts about 3.5 h. This is followed by a comedown feeling of a few hours. The usual dose is 50–125 mg with additional doses throughout the recreational session. The most frequent effects after MDMA administration are euphoria, well-being, happiness, stimulation, increased energy, extroversion, feeling close to others, increased empathy, increased sociability, enhanced mood, mild perceptual disturbances, somatic symptoms related to the cardiovascular (increase in blood pressure and heart rate) and autonomic effects (dry mouth, sweating, tremor, mydriasis tremor, jaw clenching and restlessness), and moderate derealisation, but not hallucinations. Some of the effects differ from those elicited by classical amphetamines (e.g. feeling close to others, increased empathy, increased sociability) are collectively termed "entactogenic" and MDMA is considered the prototypical drug to produce such effects (de la Torre et al. 2013; Farré et al. 2004, 2007).

The MDMA-induced acute toxic effects occur in relation to its pharmacological actions. Signs of mild toxicity include nausea, vomiting, restlessness, tremor, hyperreflexia, irritability, pallor, bruxism, trismus and palpitations. Moderate intoxication signs include hyperactivity, aggressive behaviour, panic attacks, psychosis, confusion, muscle tension, tachycardia, arterial hypertension, and an increase in body temperature. Severe intoxication can include delirium, coma, seizures, hypotension, tachydysrhythmias, hyperthermia (>40 °C), and renal failure associated with rhabdomyolysis. A serotonin syndrome (increased muscle rigidity, hyperreflexia, and hyperthermia). Intracranial haemorrhage has been described.

Heat stroke is a severe complication that can cause death; it includes hyperthermia, rhabdomyolysis, myoglobinuria, disseminated intravascular coagulation and renal failure. Fulminant hepatitis and hepatic necrosis have been reported. Hyponatraemia is an uncommon complication associated with inappropriate antidiuretic hormone (SIADH) secretion and excessive water intake. Its chronic use is linked to a progressive neurodegeneration of the serotonergic neurotransmission system (de la Torre et al. 2013; Cuyas et al. 2011).

Two main pathways are involved in MDMA metabolic clearance:

1. *O*-demethylation partially regulated by CYP2D6 followed by catechol-*O*-methyltransferase (COMT)-catalysed methylation (HMMA) and/or glucuronide/sulphate conjugation; and
2. *N*-dealkylation leading to 3,4-methylenedioxyamphetanmine (MDA), further subject to similar metabolic reactions to MDMA (*O*-demethylenation and *O*-methylation). MDMA metabolic clearance accounts for about 75 % of plasma clearance and 30 % of its metabolism is regulated by CYP2D6 (de la Torre et al. 2005; Segura et al. 2005). In addition, MDMA is a competitive inhibitor of CYP2D6; after a single dose most hepatic CYP2D6 are inactivated within 2 h, returning to a basal level of CYP2D6 activity after at least 10 days. Other isoenzymes of cytochrome P450 and a relevant contribution of renal excretion play part in their clearance.

Globally, the clinical relevance of the CYP2D6 polymorphism (de la Torre et al. 2004, 2005) is lower than that predicted by in vitro studies (de la Torre et al. 2012; Yubero-Lahoz et al. 2011, 2012).

In addition, there is some evidence that MDMA produces in the mid- to long-term selective long-lasting serotonergic neurotoxicity in animal models when administered at relatively high doses and/or after repeated administration.

Unique low doses or repeated low doses separated by large intervals did not seem neurotoxic. It has been proposed that MDMA induces a number of serotonin neuroadaptations and anatomical alterations (e.g. axotomy of serotonergic neurons). Complementary or alternative to this view of MDMA-induced neurotoxicity, there is new evidence showing that MDMA causes substantial regulatory changes in the expression of serotonergic markers, including the serotonin transporter. The direct extrapolation of these results from animal to human is difficult (de la Torre and Farré 2004; Green et al. 2012).

In humans, ligand-binding imaging studies have reported decreased 5-HTT binding throughout the cerebral cortices and the hippocampus in Ecstasy users compared with healthy controls. Furthermore, these studies have shown that decreased 5-HTT binding is associated with lower memory performance in Ecstasy users. Although some studies have observed MDMA abstinence-related recovery of 5-HTT availability in the mid-brain and thalamus there are no data on 5-HTT recovery in the cortex, and post-mortem evidence indicates that cortical 5-HTT protein reductions can be more robust and durable than indicated by neuroimaging studies. Overall, these findings are suggestive of MDMA-induced neurotoxicity, which primarily affects the serotonin system and is linked to cognitive alterations (e.g. memory dysfunction) and a higher prevalence of

psychopathology (e.g. mood disorders) among Ecstasy users (de la Torre and Farré 2004; de la Torre et al. 2013; De Sola Llopis et al. 2008; Pardo-Lozano et al. 2012).

The therapeutic use of MDMA is under investigation. Few recent randomised, controlled trials of MDMA-assisted psychotherapy for post-traumatic stress disorder have been published showing some therapeutic efficacy (Mithoefer et al. 2013). MDMA can induce abuse, but it is not clear and in some cases drug dependence occurs, but not drug withdrawal. Users reported tolerance to its desired effects, and tend to cease consumption spontaneously. MDMA can cause intoxication, in this case the DSM-V diagnostic criteria for stimulants can be applied (American Psychiatric 2013). There are no specific drugs for treating disorders caused by MDMA. Psychotropic drugs will be used according to the patient's symptoms (benzodiazepines, hypnotics, antipsychotics, antidepressants). As in the other drug addiction programmes, psychiatric and psychological support are used.

35.2.3.5 Pharmacological Proprieties and Consequences of the Use of NPS

Synthetic Cannabinoids

The most widely used NPS are currently the synthetic cannabinoids, often mixed with various herbal mixtures and sold under the brand name Spice or other names. Initially, the most widespread synthetic cannabinoid was JWH-018. After it was prohibited in some countries in 2010, it was immediately replaced by other, similar compounds, such as JWH-073. Although the various synthetic cannabinoids differ, they tend to be more potent than the tetrahydrocannabinols (THC) contained in the natural cannabis plant. Similar to cannabis, these substances tend to elevate the mood, aid relaxation and alter perceptions (United Nations Office on Drug and Crime 2013; Mustata et al. 2009). Cannabinoids are fully described in other chapter.

Tryptamines

Some tryptamines have been associated with the emergence of NPS. Their main properties can be found in the hallucinogenics part of this chapter.

Phenethylamines

Phenethylamines include a large series of compounds that range from amphetamines or entactogens, such as MDMA to hallucinogens (see the part of this chapter on hallucinogens). A large number of non-controlled phenethylamines also fall into the category of NPS. However, the main phenethylamines on the illicit markets are already under international control, including amphetamine, methamphetamine and methylphenidate, as well as MDMA ("ecstasy") and mescaline. NPS phenethylamines appeared on the market after a shortage of ecstasy that occurs between 2009 and 2010; major substitutes were other amphetamines, mCPP and, above all, mephedrone.

They are presented in the form of pills, capsules or a powder, which users can swallow, snort or inject, producing similar effects to MDMA, amphetamines and hallucinogens. Amphetamines are chemically phenylethylamine derivatives, and

their structure exhibits similarity to various endogenous neurotransmitters (norepinephrine, dopamine and serotonin) and hallucinogens like mescaline.

The effects of phenethylamines depend on its selectivity on dopaminergic, serotonergic and noradrenergic neurons. They release these neurotransmitters and in addition inhibit its re-uptake interacting with the membrane transporters.

Those with psychostimulant effects are more selective for dopamine and norepinephrine transmission, the hallucinogenic derivatives have more effects on serotonin transmission. It is important to say that hallucinogenic derivatives produce those actions even at low doses and are not usually psychostimulants.

Some derivatives with actions like MDMA can produce entactogenic effects, a greater desire for contact with others, greater empathy, love and emotional closeness to others. At low doses, phenethylamines increase alertness, give energy to fatigued individuals and increase endurance. They also tend to have some anorectic properties as they produce sympathetic nervous system stimulation with increased pupillary diameter (mydriasis), which can cause blurred vision and increased sensitivity to light, dry mouth, sweating, tremor, tension jaw (lockjaw), chewing movements or grinding of teeth (bruxism) and a slightly increasing body temperature together with increased blood pressure and heart rate (palpitations or tachycardia). At higher doses, phenethylamines induce euphoria, stronger feelings of self-esteem (including diminished fear, anxiety and insecurity), but can also increase blood pressure, raise body temperature, increase the heart rate, cause hallucinations and lead to death due to stroke, cardiac arrest and brain damage (starting with memory loss). The use of phenethylamines can entail various forms of drug-related psychosis and paranoia. The more psychedelic phenethylamines tend to bring about the intensification of bodily senses (hearing, touch, smell, vision, taste) and thus also have some aphrodisiacal effects. They also create various hallucinogenic effects even at lower doses, entailing various mental, auditory and visual distortions. The human pharmacokinetics of the majority of phenethylamines are unknown (Caudevilla-Galigo et al. 2012).

Cathinones

Currently, the most problematic group of NPS from the perspective of public health and safety seems to be the synthetic cathinones, such as mephedrone (4-(methylmethcathinone, 4-MMC, 4-methylephedrone) or methylenedioxypyrovalerone (MDPV). Cathinones are derivatives of cathinone, which is found in the khat plant *(Catha edulis)*, although most are synthetically manufactured. Mephedrone and other cathinones can come in the form of capsules, tablets or white powder that users may swallow, snort, inject, smoke or use rectally, producing similar effects to MDMA, amphetamines and cocaine.

A number of cathinones are already under international control, including cathine, cathinone and methcathinone, as well as amfepramone and pyrovalerone. The most widely used, non-controlled cathinones at the international level include mephedrone (often known in the market as “m-cat”, “meph”, “drone” or “meow”), methylone (“explosion” or “top cat”) and MDPV.

Mephedrone and the cathinones are expected to act as a central nervous system stimulant by promoting the release of monoamine neurotransmitters and likely inhibiting their reuptake. Both amphetamines and cathinones bind to norepinephrine, dopamine and serotonin transporters, each of them differing from each other by its relative binding potency. In particular, the presence of the ring substituent on the phenethylamine core modifies the pharmacological properties by giving the compound some MDMA-like effects, whereas amphetamines and cathinone derivatives without ring substituents exert mostly stimulant effects (European Monitoring Centre for Drugs and Drug Addiction 2012). The human pharmacology, including pharmacokinetics of the majority of new cathinones are unknown (Schifano et al. 2011).

The most common routes for recreational use include insufflation (snorting) and oral ingestion. Because of its solubility in water, mephedrone is reportedly used for rectal administration (dissolved in an enema or within gelatine capsules) as well as injecting intravenously. Insufflation is likely to be the most common modality. When snorted, mephedrone elicits its effects within a few minutes, with the peak being reached in <30 min followed by a rapid comedown. According to online users' advice, mephedrone dosage for snorting may range between 25 and 75 mg, with the lower threshold being at 5–15 mg, and with a level in excess of 90 mg to be considered a high dosage.

Mephedrone effects have been variously compared by users with those of cocaine, amphetamine and MDMA. Self-reported subjective effects may include: intense stimulation and alertness, euphoria, empathy/feelings of closeness, sociability and talkativeness, intensification of sensory experiences, moderate sexual arousal and perceptual distortions (reported with higher dosages only). Some 56 % of those who had used mephedrone may complain of at least one unwanted effect associated with its use. These may include: loss of appetite, dry mouth, nausea, vomiting, tremors, tense jaws, trismus, bruxism, mild muscle clenching, stiff neck/shoulders, headache (very common), dizziness/light headedness, tinnitus, seizures, nystagmus, pupil dilation, blurred vision, numbness of tactile sensitivity; anxiety, agitation, confusion, dysphoria, irritability, aggression, depression, lack of motivation and anhedonia; time distortions, long-lasting hallucinations, paranoid delusions, short-term psychosis, short-term mania, insomnia and nightmares; impaired short-term memory, poor concentration and mental fatigue; tachycardia, elevated blood pressure, respiratory difficulties, chest pain and vasoconstriction (Schifano et al. 2011; Hill and Thomas 2011; Wood et al. 2011).

The use of ephedrone (methylcathinone) has recently been associated with symptoms similar to those seen in patients with Parkinson's disease (manganism) owing to the compound manganese dioxide, which is a by-product of synthesis with permanganate (De Bie et al. 2007).

The use of MDPV was, in a number of cases, associated with highly bizarre behaviour, including a number of suicides, deaths associated with MDPV delirium and highly violent homicides (Murray et al. 2012).

Piperazines

The basic piperazine was first introduced into medicine in 1953, for its anthelmintic properties. The piperazines can be classified into two groups:

- Benzylpiperazines including 1-benzylpiperazine (BZP), and its analogue 1- (3,4-metilenodioxibenzil) piperazine (MDBP).
- The phenylpiperazines, such as 1-(3-chlorophenyl) piperazine (MCCP), 1-(3-trifluoromethylphenyl) piperazine (TFMPP), 1-(4-methoxyphenyl) piperazine (MeOPP), 1-(4-chlorophenyl) piperazine (pCPP) and 1-(*o*-methoxyphenyl) piperazine (WOFP).

BZP has been studied as an anthelmintic, but was never commercialised, unlike piperazine. The mCPP is an active metabolite of trazodone and nefazodone, both with antidepressant properties. It is used in psychopharmacological research as central serotonergic system challenge. Generically, they are known as "herbal highs", "herbal tonics", "herbal ecstasy" or "party pills". They are generally taken orally and are presented in the form of tablets or capsules. The BZP capsules contain 50 to 200 mg. The mCPP was introduced onto the market as a legal alternative to ecstasy in times of shortages. Often, the mCPP is sold as ecstasy or, in some tablets, mixed with MDMA. In fact, users are often unable to distinguish the effects of BZP from those of D-amphetamine; they report alertness, mood escalation, euphoria and a general feeling of well-being. BZP was initially legally marketed in some countries (notably New Zealand) as an alternative to methamphetamine. If combined with TFMPP, effects similar to those of MDMA ("ecstasy") are produced. Thus, BZP/TFMPP combinations have been widely used on the club and rave scene in many countries. These substances have been shown to have a mixed mechanism of action, acting on both the serotonin and the dopamine receptor systems, much like MDMA, thus showing entactogenic properties. In contrast to BZP, TFMPP is rarely used on its own. Street names of BZP include "Jax" and "Flying Angel". Tablets often contain various types of piperazines (MCCP mixtures, TFMMP, OMPP and/or pCPP). They can be found for sale on the internet, as essentially unrestricted derivatives.

Adverse effects of BZP include repetitive thought patterns, increased heart rate, hypertension, dilation of pupils, nausea, flushing, slight urinary incontinence, chest pain, hallucinations, confusion, acute psychosis, respiratory failure, renal toxicity and seizures. BZP produces toxic effects similar to those of amphetamines and other sympathomimetics. Fatal intoxications have been described (Hill and Thomas 2011; Schep et al. 2011).

Phencyclidine Derivatives

Some new phencyclidine and ketamine derivatives are considered NPS. Their main characteristics are explained in other parts of this chapter.

Plant-Based New Psychoactive Substances: Kratom

Kratom (*Mitragyma speciosa*) has been used in traditional Thai medicine as an antidiarrhoeal and it has been investigated for the treatment of opioid dependence. The cultivation and use of kratom is mostly linked to South-East Asia. However, it is also widely used recreationally, leading to its prohibition in Thailand as well as in

other countries, including Malaysia, Myanmar and Australia. There are 40 compounds in *M. speciosa* leaves, including many alkaloids such as mitragynine (thought to be the primary active constituent), mitraphylline, and 7-hydroxymitragynine (probably the most likely candidate for the primary active chemical in the plant). Kratom behaves as a mu-opioid receptor agonist like morphine, but also acts as a calcium channel blocker, and reduces NMDA-induced current. Kratom is a stimulant at low doses and a sedative at high doses. At low doses, it tends to increase physical energy and alertness and increases the ability to do monotonous physical work. At higher doses, it helps to reduce physical and emotional pain and tends to generate a feeling of well-being before eventually developing its sedative properties, creating a mixed state of wakefulness and dreaming. Withdrawal symptoms for chronic users of kratom may include muscle aches, irritability, crying, runny nose, diarrhoea and muscle jerking (Prozialeck et al. 2012).

35.2.3.6 Clinical and Diagnostic Aspects

Novel psychoactive substances can induce substance use disorder, intoxication and in some cases withdrawal syndrome (for those with psychostimulant properties). Depending on the substance and pharmacological effects, the Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-V) criteria for hallucinogens or stimulants can be applied (American Psychiatric 2013).

The therapeutic aim in these cases is to reduce consumption and achieve abstinence. In some cases of NPS use cessation can be easy because there is no physical dependence; in other cases (with a more psychostimulant profile) some symptoms of withdrawal syndrome can be observed. There are no specific drugs for treating disorders caused by these substances. Psychotropic drugs will be used according to the patient's symptoms (benzodiazepines, hypnotics, antipsychotics, antidepressants). As in the other drug addiction programmes psychiatric and psychological support components are used.

In the case of MDMA use disorder patients with dependence and persistent severity criteria were observed. In many cases it may be useful treat with pharmacological and psychological therapy.

It is very important to carry out a psychiatric evaluation by a specialist to diagnose a substance use disorder, and evaluate the comorbidity of psychiatric illnesses. In many cases early pharmacological treatment is necessary. It is important to be aware of cases of poisoning by NPS, as the pharmacodynamics are not yet known. It is recommended that samples are stored for study. To conclude, the emergence of new psychoactive substances as drugs of abuse is a serious problem which impacts global public health.

Inhalant Addiction

36

Tania Real, Silvia L. Cruz, and María Elena Medina-Mora

Contents

Abstract

Inhalants are a special class of drugs that require particular attention from health and social welfare experts and policy makers. They are substances of abuse not included in the International Regulations. They are also less frequently targets for health and social interventions as well as for research funding. Inhalants are

the only drugs of abuse defined by the route of administration rather than by their attributes, specifically by similar mechanisms of action or common pharmacological effects. They include a broad group of substances with different uses, short and long-term negative effects, and consequences. These products have legal uses in industry and households and are therefore readily available. Inhalants are used by young students and populations with special needs, mainly children and adolescents from poor sectors of society, workers who use solvents for their everyday work (such as varnishers, house painters, and anesthetists), and heavy drug users, especially when they lack access to other substances. The short-term effects of inhalants are similar to alcohol and other central nervous system depressants and can produce impaired motor coordination, emotional liability, and speaking difficulties. Chronic effects include neurotoxicity, cognitive impairment, headaches, diminished sensorial abilities (loss of vision, audition, and coordination), and an increase in mental disorders and sleep disturbances. Inhalant use prevention involves different strategies, including education, skill building, environmental changes, and policy development. There is little research on evidence-based treatment for inhalant addiction. However, treatment should include supportive psychotherapy, family and psychosocial interventions, general health care proper nutrition, and vitamins or nutritional supplements. The long-term outcome of inhalant addiction is usually progressive neurocognitive deterioration with multiple medical complications.

36.1 Introduction

Inhalants are a special group of substances with varied effects, differences in use patterns and populations affected, and with special needs for prevention, treatment and policy formulations. This chapter focuses on this issue; it is divided in 6 sections, beginning with a general overview of the substances and definitions. This is followed by a description of prevalence, the groups of affected population and use patterns in different regions of the world. Particular attention is paid to use among groups with special needs, to their effects and consequences; the social determinants that underlie the problem and opportunities for solution are also addressed. These sections are followed by a brief overview of the evidence for prevention and treatment. The chapter ends with a discussion on policies to address the problem.

36.2 Definition and Classification

A working definition proposed by Balster and colleagues states that:

> Abused inhalants contain volatile substances that are self-administered as gases or vapors to induce a psychoactive or mind-altering effect. These volatile substances are available in legal, relatively inexpensive and common household products, which can be gases, liquids, aerosols or, in some cases, solids. (Balster et al. 2009)

NIDA's definition (2012) includes the main issues that characterize this varied group of substances and their effects: the intentionality of their use, due to the chemicals' mind-altering effects; the nature of the short-term effects (most of them produce a rapid high that resembles in some aspects alcohol intoxication); the effects when sufficient amounts are inhaled, as nearly all solvents and gases produce a loss of sensation and even unconsciousness; the long-term irreversible effects that can include hearing loss, limb spasms, and bone marrow and brain damage; and lastly, the risk of death when sniffing high concentrations of inhalants, which may result in death from heart failure hypothermia or suffocation.

A wide range of substances are grouped together into this class, which by its very nature challenges definitions and classifications. Inhalants include (1) solvents (liquids or semisolid substances that evaporate and include glue, shoe polish, toluene, and gasoline, among others); (2) aerosol sprays (volatile substances or gases such as spray paints, hair sprays, cleaners for computers, etc.); (3) gases (anesthetics for medical use such as ether, chloroform, butane, and refrigeration products); and (4) nitrites that include products containing butyl nitrite and amyl nitrite, known as "poppers," locker room deodorizers, or "rush," and nitrous oxide known as "whippets."

The physicochemical classification is: (a) gases or can easily become vapors at room temperature (without heating); (b) nonpolar molecules with high affinity for lipids and can therefore cross all biological membranes; (c) flammable; (d) usually lighter than water in their liquid form, but as vapors are heavier than air, meaning that they are not easily dispersed from rooms where they have been inhaled (Cruz 2011).

Since many substances meet these criteria, they can be classified on the basis of chemical structure (hydrocarbons, ethers, ketones, etc.), commercial use (solvents, anesthetics, propellants, etc.), physical state (gases, liquids, aerosols), or effects on the central nervous system (depressants, vasodilators, etc.). Each classification has its own limitations, and some substances may fit into several categories. For example, butane is a hydrocarbon gas used both as a fuel and a propellant; nitrous oxide is a propellant and also an anesthetic gas used in dentistry. Moreover, a single substance can have different names such as toluene, methylbenzene, phenylmethane, or toluol. This compounds the difficulties associated with inhalant research. Table 36.1 shows some commonly misused compounds and their synonyms and chemical structure, examples of commercial products, threshold limit values (TLV: maximum average concentration to which workers can be exposed 8 h/day, 5 days/week, without experiencing significant adverse health effects), and vapor concentrations in air that are dangerous to life and health (IDHL). This table also includes CAS#, a unique chemical abstract service number that may be used to obtain key information on individual compounds. A detailed table of the physicochemical properties of main inhalants can be found elsewhere (Bowen and Cruz 2014).

Although there is insufficient evidence to establish a scientifically based pharmacological classification of inhalants, it is possible to distinguish at least three different categories with various mechanisms of actions: (a) solvents, fuels, and

Table 36.1 Synonyms, products and safety limits of inhalants

Class	Compound	Structure	Synonyms	CAS#	Products	TLV (ppm)	IDLH (ppm)
Hydrocarbon, acyclic	*n*-Hexane		Hexyl hydride, dipropyl	110-54-3	**Gasoline**, solvents, glues, varnishes	50	1,100
Hydrocarbon, alicyclic	Cyclohexane		Hexamethylene, Hexanaphtene	110-82-7	Lacquers, resins, varnish removers, solvents, cigarette smoke	300	1,300
Hydrocarbons, aromatic	Benzene		Benzol, phenyl hydride, cyclohexatriene	71-43-2	Gasoline	0.5	500
	Toluene		Toluol, methyl-benzene, phenylmethane	108-88-3	Solvents, paints, thinners, glues, lacquers, gasoline, inks, cigarette smoke	50	500
	Xylene		Xylol, dimethyl-benzene, methyl toluene	1330-20-7	Cleaning agents, thinner. Used in printing, rubber and leather industries	100	900
	Ethyl-benzene		Phenyl ethane, ethyl benzol	100-41-4	Gasoline, paints, inks. Used as styrene precursor	100	800
	Propyl-benzene		Phenyl propane, isocumeme	103-65-1	Gasoline. Used in textile dyeing and printing	N.E.	N.E.
Hydrocarbons, halogenated	1,1,1-TCE		Trichloroethane, TCE, perchloroethylene, tetrachloroethane, methyl chloroform	71-55-6	Cleaning products, paints, correction fluids, degreasers	350	700
	1,1,2-Trichloro-ethylene		TCE	79-01-6	Solvents, dry cleaning products,, degreasers (car parts) Plastic spray fixative	50	1,000

	Diethyl-ether		Ethyl ether, octapentane, ethoxy ethane	60-29-7	Anesthetic, solvents, fuels	400	1,900
	Chloroform		Trichloromethane Methyl trichloride	67-66-3	Anesthetic, spot removers, precursor for refrigerants	10	500
	Halothane		Fluothane	151-67-7	Anesthetic	50	N.E.
Inorganic	Nitrous oxide		Dinitrogen monoxide	10024-97-2	Anesthetic, laughing gas, propellant (hair sprays, whipped cream, cooking spray), engine combustion enhancer	50	N.E.
Hydrocarbons, acyclic	Propane		Dimethyl methane, LP gas	74-98-6	Industrial fuel, refrigerant, aerosol propellant	1,000	2,100
	Butane		Methylethyl ethane, Freon 600 LP gas	106-97-8	Lighter fuel, gas tanks for cooking, refrigerant, aerosol propellant (deodorant sprays)	800	N.E.
Hydrocarbons, Halogenated	1,1-difluoroethane		Ethylene fluoride, Freon 152 a, R152a, HCF152a, Dymel	75-37-6	Propellant (PC duster), refrigerant (air conditioning)	1,000	N.E.
	1,1,1,2-Tetrafluoroethane		Freon 134 R134	811-97-2	Propellant (PC duster), refrigerant (car air conditioning systems)	N.E.	N.E.

anesthetics; (b) nitrous oxide; and (c) volatile alkyl nitrites. The first is the most extensive group and includes inhalants misused throughout the world in the form of gasoline, industrial solvents, adhesives, paints, sprays, inks, pen markers, and many other commercial products. Among solvents, toluene is the most frequently misused and the best-studied inhalant compound. It is the main component of paint thinners (mixed with xylene, ethylbenzene, and other solvents in different proportions), inks, adhesives, and degreasing agents. Commercial xylene (a mixture of the three isomers: ortho-, metha-, and para-xylene) is used in the leather and rubber industries and histology laboratories. The solvent known as 1,1,1-TCE or trichloroethylene is also present in correction fluids, but no longer produced in most developed countries because it is harmful to the ozone layer. Gasoline is a mixture of several solvents, which may or may not contain lead. Several anesthetic gases such as halothane, ether, and chloroform are included in the same group with solvents because they share some of the effects and mechanisms of action of misused solvents.

Nitrous oxide is in a class of its own because of its unique pharmacological profile and affinity for specific receptors. It is used as a propellant in whipped cream products and as an anesthetic gas for dental procedures. As for nitrites, they are smooth muscle relaxant and vasodilator drugs rather than depressant substances and are inhaled from small bottles, some of which "pop" when opened (hence the name "poppers") (Cruz and Bowen 2008).

36.2.1 Epidemiology: How Widespread Is Its Use?

Worldwide inhalant misuse has mainly spread among young people. Although there are variations in the age of onset, the trend in most countries is toward an increasingly early start. Age at first use is generally 6–8 years, while peak age for abuse is 14–15 years (O'Malley 2012). The period of risk for drug use initiation among special populations such as youth from Indian communities has been reported as between the ages of 10 and 13 years, with the onset among some individuals being as young as 5–6 years of age (Hillabrant 2001).

In the Americas, there are countries like Canada and the United States that have seen a decrease in consumption. However, in Latin America and the Caribbean, it is a growing problem and has gone from being a drug consumed by street children to one that is consumed by children and young students and even university students (OEA 2011).

According to a study on young Americans (Johnston et al. 2014), inhalant consumption increased from the late 1970s to the mid-1990s, especially in 8th, 10th, and 12th grade. Trends have changed and in 2001, consumption began to decrease. The last measurement in 2013 shows that annual prevalence was 5.2 % in 8th grade, 3.5 % in 10th grade, and 2.5 % in 12th grade. Despite the variations, the trend is for consumption to decline, a trend that is believed to be associated with information campaigns.

In Canada, the Report on Alcohol and Drug Use by Students (Young 2011) indicated that among 7th and 12th grade students, inhalants are the fourth most ever

consumed drug (2.2 % and 3.8 %), respectively, preceded by alcohol, cannabis, and ecstasy, and prevalence in the last year reached 2.6 % and 4.4 %.

In Mexico, this practice has experienced periods of increase and decrease among students in various regions. For instance, in Mexico City, annual prevalence increased from 4.4 % in 2006 to 7.5 % in 2009, to decrease again in 2012 to 5.9% among high school students, with use remaining stable after 2009 (Villatoro et al. 2012). More recent surveys show that inhalation rates have remained unchanged. According to the National Household Survey 2011 conducted among the population ages 12–65, annual prevalence of use in the previous year was low, 0.1 % with no significant modifications from 2008 (SSA et al. 2012). This same trend is reported by the Epidemiological Surveillance System that gathers information on cases seeking treatment in nongovernmental organizations. Inhalants were the drug of "impact" defined as the one which, according to patients, constituted their main problem of abuse in 7.6 % of patients in 2009 and 7.2 % in 2011 (SSA 2013).

In most Latin American and Caribbean countries, apart from tobacco and alcohol, inhalants are the most commonly used substance after cannabis, especially among high school students, although there are countries where it is the first drug of choice (OEA 2011).

The lowest prevalence of ever use has been reported in Venezuela (0.7 %), Dominican Republic (1.1 %), Honduras (1.6 %), Guatemala (2.1 %), and Nicaragua (2 %) in surveys conducted among high school students between 2003 and 2009. The lowest prevalence in the past year in this same population was reported in the same countries, together with Uruguay (1.4 %). And the lowest use last month was also reported in the same countries: with less than 0.4 % reporting use.

The highest prevalences in the three measurements ever use, in the past year and last month, were found in Brazil (15.6 %, 14.3 %, 9.9 %), Barbados (19.6 %, 9.9 %, 6.4 %), Guyana (21.7 %, 10.5 %, 6.9 %), Trinidad and Tobago (26.3 %, 13.2 %, 7.4 %), and Jamaica (28.1 %, 13.9 %, 9.4 %) in surveys conducted between 2004 and 2007.

College students also report use of these substances. In countries in the Andean Region, a study showed that during the past year, the highest prevalence was reported in Bolivia (1.8 %) followed by Colombia and Peru (1.4 % and 1.7 %) and Ecuador with 0.77 %.

There are also differences by sex: in Argentina, Bolivia, Colombia, Costa Rica, Dominican Republic, El Salvador, Guatemala, Honduras, Nicaragua, Panama, Suriname, and Uruguay, men have higher rates. In countries such as Antigua, Barbados, Granada, and Trinidad and Tobago, rates are higher among women, especially in Jamaica where the proportion is over twice that of men. In the United States, girls in 8th and 10th grade have slightly higher consumption (OEA 2011). In Mexico, household surveys show that more males than females use solvents (ENA 2011), but among high school students, gender differences have vanished (Villatoro et al. 2012). A similar situation is observed in Ontario, Canada, among high school students, with no difference in rates last year by sex, 5.3 % and 5.9 % among males and females, respectively (CAMH 2011). In Chile in secondary students (13–17 years), last year prevalence was 3.7 % and 3.1 % for males and

females, respectively, and in Ecuador 3.1 % males and 2.2 % females reported having used in the last 12 months (UNODC 2010).

In Europe, rates for students between the age of 15 and 16 varied between 17 % in the Isle of Man and 15 % in Ireland to 3 % in Bulgaria, Ukraine, and Lithuania (ESPAD 2007). In Africa, solvents and inhalants were the seventh drug of choice with a prevalence of 3.2 % in 2009.

In 2008, in Central Asia, UNODC (2008) reported that inhalant consumption among young people had increased and in some cases exceeded that of cannabis. For example, Tajikistan has a prevalence over the past 12 months of 8.4 % for boys and of 4.2 % for girls. In the past month, the figure was 2.1 % for boys and 3.6 % for girls. In Kazakhstan, the prevalence for boys was 2.4 % as opposed to 2 % for girls in the past year and 1.3 % and 1.1 % in the past month. Kyrgyzstan reported 2.4 % of boys and 1.7 % in girls in the past year, and for the last month, the figures are 1.6 % and 1.1 %. An earlier survey in this country (2006) reported inhalants as the first drug of use, with 5.4 % ever use. Lastly, in Uzbekistan, figures for the past year are 0.4 % for boys and 0.3 % for girls and 0.3 % versus 0.2 % in the past month.

A final word of caution, the rates reported in this section of the chapter are drawn mainly from surveys, that not always use the same definitions, and furthermore, these sources might underestimate prevalence of use rates among difficult-to-reach populations, not included in survey approaches, such as street children and prisoners, described in the following section. Rates of use among these groups are considerably higher.

36.2.2 Use Among Special Populations

Studies conducted in different parts of the world show that young people from low-income, chaotic, broken, or abusive homes appear to have the highest rates of use (Oetting et al. 1988). According to O'Malley (2012), in the United States and Canada, long-term use of inhalants is more common in inner-city and remote rural community residency; it is also associated with lower socioeconomic class, Latin American immigration, and family dysfunction.

Villatoro et al. (2012), analyzed data from national household surveys in Mexico and, found that those drug users that reported having ever inhaled, as compared to cannabis users that had not experimented with these substances, came from more disorganized and violent communities and also reported having being involved in fights, selling drugs, and other problem behaviors more frequently. Storr et al. (2004) using data from a nationally representative population sample ages 12 and older in the United States ($n = 25{,}500$) examined whether living in disadvantaged communities increased the likelihood of coming into contact with drug dealers as compared with persons living in more advantaged areas, and found that the physical and social characteristics of a neighborhood determined the likelihood of becoming involved with drugs.

High inhalant abuse rates have also been documented among street children living in South America, Eastern Europe, and Asia (Forster et al. 1996;

Pagare et al. 2004). For instance, in a study conducted in Mexico in 100 cities, rates of use varied from 3 % among adolescents working on the streets to 72 % among those living in the streets; the substance of choice being toluene (Medina-Mora et al. 1999).

This practice has also been reported across indigenous communities in Australia and North America (Beauvais and Oetting 1988; Chalmers 1991). In these communities, lifetime prevalence rates of petrol sniffing among adolescents reach 50–60 % and appear to be associated with the isolation (both geographical and social), poverty, and unemployment prominent among these marginalized groups (Cairney et al. 2002). According to Remington and Hoffman (1984), inhalation of gasoline tends to occur in poor, isolated communities and on Indian reservations where unemployment is widespread and few organized social activities are available to youth.

The National Inhalant Prevention Coalition (NIPC) reported that 20 % of the Kickapoo Tribe is "addicted to spray paint," this group's drug of choice. According to this Coalition, it alleviates hunger, and the periods of intoxication last longer than those produced by alcohol. Users also report that paint-induced hallucinations are easily incorporated into tribal traditions (News Briefs, NIPC 1997). A survey of Navajo 8th graders found that almost 25 % have tried inhalants, with 12 % having used inhalants in the previous month. This survey reinforces the findings of other studies that report that the majority of inhalant abusers are young. Leal et al. (1977) also found that toluene abusers in Mexico City declared that solvent sniffing alleviated hunger and that they enjoyed the altered perceptions it produced.

36.2.3 Patterns of Use

As is the case with other drugs, inhalers can be classified as experimenters, regular users, heavy users, and persons with dependence. Among students, especially those in early adolescence, the most common pattern involves experimentation with a low proportion of regular users and an even smaller proportion of students that have developed dependence. For instance, among American and Australian students, experimental inhalant use rates during early adolescence are high (26 % of 12-year-old students), whereas the proportion that reports inhaling on a regular basis is over six times smaller (4 %) (Johnston et al. 2003; White and Hayman 2004). In Mexico City and Jalisco, experimentation rates (using one to five times) among young students (7–9 years of school) are also considerably higher (66 % and 76 %, respectively) than rates for use on over five occasions (44 % and 24 %) of all persons that have ever used (Villatoro et al. 2012; Chávez et al. 2013). This pattern differs from the one observed among adolescents living on the streets who are heavily involved in inhalation, with daily heavy use being the most common pattern combined with periods of complete abstinence (Medina-Mora and Berenzon 1997).

Few studies report dependence rates among them. Perron and colleagues (2011), using data from the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) household sample of persons ages 18 and older in the

United States, documented that 19.5 % of lifetime inhalant users met the criteria for DSM-IV inhalant use disorder (abuse 17.2 % or dependence 2.3 %).

Inhalants are usually "sniffed" directly from the container to the nose, but inhaling fumes through the mouth ("huffing") is also common. The open tube of glue or nail polish is usually placed close to the nose and the fumes are inhaled. Sometimes users heat substances to speed up the vaporization process which increases the risk of gas explosions. Other forms of use include inhaling from damp rags or shirt sleeves or from plastic or paper bags ("bagging"). Fatal accidents may occur when the inhaler places the whole bag over his head; balloons filled with substances such as nitrous oxide have also been reported (NIPC 1997). Some authors have reported that the route of administration is related to environmental factors such as the presence of police and the need to disguise use (Medina-Mora and Berenzon 1995). A case study in India reports petrol inhalation by a 10-year-old boy who began to inhale it accidentally by putting his face to the keyhole of the petrol tank on his father's motorbike (Basu et al. 2004).

Preference for specific substances varies according to the characteristics of the groups that use them and their effects; Takagi et al. (2010), for example, when assessing preferences for types of paint among inhalers in Australia, found that compared to non-chrome users, chrome-using groups was more likely to report deliberately inhaling to experience altered perceptions (such as visual and auditory hallucinations). A greater proportion of chrome users reported that the perceptual alterations they experienced after sniffing paint differed between paint colors, with more vivid hallucinations being produced by chrome colors. Similarly, Leal et al. (1977) reported that children living on the streets in downtown Mexico City preferred pure toluene for its psychotropic effects and lower level of toxicity. Cruz and Domínguez (2011) have also documented hallucinations among heavy inhalers in Mexico who use toluene or a mixture of solvents.

Common choices for solvents among American Indian youth and Alaskan Natives are gasoline (28 %), glue (23 %), paint removers and nail polish remover (18 %), and paint sprays (17 %). In this group, as is often the case with street children (Medina-Mora et al. 1997), most of the substances inhaled contain mixtures of chemicals, making it almost impossible to determine which compounds are responsible for the effects experienced by the abuser and observed by therapists (Oetting et al. 1988).

Trotter et al. (1977) reported that inhalant abuse was sometimes combined with drinking the liquid residue left in aerosol cans after sniffing the propellant (Trotter 1997). Hillabrant (2001) published interviews with Navajo adolescents who reported the fad of drinking hair spray, users of which faint after five bottles an hour.

Some groups in Mexico use "compressed air" at special gatherings known as "perreos" or "grinding, booty dancing, bumping, or housing" in the Caribbean. Inhalants and alcohol are the substances consumed; attendees may buy a piece of rag soaked in toluene that has been flavored. Risky sexual behavior and fights are common (Gutiérrez et al. 2007). Having sex under the effects of poppers has been documented among gays and; use of these substances has been associated with

having casual partners (Lampinen et al. 2007). In Brazil, lança perfume (chloroform/ether) is used by students (Mesquita et al. 1998) mainly by those pretainig to a upper-class ones (Sanchez 2012).

36.3 Health Effects

Inhalants: Short-term effects are similar to alcohol and other central nervous system inhibitors as regards initial stimulation and persistence. They act as anxiolytics, antidepressants, and anticonvulsants and are associated with impaired motor coordination, emotional lability, and difficulty speaking. Chronic effects include neurotoxicity, cognitive impairment, headaches, diminished sensorial abilities (loss of vision, audition, and coordination), and an increase in mental disorders and sleep disturbances.

There is evidence that the more widely used inhalants share cellular mechanisms and have similar effects to other drugs, particularly depressors of the central nervous system (Cruz 2011) although the use of these substances has also been associated with illusions and hallucinations (Cruz and Dominguez 2011). When used by pregnant rats, they affect development, and irregular heartbeat during intoxication has also been described (Cruz et al. 2003). Unfortunately, a significant shortage of information remains, despite the increase in research projects addressing the neurobiology of inhalants; the majority are still conducted on toluene. Little is known of abstinence, and researchers do not know the extent to which cognitive or other effects may be reversible, although some laboratory experiments with enriched environments have provided evidence of reversibility (Lubman et al. 2008; Páez-Martínez et al. 2013).

36.3.1 Acute Effects

Inhalants vary in their chemical composition and consequently in how and where they act. In fact, it is rather surprising that such a dissimilar group of substances should have the same effects, although this is partly due to their common administration route. Misusing inhalants implies introducing gases other than air into the body causing poor brain oxygenation (hypoxia) and the attendant deleterious consequences. This happens with all inhalants regardless of their pharmacological profile and constitutes a significant health hazard in itself.

Once in the body, inhaled vapors rapidly achieve various specific molecular targets to induce a state of intoxication similar to that produced by other central nervous system depressant drugs such as alcohol and barbiturates. The pulmonary route is highly efficient because the lungs are profusely irrigated and have extensive absorption surface. This results in rapid intoxication, which is, however, short-lived due to inhalants' high volatility. In order to maintain the effects, users repeat the experience every few minutes to maintain the desired level of active substance in the brain.

Several solvents and fuels produce a transient state of excitation followed by a more persistent sedation, lack of motor coordination (ataxia), slurred speech, cognitive impairment, and slow reactivity toward the stimuli (Sharp et al. 2008). At high concentrations, illusions and hallucinations are common and known to play an important role in the motivation to inhale and socialize (Cruz et al. 2011; MacLean 2007). When anesthetic gases are intentionally used, sedative effects combined with psychoactive actions can be extreme.

Other effects depend on the type of compound inhaled. Let us consider the case of solvents. The respiratory system is the first to come into contact with the irritant vapors of these substances, producing coughing, frequent nose bleeding, rashes, and dry skin around the nose and mouth. Irritation is frequent in all parts of the body (usually hands and arms) that come into contact with rags or tissue papers soaked with solvents because – as degreasing agents – solvents damage the dermal lipid layer. Among this type of inhalants, apparently only toluene produces notoriously detrimental effects in acoustic perception, initially described as a strong buzz and chronically associated with inner ear damage. On the other hand, if the gas inhaled is nitrous oxide (also known as laughing gas), hilarity, mood swings, altered perception, and anesthesia may occur. Inhalation of 1,1-difluoroethane, a gas used as a propellant in computer dusters, can cause frostbite in the tongue, mouth, larynx, and other soft tissues in addition to its psychoactive actions.

Volatile alkyl nitrites differ from all other inhalants because they produce vasodilation and smooth muscle relaxation rather than cognitive effects. Amyl nitrite was introduced as medication for the treatment of angina pectoris until it was replaced by nitroglycerine. Amyl, butyl, and isobutyl nitrites are sought as sexual enhancers due to their ability to increase genital irrigation. These compounds decrease blood pressure, increase heart rate, and, under some circumstances, can cause syncope. These harmful cardiovascular effects may be enhanced if alkyl nitrites are combined with phosphodiesterase-5 inhibitors, the active ingredients of medications used to treat erectile dysfunction.

36.3.2 Chronic Effects

Repeated inhalant use produces chronic irritation of the respiratory airways with breathing difficulties and increased frequency of respiratory illnesses, anosmia (decreased capacity to detect odors), and general cognitive impairment. Chronic inhalant users have a higher incidence of neurobiological abnormalities including diffuse cerebral and cerebellar atrophy, enlarged brain ventricles, and general white matter damage. These abnormalities have been correlated with attention dysfunction, impaired motor control, and memory loss together with reduced speed of information processing, among other detrimental effects (Yucel et al. 2008). Inhalation of toluene-based products can cause hearing loss, visual impairment, and severe ataxia (Filley et al. 2004).

Benzene, a component of gasoline, produces anemia and leukemia because it impairs blood cell formation in the bone marrow. The toxicity associated with

gasoline inhalation may not only be linked to benzene but also to the presence of lead in countries that do not use unleaded gasoline. Hexane, another organic solvent used in inks and other products, causes peripheral neuropathy because it is metabolized to 2,5-hexanedione, a highly toxic compound.

Halogenated compounds, in other words, those containing chloride, fluoride, or bromide in their structure, such as 1,1,1-trichloroethane, trichloroethylene (a degreasing agent and spot remover), halothane (a liquid anesthetic), or 1,1-difluoroethane (PC duster) can produce liver and kidney failure as well as cardiac arrest.

Repeated exposure to nitrous oxide produces a vitamin B_{12} deficiency, which may lead to damage to the neuron's myelin sheath manifested as ascending lower extremity weakness and numbness (Lin et al. 2011). As for nitrites, chronic users of this compound can experience bilateral vision loss due to retinal damage (Audo et al. 2011).

36.3.3 Prenatal Effects

The fact that the gender gap is being reduced poses specific challenges for service providers and researchers owing to the harmful effects of inhalants in women of reproductive age. A fetal solvent syndrome, similar to that caused by alcohol, has been described in babies born from mothers who used inhalants during pregnancy. This syndrome includes facial anomalies, delayed growth, and impaired neurobehavioral development (Bowen 2011). Low weight at birth and craniofacial abnormalities have also been documented in both clinical and preclinical studies (Hannigan and Bowen 2010). Follow-up studies of children exposed to inhalants during gestation have shown growth retardation, learning impairment, cerebellar dysfunction (affecting balance), language deficiencies, and hyperactivity. It is worth mentioning that some of these studies cannot rule out the use of other drugs and, in fact, it is fairly common for inhalants to be used in combination with other psychoactive substances. However, animal studies in which environmental conditions are controlled and only solvents are used support these findings.

36.3.4 Molecular Effects

The available evidence indicates that toluene, the best-studied misused solvent, has a complex mechanism of action, which includes effects on diverse molecular targets. Although detailed description of toluene's mechanism of action is beyond the scope of this chapter and has been reviewed elsewhere (Bowen et al. 2006), a few relevant data might be worth noting. Toluene inhibits the function of certain channels activated by excitatory neurotransmitters such as the glutamatergic NMDA receptors (Cruz et al. 1998) and nicotinic receptors (Bale et al. 2005a). At similar concentrations, toluene enhances the function of inhibitory neurotransmitter receptors such as GABA (Bale et al. 2005b) and glycine (Beckstead et al. 2000). Calcium channels, potassium channels, and sodium channels are also

affected by toluene (Shafer et al. 2005; Cruz et al. 2003; Del Re et al. 2006). Like other drugs of abuse, toluene increases dopamine release in key areas of the dopaminergic mesolimbic system. Less data are available on other solvents, but evidence indicates that at least the effects on GABAergic and glutamatergic systems are common to many substances including the majority of inhaled gases.

36.3.5 Morbidity and Mortality

Mortality is associated with this practice. Sudden sniffing death is a rare but serious complication that may occur at any time, even after single use; in other words, it is not necessarily associated with repeated or prolonged exposure. Death can be due to a combination of factors including poor oxygen supply, a direct cardiac effect (arrhythmias), and sensitization to catecholamine stimulatory effects. Sudden death may occur when an intoxicated user is startled because catecholamines are released, the heart function is increased, and cardiac arrest becomes more likely (Bowen 2011). It has also been reported as a result of adrenaline surge. It can occur during abuse or in the next few hours because solvents, dissolved in lipid-rich cell membranes, dissipate slowly.

Other causes are derived from the interaction between the substances abused, the user, the route of administration, and the environment. Suffocation and trauma may occur when a user puts a plastic bag sprayed with a solvent over his or her head to enhance the amount inhaled; the plastic bag may occlude the airway if the user loses consciousness. Death by aspiration, usually of vomit, is similar to that observed for alcohol and other depressants and results from a combination of a decreased level of consciousness and the loss of protective airway reflexes. Risk of accidents is high as users become less inhibited and less alert and oriented, which facilitates engagement in risky behaviors (Williams et al. 2007).

Lifestyles of certain subgroups such as street children raise the burden related to violence and increase the risk of HIV from sexual abuse and prostitution (Medina-Mora et al. 1997). In a survey conducted in 100 cities in Mexico among working children and adolescents ages 6–17, Medina-Mora found that fewer than 1 % declared prostitution as their source of income. Increased risk of seroconversion among the street population has been reported in other sites (Roy et al. 2003).

The Toxic Exposure Surveillance System (TESS) database of the American Association of Poison Control Systems showed 63 deaths in 11,670 cases of intentional inhalant abuse reported from 1996 to 2001 to poison control centers in that country, linked to gasoline inhalation (45 %), air fresheners (26 %), and propane/butane (11 %) (Spiller 2004). In two particular states, Virginia and Texas, a higher rate was found, 39 and 144, respectively, the majority linked to fuel inhalation.

There is a wide range of diseases linked to this practice that includes ichthyosis-like dermatitis on the extremities, decreased visual acuity, toxic hepatitis, distal renal tubular acidosis, metabolic acidosis, leukemia, and aplastic anemia.

There is also evidence of tolerance, dependence, and withdrawal, among many other disorders: despite this evidence, there is insufficient data to allow the assessment of the proportion of the global burden of disease related to this behavior (Degenhardt and Hall 2012).

36.4 Correlates

In a review published in 2008, Medina-Mora and Real found evidence of high rates of psychiatric comorbidity, mood, anxiety, and personality disorders being common among lifetime inhalant users. They also reported a higher prevalence of lifetime dysthymia and anxiety disorders among female inhalant users, although a lower prevalence of antisocial personality disorder. Among inhalant users with comorbid disorders, those who developed social or specific phobia had experienced the onset of these disorders prior to the initiation of inhalant use; all other mood and anxiety disorders usually developed following the onset of inhalant use. Odds of psychiatric disorders were higher for inhalant users who were women, poor, and less educated and with an early onset of inhalant use, family histories of psychopathology, and personal histories of substance abuse treatment.

These same authors also concluded from their review of the literature that among incarcerated youth, compared to users of other substances, inhalant users showed significantly higher levels of criminal behavior, antisocial attitudes, current psychiatric symptoms, earlier onset of offending and substance use, and more extensive histories of head injury, kidney disease, hormonal problems, mental illness, suicidality, trauma, and substance-related problems (Medina-Mora and Real 2008).

The complexity nature of this problem as described requires complex, culturally sensitive interventions at the individual, familial, and community level and public policies designed to reduce the risk associated with the substances themselves and to control availability with a particular focus on children and adolescents, the modification of the social determinants underlying this disorder, the reduction of health disparities, and the promotion of development.

36.5 Prevention

Prevention entails various strategies, including education, skill building, environmental changes, and policy development. School setting prevention programs suggest the importance of involving the whole community: students, teachers, administrators, school nurses, guidance counselors, school social workers, school psychologists, librarians, parent volunteers, school police and safety officers, coaches, clerical staff, cafeteria workers, custodians, and bus drivers (Virginia Department of Education 2007).

Other authors report that efforts to prevent volatile substance abuse should focus on community interventions. In particular, information should be distributed to health workers, educators, media representatives, and parents (Dell 2003).

Many strategies focus on educating very young children about the dangers of inhalants and disseminating messages that depict inhalants as poison. In Texas in the United States, some of these programs have attempted to redefine the problem as a public health rather than a substance abuse issue. This perspective facilitates the involvement of community partners, nurses, emergency room personnel, medical associations, and poison treatment centers.

Other prevention interventions have been developed and provide educational materials and resources for families, school, and media. Products include staff training and curricula for schools and resources for teaching parenting skill (NIDA 2005).

Some populations require special attention among them the Indigenous populations. Interesting cultural adaptations can be found, for example, in programs for Alaskan Natives aimed at making students aware of the dangers of inhalants (Hillabrant et al. 2001). A program for young migrants from Morocco, included attention for basic needs and identification and intervention with those recently involved with inhalants. The program also included workshops on health promotion, sports and art activities (Foundation Search 2002). As in treatment, prevention includes teaching and helping children, teenagers and their families to build strengths, increase cultural self-identity, develop social and emotional skills (Dell et al. 2003).

36.6 Treatment

Considering the broad range of compounds included in the inhalants category, several approaches are required to deliver effective treatment to chronic users.

36.6.1 Recovery Potential and Treatment

Despite the impact of the negative effects of inhalant misuse reviewed in this chapter, there is some evidence of the potential for recovery from deleterious cognitive and neurological effects that occurs following abstinence from solvent misuse, depending on the extension and duration of inhalant misuse (Dingwall and Cairney 2011). Bowen and Cruz (2014) described evidence indicating that the myeloneuropathy associated with chronic use of nitrous oxide improves with inhalant discontinuation and vitamin B_{12} supplementation (Alt et al. 2011) and that retinal damage produced by chronic nitrite inhalation can recover after cessation (Audo et al. 2011). Unfortunately, some negative sequelae, such as benzene-induced leukemia or liver toxicity produced by halogenated compounds, would appear to be more devastating. Support in the form of cognitive behavioral therapy, attention to organic damage (e.g., hearing or sight loss), and treatment of psychiatric comorbid disorders when needed are important components of successful treatment programs.

In this same review, Bowen and Cruz (2012) conclude that to date, there is no available pharmacological therapy for treating this substance use disorder, but some

evidence of limited success has been found, such as using risperidone to control paranoid psychosis in a man who had been inhaling gasoline and carburetor cleaner daily for 5 years (Misra et al. 1999). Other authors have reported that the severity of the symptoms of inhalant-induced psychotic disorder, which was reduced when treated with either carbamazepine or haloperidol (Hernandez-Avila et al. 1998). Moreover, daily administration of lamotrigine decreased craving in a 21-year-old man with a 4-year history of inhalant misuse (Shen 2007). More investment in research will lead to better pharmacological treatment.

Psychosocial interventions have proved effective. These include housing, programs aimed at promoting school attendance and retention, alternatives such as art activities, counseling, and outreach for children at risk of becoming street children (Echeverría and Tavera 2007).

Good treatment models are an important factor in improving the quality of life of those affected and reducing the costs for society; availability of services and service utilization complete the equation. We know from the World Mental Health Survey that the treatment gap for mental disorders including substance use disorders is important, between 35.5 % and 50.3 % in developed countries and 76.3 % and 85.4 % in developing countries (Demyttenaere et al. 2004), and that the treatment gap in some countries such as Mexico is similar for substance use disorders (Borges et al. 2007) but few studies report rates of service utilization by type of substance in subjects, with dependence on inhalants.

Perron and colleagues (2011) within the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) reported that among those with dependence (2.3 %), 66 % were using some sort of service, mainly 12-step programs (68.5 %) followed by drug rehabilitation programs (61.2 %) and private practitioners (55.6 %). A total of 15 % reported at least one barrier to receiving services with the low-income group reporting more barriers (22.8 %). The most common treatment barriers were related to a lack of understanding of what dependence means; between 41 % and 43 % declared that "the individual should be strong enough to handle it alone" or "thought the problem would get better by itself." The same proportion (42 %) reported that they did not want to seek help. In around a third (28.8 %), barriers were related to stigma, "feeling too embarrassed to discuss it with anyone." Lack of resources was reported by one fifth of those with dependence (23.2 %). This suggests the need to introduce policies to increase both treatment and service utilization coverage.

36.6.2 Policy Options

As reviewed in this chapter, inhalant misuse is a phenomenon characterized by significant inequalities as regards the social context of the most severely affected users who tend to come from poorer, more disorganized, or isolated communities, who are more likely to be exposed to low-quality substances, violence, and other adverse experiences. They also have fewer education and job opportunities and worse health outcomes and socioeconomic consequences such as dropping out of school,

unemployment, employment in the informal sector, stigmatization, and barriers to accessing health care. This scenario calls for the inclusion of intervention efforts to reduce these social determinants within a framework of community intervention.

Some recommended measures include meeting the need for education and employment, ensuring health care, and providing alternatives to inhalation such as sports and other recreational and artistic activities along with actively seeking persons at risk of using substances and counseling (Rodgers 1999). Community interventions aimed at reducing disorganization and violence include environmental design, urbanization, the participation of organizations that provide support to families, prevention programs that promote group cohesion and conflict resolution without violence, and in general empowering communities to make accurate diagnoses, develop action plans, formalize processes, and monitor progress (World Bank 2011; Zakocs and Edwards 2006).

A good example of a policy aimed at reducing the risk associated with the toxicity of substance*s* was the development in Australia of Opal fuel, which contains very low levels of the aromatic compound that causes intoxication, benzene, toluene, and xylene, making it less attractive for inhalation (d'Abbs and MacLean 2008). Other examples of this type of interventions are the modifications of the formula for aerosol spray paints replacing aromatic chemicals toluene and xylene with less intoxicating ones (ADCA 2010) and the development of water-based glues for school use.

Controlling availability with a special focus on children and adolescents in supermarkets, hardware stores, or service stations and setting up commercial organizations to prevent the sale of inhalants to these population groups are other examples.

Harm reduction interventions aimed at educating about the particular dangers associated with certain substances and means of administration, to reduce the risk of accidents and mortality, are controversial but may be considered as a first step when approaching heavy user populations.

Legislation can provide governments, retailers, and community and health workers with the means to address misuse such as removing products from users or stores, moving users to safe places, mandating treatment, and placing restrictions on the packaging and sale of inhalants. Existing laws do not usually make inhalant possession illegal (ADCA 2010).

Educating frontline health workers, teachers, police, and community counselors requires training them to identify those at risk, evidence-based interventions, and referral to services.

Parents, teachers, police, and community organizations must be informed about substances with the potential for abuse and the identification of persons that are abusing, proper handling, and referral of cases are all necessary to reduce inhalant misuse related harms.

Investment in basic and applied research on substance misuse is required, to ensure that research translates from the molecular to the clinical level and to the community.

36.7 Conclusion

Inhalants are the only drugs of abuse defined by the route of administration rather than their attributes, specifically similar mechanism of actions or common pharmacological effects. They are substances of abuse not included in the International Regulations and are seldom a priority for health and social interventions or for research funding. Inhalant products have legal uses in industry and households and are therefore inexpensive and readily available. They are more commonly used by young students and children and adolescents from poor sectors of society or heavy drug users when they lack access to other substances.

The short-term effects of inhalants are similar to those of alcohol and other central nervous system depressants and may produce impaired motor coordination, emotional lability, and difficulty speaking. Chronic effects include neurotoxicity, cognitive impairment, headaches, diminished sensorial abilities (loss of vision, audition, and coordination), and an increase in mental disorders and sleep disturbances. Inhalant use prevention involves different strategies, including education, skill building, environmental changes, and policy development. There is little research focusing specifically on the different compounds that are included in this heterogeneous group of substances classified as inhalants. Evidence-based treatment for inhalant abuse and dependence is scarce. However, treatment should include supportive psychotherapy, family and psychosocial interventions general healh care, proper nutrition, and vitamins or nutritional supplements. The long-term outcome of this addiction is usually progressive neurocognitive deterioration with multiple medical complications.

Treatment of Anabolic-Androgenic Steroid Related Disorders

37

Harrison G. Pope Jr. and Gen Kanayama

Contents

Abstract

The family of anabolic-androgenic steroids (AAS) comprises the male hormone testosterone and its many synthetic relatives. Although elite athletes have used AAS for muscle and performance gains since the 1950s, widespread AAS use did not emerge into the general population until the 1980s. Thus, AAS abuse is the youngest of the world's major forms of substance abuse, with most AAS users still below age 50. There are now some tens of millions of AAS users worldwide, primarily male and primarily in Western societies. Contrary to

common belief, most AAS users do not engage in competitive athletics, but simply want to become leaner and more muscular. AAS users may occasionally experience serious psychiatric effects, including hypomania or mania during AAS exposure and depression during AAS withdrawal. Long-term medical effects include especially cardiomyopathy, atherosclerotic disease, and prolonged suppression of the hypothalamic-pituitary-gonadal axis. About 30 % of AAS users develop dependence syndromes, likely caused by a confluence of psychosocial factors (e.g., using AAS to "self-treat" muscle dysmorphia), neuroendocrine factors (e.g., repeatedly resuming AAS use to self-treat hypogonadism during AAS withdrawal), and hedonic effects. A hedonic component is supported by evidence that male hamsters will self-administer testosterone to the point of death. Treatment of AAS dependence remains largely empirical, in part because most AAS abusers are still too young to have developed adverse effects. Thus, few have desired or sought treatment. This situation may change in future decades, however, as growing numbers of aging AAS users enter the age of risk for long-term adverse effects.

37.1 Introduction

Anabolic-androgenic steroids (AAS) are a family of hormones that includes the natural male hormone testosterone and more than 100 other synthetic relatives of testosterone (Kanayama et al. 2010b; Kanayama and Pope 2012). All AAS possess both anabolic (muscle building) and androgenic (masculinizing) properties; it is equally correct to refer to these hormones simply as "androgens" (Kanayama and Pope 2012). Since the 1950s, AAS use has been widespread in elite athletes and bodybuilders, who have long recognized that AAS allow them to achieve muscle gains far beyond those attainable by natural means. However, it was not until the 1980s that AAS use began to emerge from the elite athletic world and into the general population. Now, some two million American men, and millions more worldwide, have used these drugs illicitly. Most of these newer users are not competitive athletes at all, but simply men who wish to get leaner and more muscular (Kanayama and Pope 2012; Melnik 2009). The majority of these men are in their 20s or 30s, contrary to widespread belief, with only a minority starting AAS use as teenagers (Kanayama et al. 2007). AAS use is very rare in girls and women, since women do not often aspire to be extremely muscular and are also vulnerable to the androgenic effects of AAS such as beard growth, deepening of the voice, and masculinization of secondary sexual characteristics. Although some anonymous surveys have suggested that substantial numbers of teenage girls have used AAS, these surveys have almost certainly produced inflated estimates as a result of false-positive responses on questionnaires (Kanayama et al. 2007). For these reasons, the following discussion will be focused primarily on treatment of male AAS users, although the general principles expressed would presumably apply to the rare cases of women as well.

Although AAS pose important medical and psychiatric risks (see below), AAS users rarely seek treatment. Indeed, one recent study reported that 56 % of illicit AAS users had never disclosed their AAS use to any physician that they had seen (Pope et al. 2004). There are several reasons for this phenomenon. First, many AAS users perceive their use of AAS to be a positive and healthy activity, when combined with intensive exercise and optimal diet as part of the "bodybuilding lifestyle." Commercial and societal forces are partly responsible for this misperception of AAS: muscular male bodies are portrayed as an ideal in advertising, magazines, television, and movies. Even children's action toys, such as "G.I. Joe," have grown from ordinary-looking men in the 1960s and 1970s to muscle-bound specimens by the 1990s. Advertisers sometimes tout their products as "on steroids," but they would never claim that their products were "on marijuana" or "on cocaine." Given this societal climate, it is not surprising that AAS users rarely perceive their drug use as a psychiatric disorder requiring treatment (Kanayama et al. 2010b).

Second, AAS differ from conventional drugs of abuse. Most drugs of abuse described in this volume deliver a prompt "reward" of intoxication immediately after ingestion. However, AAS produce little or no reward of intoxication; instead, the user is seeking a long-term reward in the form of a more muscular body, athletic success, or admiration from peers or potential sexual partners. Thus, conventional methods of treating substance abuse may be inappropriate unless modified specifically for AAS users (Brower 2009).

Third, AAS users often have little respect for doctors. Internet sites for illicit AAS users are replete with derogatory remarks about health professionals. AAS users often regard physicians as "geeks" or "pencil necks" who have no understanding of the bodybuilding world. In one recent study, for example, 40 % of AAS users reported that they trusted information about AAS from their drug dealers at least as much as information from any physician that they had seen (Pope et al. 2004). There is some basis for this distrust: for decades, many medical professionals asserted that AAS were ineffective for gaining muscle mass. This claim, based on two decades of seriously flawed studies, caused doctors to lose their credibility among many athletes (Kanayama et al. 2008). Now, most professionals finally concede that AAS are effective for gaining muscle mass, but still remain largely uninformed about the extent and nature of the AAS-using subculture. Several recent papers have stressed that clinicians should attempt to become more familiar with AAS and AAS-associated syndromes (Kutscher et al. 2002; Melnik 2009).

Given the above considerations, it is understandable that AAS users rarely request treatment to stop using these drugs. Nevertheless, there are a number of specific situations that bring AAS users to the attention of clinicians. These include (1) AAS-dependence syndromes, (2) hypomanic and manic syndromes during AAS exposure, (3) syndromes of depression and anxiety associated with AAS withdrawal, (4) body-image disorders associated with AAS use, (5) co-occurring substance use disorders, (6) medical conditions associated with long-term AAS use, and (7) forensic situations, such as cases of AAS-induced violence or criminality. In the sections below, we begin with a general discussion of

the initial identification and assessment of AAS users and continue with each of the seven clinical issues enumerated above.

37.2 Identification and Assessment

37.2.1 Identification

AAS use is one of the few types of substance use where a diagnosis is often suggested simply by looking at the patient as he walks through the door. As we have described elsewhere (Kouri et al. 1995), there is a fairly sharp upper limit of muscularity that can be achieved by a lean individual without the help of drugs. We have published a formula to calculate muscularity, expressed as the "fat-free mass index" (FFMI), which clinicians can apply if they know the height, weight, and approximate percentage of body fat of the patient (Kouri et al. 1995). Men who have low body fat and display an FFMI of greater than approximately 26 kg/m^2 are almost certainly using drugs even if they deny it. Clinicians who suspect AAS use in any patient should follow several guidelines to take a specific history.

37.2.2 History

The clinician may lead into the topic of AAS by asking about athletic or fitness-related activities. Young men who lift weights regularly are at greatest risk to use AAS (Brower 2009). Other lead-in questions include the use of over-the-counter and mail-order dietary supplements such as vitamins, minerals, amino acids, and creatine. The use of such legal performance- or image-enhancing substances is commonly associated with use of illicit substances such as AAS (Hildebrandt et al. 2011). Finally, has the patient ever tried AAS or thought about using them? Patients thinking about AAS use are good candidates for prevention. Why is the patient interested in using, and what has prevented the patient from using to date? In addressing these questions, it is particularly critical for the clinician to be nonjudgmental while still discouraging use.

For patients who admit having tried AAS, both the perceived benefits and any adverse consequences of use are important to determine. The dates of first and last use, the names and doses of AAS used, sources of drugs, and routes of administration should be ascertained. Patients who inject AAS should be asked about needle sharing, although fortunately this practice now appears to be rare among AAS users (Ip et al. 2011). Sources of drugs include prescriptions, diversion from the legal market (including the veterinary market), and the illicit market. Unlike many other drugs of abuse such as heroin and cocaine, AAS are legally available without a prescription in many countries outside of the United States. Thus, potential AAS users can easily travel to nearby countries and also find Internet sites offering to sell AAS from overseas (Brennan et al. 2013). Drugs purchased through these sites, and then shipped by mail into the United States, often reach users without

being intercepted. Patients and clinicians should remember that drugs obtained from the illicit domestic market and from overseas sources are frequently counterfeit, adulterated, falsely labeled, and sometimes non-sterile. Thus, the user does not necessarily know what and how much he is taking.

Inquiry into the patterns of use is also important. Illicit AAS users typically combine ("stack") multiple types of AAS, including both oral and injected intramuscular forms, in order to achieve doses that are 10–100 times the amounts ordinarily prescribed for therapeutic indications (Ip et al. 2011; Kanayama et al. 2010b). Such doses may result in total AAS serum concentrations that may exceed 50 times natural male physiologic concentrations of testosterone (Kanayama and Pope 2012). AAS are usually taken in "cycles" (courses) of 4–16 weeks or more, often characterized by taking small doses at the beginning, building to large doses and combinations in the middle, and tapering doses at the end – a pattern referred to as a "pyramid." The clinician gains useful information when exploring the role of cycling with an individual AAS user. Does the patient cycle off AAS to avoid testing positive on drug screening? Does the patient cycle off AAS to give his body a rest, allowing his endogenous hormonal system a chance to regain normal functioning? Does the patient experience depression or other withdrawal symptoms during "off periods"? Dependent users may eliminate cycling altogether in favor of prolonged, continuous use in order to avoid withdrawal symptoms (see below).

Finally, a history of other drug abuse should be obtained. Users often combine other drugs with AAS to augment performance- and image-enhancing effects (e.g., human growth hormone, insulin-like growth factor I [IGF-I], human chorionic gonadotropin, clenbuterol, thyroid hormones, insulin, etc.), to reduce undesirable side effects such as gynecomastia (e.g., tamoxifen, letrozole, anastrozole), and to mask urine testing (e.g., probenecid, diuretics) (Hildebrandt et al. 2011; Ip et al. 2011). Also, in contradiction to the image of the healthy bodybuilding lifestyle, a large portion of AAS users display a history (and often an extensive history) of other forms of classical substance abuse or dependence (Dodge and Hoagland 2011; Garevik and Rane 2010; Kanayama and Pope 2012; Skarberg et al. 2009).

37.2.3 Physical Examination

The physical examination is essential to detect the somatic consequences of using AAS. Generalized muscle hypertrophy with a disproportionately large upper torso (neck, shoulders, arms, and chest) is readily apparent. The skin is examined for acne (on the face, shoulders, and back) and needle marks in large muscles (especially the gluteals, but sometimes the thigh and deltoids). Gynecomastia, caused by metabolic conversion of excess testosterone to estrogen, may be detectable by palpation or even simple observation in some men. By contrast, the testicles become atrophic as they shut down testosterone production when exogenous AAS are administered in high doses; this may lead to azoospermia and sterility (de Souza and Hallak 2011; Kanayama et al. 2010a). Male pattern

baldness, hirsutism, hypertension, hepatomegaly, right upper quadrant tenderness, jaundice, and prostatic hypertrophy are also possible, but are not reliably associated with AAS use. In women, hirsutism, deepening of the voice, and clitoral hypertrophy may be detected.

37.2.4 Mental Status Examination

The clinician should assess the patient's appearance for excessive muscularity as described above, sometimes disguised by oversized clothes, especially in patients with muscle dysmorphia who become preoccupied that they do not look big enough and hence wish to hide their bodies (Rohman 2009). The patient's cooperation may vary depending on his defensiveness or denial of AAS use. Speech and sensorium are generally normal. However, if the patient is experiencing hypomanic or manic symptoms from current AAS use, he may display irritability, agitation, and possibly grandiose beliefs. Patients experiencing depression from AAS withdrawal may exhibit depressed mood, dysphoria, anxiety, psychomotor retardation, and possible suicidal ideation.

37.2.5 Laboratory Examination

Laboratory abnormalities reported in AAS users are summarized in Table 37.1. Standard urine screens for drugs of abuse do not include AAS, so urine testing for AAS must be performed at a reference laboratory. Such testing can detect only recent AAS use: orally active AAS disappear from the urine within weeks, and most intramuscular preparations within a few months. However, given the association between AAS use and other illicit drug use, standard urine screens for illicit drugs should also be ordered.

Important blood chemistries include skeletal muscle enzymes, but these can be elevated even in non-AAS users after intensive weight training. AAS users may occasionally display pronounced elevations of creatine kinase from rhabdomyolysis. Standard "liver function tests," such as transaminases and lactic dehydrogenase, are nonspecific, since these enzymes are also present in the muscle and may be elevated from weight training (Dickerman et al. 1999). Many AAS users are erroneously thought to have liver disease when in fact their elevated transaminases are entirely muscular in origin. Elevation of chemistries specific to the liver, such as bilirubin and gamma-glutamyltransferase, may suggest true hepatic abnormalities.

HDL cholesterol is typically decreased during AAS use, particularly when individuals use orally active, 17α-alkylated AAS such as methandienone (Dianabol), oxymetholone (Anadrol), or stanozolol (Winstrol). The total cholesterol/HDL ratio, typically considered normal when less than 5.0, may be grossly elevated, with some men in our experience achieving ratios of greater than 20 as a result of extreme decreases in HDL levels. Such high ratios are likely associated with markedly increased atherogenic potential and may well contribute to the

Table 37.1 Laboratory abnormalities in anabolic-androgenic steroid users

Blood work	
Muscle enzymes	↑ ALT, AST, LDH & CK
Liver function tests	↑ ALT, AST, LDH, GGT & total bilirubin (caution: ↑ ALT, AST, & LDH are often muscular in origin and do not indicate liver disease)
Cholesterol levels	↓ HDL-C, ↑ LDL-C
	↑ Or no change in total cholesterol & triglycerides
Hormonal levels	↑ Testosterone & estradiol (with use of testosterone esters)
	↓ Testosterone (without use of testosterone esters or during withdrawal)
	↓ LH & FSH
Complete blood count	↑ RBC count, hemoglobin & hematocrit
Urine testing	
AAS:	Positive
Other drugs of abuse:	May be positive
Cardiac testing	
Electrocardiogram:	Left ventricular hypertrophy (seen in intensive weight trainers also)
Echocardiogram	Decreased ventricular ejection fraction, impaired diastolic function
Semen analysis	↓ Sperm count & motility, abnormal morphology

ALT alanine aminotransferase, *AST* aspartate aminotransferase, *LDH* lactate dehydrogenase, *CK* creatine kinase, *GGT* gamma-glutamyltransferase, *HDL-C* high-density lipoprotein cholesterol, *LDL-C* low-density lipoprotein cholesterol, *LH* luteinizing hormone, *FSH* follicle-stimulating hormone, *RBC* red blood cell

apparently increased prevalence of atherosclerotic disease in older AAS users (Kanayama et al. 2010b).

AAS also stimulate production of red blood cells, although the magnitude of this effect varies substantially across individuals. In our recent experience, we have seen several men who displayed hematocrits of 55–60 % while using AAS – placing them at increased risk for thrombotic or hemorrhagic complications.

Blood testosterone concentrations may be grossly elevated in patients who are administering exogenous testosterone, with serum concentrations typically several times the upper limit of normal (Kanayama et al. 2013). Conversely, testosterone concentrations may be grossly depressed in patients who are administering other types of AAS and hence inhibiting their own endogenous testosterone production. Testosterone levels may also remain depressed for months, and in rare cases even indefinitely, following AAS withdrawal (de Souza and Hallak 2011; Kanayama and Pope 2012).

37.3 AAS Dependence

Recent studies have increasingly documented that AAS can create a dependence syndrome, characterized by long-term use of these drugs, often for many years, and

frequently in spite of adverse effects (Kanayama et al. 2009). AAS dependence may be part of a larger pattern of dependence on appearance- and performance-enhancing drugs, involving other agents in addition to AAS, such as human growth hormone, insulin, and thermogenic agents such as clenbuterol, amphetamines, and thyroid hormones (Hildebrandt et al. 2011). As many as 30 % of men who use AAS may eventually develop such dependence syndromes (Kanayama et al. 2009), and thus there are likely some millions of cases worldwide.

We have suggested that AAS dependence may arise via three different pathways, any or all of which may contribute to the syndrome in a given individual (Fig. 37.1) (Kanayama et al. 2010a). First, there appears to be a "body-image" pathway, in which the individual becomes preoccupied that he will lose muscle size when he stops taking AAS and hence becomes reluctant to discontinue these drugs even for a short interval. Treatment for such symptoms, especially the extreme case of "muscle dysmorphia," can be performed with cognitive behavioral therapies or selective serotonin reuptake inhibitors (SSRIs). We discuss muscle dysmorphia in more detail below.

Second, use of exogenous AAS leads to suppression of the hypothalamic-pituitary-testicular (HPT) axis (de Souza and Hallak 2011; Tan and Scally 2009). Thus, when a man discontinues a course of AAS, especially if that course has been prolonged, he will likely experience hypogonadism, which in some cases may persist for months or even years after AAS are discontinued. Hypogonadism may be associated with loss of sex drive, fatigue, and occasionally serious depression; these symptoms may prompt users to quickly resume AAS in order to make the dysphoric feelings go away. This pathway to AAS dependence was first postulated more than 20 years ago (Kashkin and Kleber 1989) and has been increasingly acknowledged in recent years. Indeed, it now appears that protracted severe hypogonadism may be much more common in long-term AAS users than previously suspected and that indeed some users may develop irreversible hypogonadism, possibly attributable to direct toxic effects of long-term AAS exposure on the testis or on other components of the HPT axis (de Souza and Hallak 2011; Kanayama and Pope 2012). Therefore, in individuals displaying AAS-withdrawal hypogonadism and expressing a genuine desire to not resume AAS, it is desirable to institute aggressive endocrinological treatment with agents that stimulate the HPT axis in order to "jumpstart" natural endogenous testosterone production and thus reduce the individual's desire to resume illicit exogenous AAS (Tan and Scally 2009). Such treatment may include clomiphene to stimulate pituitary secretion of luteinizing hormone and follicle-stimulating hormone, together with human chorionic gonadotropin (HCG) to stimulate testicular production of testosterone and spermatozoa. Initially, the patient may also require temporary exogenous testosterone administration, typically using one of the several commercially available testosterone gels, in order to maintain adequate testosterone levels while waiting for clomiphene and/or HCG to stimulate resumption of endogenous function. In a typical treatment course of this nature, one would first taper off testosterone, then subsequently discontinue HCG, and then finally taper clomiphene, all while regularly monitoring testosterone levels (Tan and Scally 2009). Individuals still unable to

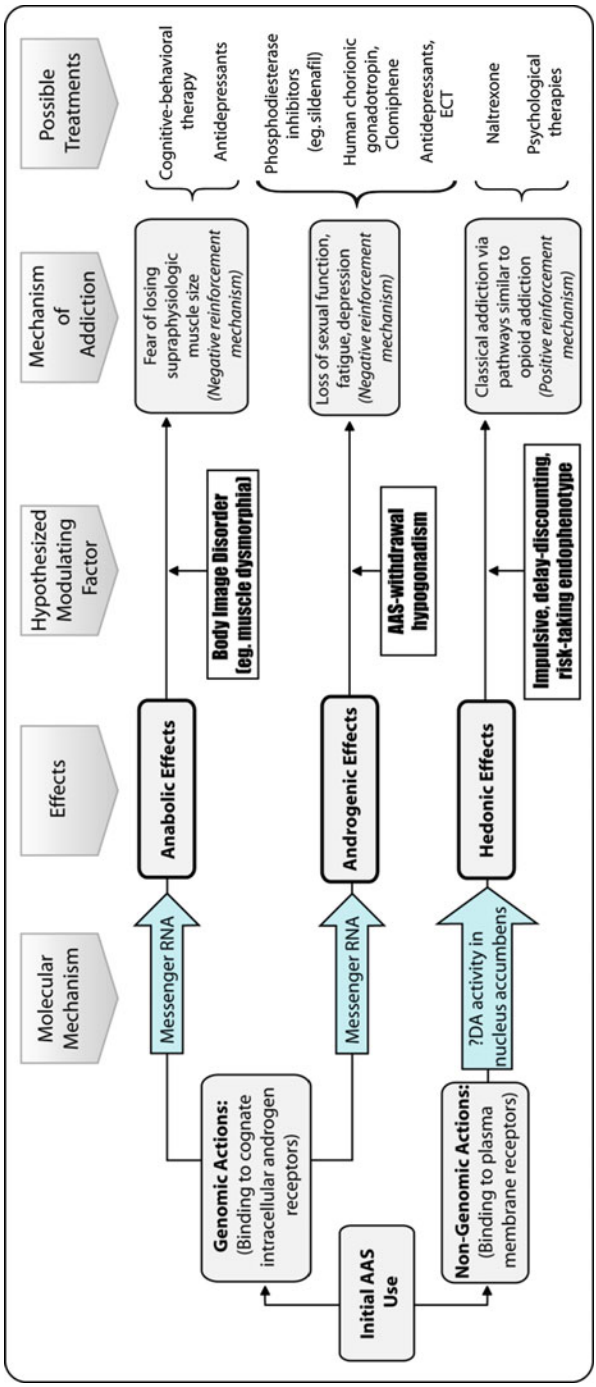

Fig. 37.1 Three potential pathways for the development of anabolic-androgenic steroid dependence and consequent possible treatment strategies (Adapted from Kanayama et al. 2010a)

maintain adequate testosterone levels on their own, even after several months of neuroendocrine treatment, may conceivably represent cases of irreversible hypogonadism attributable to a direct toxic effect of AAS and hence may require testosterone replacement indefinitely. Most psychiatric clinicians will likely wish to seek endocrinological consultation for these interventions.

Third, AAS may induce a dependence syndrome via a hedonic pathway, presumably mediated by receptor sites on cell membranes, rather than by classical anabolic or androgenic effects that are genomically mediated. Persuasive evidence for such a hedonic pathway arises from animal studies, which have shown that rats and mice display conditioned place preference for AAS and that male hamsters will self-administer AAS to the point of death (Wood 2008). Interestingly, AAS self-administration in hamsters can be blocked by administration of the opioid antagonist naltrexone (Wood 2008). A number of other clinical and preclinical studies have pointed to interactions between AAS and endogenous as well as exogenous opioids, thus suggesting that the hedonic pathway to AAS dependence may involve opioidergic mechanisms (Nyberg and Hallberg 2012; Wood 2008). One implication of this research is that human AAS dependence might respond, at least in part, to treatments empirically validated for opioid dependence, such as motivational therapies, contingency management, behavioral couples therapy, or behavioral family counseling. In the management of opioid dependence, some of these treatments have been successfully used in conjunction with naltrexone – raising the possibility that the addition of naltrexone might be effective in AAS dependence as well. However, these modalities have not yet been systematically tested in treatment of AAS dependence. We refer the reader to the full article from which Fig. 37.1 is taken (Kanayama et al. 2010a) for a detailed discussion of each of these three possible pathways to AAS dependence, together with details of potential treatment strategies.

37.4 AAS-Induced Hypomania and Mania

A substantial literature over the last 20 years has demonstrated that AAS produce hypomanic or manic syndromes in some individuals, sometimes accompanied by aggressive or violent behavior, and very rarely psychotic symptoms (Hall et al. 2005; Pope and Katz 2003). These effects are rare in individuals taking the equivalent of 300 mg of testosterone per week or less, but they appear to become progressively more common with higher doses, especially above 1,000 mg per week (Pope and Katz 2003). These syndromes were initially noted in field studies of illicit AAS users, and some investigators questioned whether the effects were actually due to AAS themselves, as opposed to expectational factors, personality variables, or subcultural influences. However, several studies have now demonstrated that such syndromes can develop even in normal volunteers taking supraphysiologic doses of AAS under placebo-controlled double-blind laboratory conditions (Pope and Katz 2003). Therefore, the mood-altering effects of AAS almost certainly have a biological basis, even though they can undoubtedly be

modified by contextual factors. Hypomanic and manic syndromes appear to be quite idiosyncratic, with a majority of AAS users displaying few such symptoms, even with high doses of AAS, but with occasional individuals showing severe symptoms, sometimes accompanied criminal violence (see below).

Little has been written about the treatment of such episodes beyond anecdotal reports. Thus, the best treatment recommendations would seem to include removal of the offending agent and temporary treatment, if necessary, with neuroleptics or other antimanic drugs. In general, it appears that manic or hypomanic episodes will remit quickly when AAS are stopped and that clinicians should then be alert for the onset of depressive symptoms associated with abrupt AAS withdrawal. If a patient reports a history of mood disorder prior to AAS use or continues to exhibit manic or psychotic symptoms for more than a few weeks after AAS are stopped, it would seem important to consider the possibility of an underlying major mood disorder independent of AAS.

37.5 AAS-Withdrawal Depression

As mentioned above, AAS-withdrawal hypogonadism has been increasingly recognized as an important problem in long-term AAS users. During AAS withdrawal, most men do not display marked depressive symptoms, even when their testosterone levels are grossly below the normal range. However, a small number of men develop pronounced depressive symptoms, sometimes accompanied by suicidal ideation and even completed suicide (Kanayama et al. 2010b). In mild cases, depressive symptoms may remit spontaneously as endogenous testosterone production gradually recovers. However, more severe or prolonged cases of depression may require both endocrinological interventions to restore HPT axis function, as described above, together with antidepressant treatment. Depression accompanying AAS withdrawal appears to respond well to SSRIs such as fluoxetine (Malone and Dimeff 1992). Antidepressant agents of this class may be particularly useful since they may also benefit muscle dysmorphia and other forms of body dysmorphic disorder that may accompany AAS use (Phillips et al. 2008).

37.6 Body-Image Disorders Associated with AAS Use

Recent years have seen increasing recognition of a form of body dysmorphic disorder called “muscle dysmorphia,” or “reverse anorexia nervosa,” in which the individual perceives himself to be small and frail, even though he is actually large and muscular (Rohman 2009). Men with muscle dysmorphia will often engage in compulsive weightlifting and bodybuilding, even to the exclusion of other activities that they enjoy. They also will frequently avoid situations in which their body will be seen by others, such as going to the beach or changing in a locker room, for fear that they look too small. Not surprisingly, such individuals may use AAS to “treat”

their preoccupation, but paradoxically, many describe worsening symptoms of muscle dysmorphia following initiation of AAS use. As mentioned earlier, muscle dysmorphia may contribute to AAS dependence, because individuals may become extremely anxious that they are losing muscle size or gaining fat after stopping AAS, and thus quickly resume use.

In individuals presenting with muscle dysmorphia and other similar concerns about body physique, the possibility of AAS use should always be considered and investigated. Successful treatment of the underlying body-image disorder may be helpful for deterring future AAS use – although individuals with muscle dysmorphia may be reluctant to admit that they have a condition requiring treatment, as is often the case with other forms of body dysmorphic disorder. We are not aware of systematic studies of treatment of muscle dysmorphia per se, but it seems reasonable to follow general principles of treatment of other forms of body dysmorphic disorder, relying on cognitive behavioral therapy and pharmacological interventions such as SSRIs – modalities of demonstrated efficacy in body dysmorphic disorder generically (Phillips et al. 2008).

37.7 Co-occurring Substance Use Disorders

A growing literature has demonstrated that polypharmacy is widespread among AAS users. These individuals may use a variety of other performance- and image-enhancing drugs, such as human growth hormone, insulin, and agents for fat loss, and they frequently also display abuse of, or dependence on, classical drugs of abuse such as cannabis, amphetamines, cocaine, and opioids (Dodge and Hoagland 2011; Hildebrandt et al. 2011; Kanayama and Pope 2012; Skarberg et al. 2009). In particular, the association of AAS use with opioid use may in part reflect similarities between these classes of drugs in their reward mechanisms, as discussed earlier (Nyberg and Hallberg 2012; Wood 2008). In our experience, concomitant opioid abuse or dependence is particularly common in North America, where we have evaluated many AAS users who were first introduced to oral opioids or intravenous opioid agonist-antagonists such as nalbuphine and then progressed to intravenous use of classical opioids such as morphine and heroin. We are aware of several cases in which such individuals later died from inadvertent overdoses of intravenous opioids. In Europe, a specific link between AAS and opioid use appears less prominent, with AAS use commonly associated with other abuse of drugs such as cocaine, cannabis, and amphetamines (Garevik and Rane 2010; Skarberg et al. 2009).

It follows from these observations that clinicians should assess history of classical drug abuse in all individuals presenting with AAS use and conversely should consider the possibility of AAS use in individuals presenting with classical drug abuse. In either case, classical substance abuse or dependence in current or former AAS users may well itself require treatment; the reader is referred to the corresponding chapters in this volume regarding principles for such treatment.

37.8 Medical Conditions Associated with AAS Use

Long-term use of AAS may be associated with a variety of medical complications, the full extent of which is only gradually becoming appreciated. One reason for our still-limited knowledge of these effects, mentioned earlier, is that AAS use did not become widespread in the general population until the 1980s. Thus, a majority of the world's AAS users are still young and have yet to pass through the age of risk for medical complications of long-term use. To cite an analogy proposed in our earlier publications (Kanayama et al. 2008), imagine that widespread cigarette smoking did not exist until the 1980s and that the great majority of the world's cigarette smokers were still below age 50 today. In that scenario, we would have only a limited recognition of the potential long-term risks of cigarette smoking and might substantially underestimate the true amount of morbidity and mortality that would ultimately occur.

An analogous situation may exist with regard to AAS. Recent years have seen growing evidence that AAS produce adverse cardiovascular effects (e.g., cardiomyopathy, myocardial infarction, cerebrovascular accidents), protracted neuroendocrine disruption (as discussed above), and effects on other organ systems (e.g., focal segmental glomerulonephritis) (Kanayama and Pope 2012). It is our impression that these adverse consequences are more frequent and more serious than most authorities (including ourselves) would have anticipated even a few years ago. Mounting evidence also suggests that supraphysiologic concentrations of AAS may produce apoptotic effects in a variety of cell types, including the myocardial and skeletal muscle cells, epithelial cells, Leydig cells, and neuronal cells (Kanayama et al. 2013). The finding of neuronal apoptosis raises the specter of potentially irreversible cognitive deficits in AAS users – a phenomenon that we have already tentatively observed in a pilot study (Kanayama et al. 2013).

It follows that aging AAS users may increasingly come to clinical attention as a result of various medical or neurological effects. Thus, substance-abuse professionals may receive referrals of such patients from medical clinicians, many of whom may themselves be unfamiliar with illicit AAS use. Such patients may need to discontinue AAS immediately as a result of medical dangers. Many of these patients may never have previously disclosed their AAS use to any clinician and may be very uncomfortable with the idea of entering treatment and discontinuing AAS. Prompt, knowledgeable, and sympathetic intervention, addressing all of the three AAS-dependence pathways postulated above, may be required to achieve a good outcome.

37.9 AAS in Forensic Situations

AAS users may occasionally come to clinical attention through the courts as a result of violent or criminal behavior. Specifically, a number of papers have described individuals, often with no prior history of psychiatric disorder, violence, or criminal behavior, who became uncharacteristically violent, and sometimes committed murder while intoxicated with AAS (Hall et al. 2005; Kanayama et al. 2010b;

Pope and Katz 2003). In such cases, AAS are not necessarily the proximal trigger to violence; the direction of causality may sometimes be reversed, in that some individuals may deliberately ingest AAS in preparation for committing a crime (Lundholm et al. 2010). A recent example of such a case was Anders Breivik, convicted of killing 77 Norwegian civilians in the summer of 2011. In his extensive manifesto, Breivik details his systematic use of AAS, which he ordered through the Internet, in preparation for his terrorist attacks (Kanayama and Pope 2012).

In some cases of criminal violence, the role of AAS use may be missed because the possibility is never considered. However, AAS use should be suspected in any usually muscular man apprehended for violent behavior, especially if it appears that this violence is not characteristic of his usual personality. The clinician's index of suspicion should be particularly raised if such a man rapidly develops vegetative symptoms of depression after being incarcerated, but then improves a few weeks or months later. This pattern may indicate AAS withdrawal, precipitated by the abrupt discontinuation of AAS following incarceration, with a gradual remission of depressive symptoms as suppressed hypothalamic-pituitary-testicular function gradually returns to normal. Of course, this pattern of biological depression must be distinguished from the situational depression associated with incarceration itself.

In cases where AAS use is acknowledged by the defendant and appears to have been a clear precipitant of criminal behavior, forensic clinicians may be asked to offer an opinion that the defendant exhibited "involuntary intoxication" or "diminished capacity" from AAS. The legal aspects of this defense are beyond the scope of this chapter. However, it seems clear that if an individual is released and placed on probation after a crime believed associated with AAS, it may be wise to require random, unannounced, observed urine tests for AAS to ensure that he does not resume these drugs.

37.10 Conclusion

Of the various major forms of substance abuse and dependence described in this volume, AAS abuse and dependence may be the least familiar to the average clinician. However, the frequency of AAS abuse and dependence, together with the various medical and psychiatric syndromes associated with it, is now beginning to be better recognized. Greater awareness of this problem among clinicians may lead to the detection of many more cases, and a better understanding of how best to treat them.

37.10.1 Key Points

- Anabolic-androgenic steroid (AAS) use must be approached differently from other forms of substance abuse, because AAS do not produce an immediate reward or "high" in the manner of conventional drugs of abuse, and are linked to body dysmorphic disorder.

- AAS users rarely see their drug use as pathological, rarely seek treatment, and may have contempt for physicians.
- AAS users often display a history of abuse of or dependence upon other drugs, especially opioids.
- Some individuals experience hypomanic or manic symptoms during AAS exposure and depressive symptoms during AAS withdrawal.
- AAS may produce a well-documented dependence syndrome, for which an animal model exists. This dependence syndrome may arise through several pathways, including a "body-image" pathway, a neuroendocrine pathway, and a hedonic pathway, each of which may dictate specific treatment interventions.

Abstract

Abuse of and dependence on prescription drugs is an increasing problem and is closely related to the increasing use of prescription drugs worldwide. The problem of prescription drug abuse includes both weak and strong opioids for pain management; sedating drugs like benzodiazepines, barbiturates, and newer hypnotics; and stimulant drugs used for the treatment of narcolepsy and ADHD. Several other prescription drugs also have the potential for abuse. In this chapter prescription drug abuse is set in an historical context. The concept of prescription drug abuse is discussed and the types of drugs that are abused are reviewed. The special considerations that need to be upheld when diagnosing and understanding prescription drug abuse are highlighted. The chapter also contains information on the epidemiology of prescription drug abuse. As prescription drugs are effective drugs that are needed for the treatment of serious diseases, special responsibility for the prevention of the problem of prescription drug abuse is placed on the prescribing doctor. Lastly special considerations in treating prescription drug abuse and especially long-term benzodiazepine use are reviewed.

38.1 Introduction

For as long as we have had medicinal drugs, we have had abuse of these drugs. Similarly, drugs of abuse have long been used for their therapeutic potential, real or perceived. Cannabis, opium and its derivatives, cocaine, and barbiturates are good examples. Much of the legislation requiring prescription by doctors was brought in to prevent the abuse of medicinal drugs and narcotics and even alcohol. At the time there was a belief that having doctors administer the use of these drugs would prevent some of the problems connected with them. This is, for good reason, still a widely held belief. But as we shall see in the following text, requiring prescription of these drugs does not solve the problem of abuse. Nonetheless it may be the best system available for the distribution of these potentially harmful helpers. It does, however, place a great deal of responsibility on the professionals entrusted with this task.

Historically there are many examples of drugs of abuse being used as medicines. The use of cannabis for medical purposes has its roots in the ancient civilizations of China, Egypt, and Greece. The use of opiates for both medical and recreational purposes went hand in hand in old cultures in the Middle and Far East. This was also probably true for South American use of cocaine and was certainly true when the drug came to Europe in the second half of the nineteenth century. Sigmund Freud wrote four papers on the medical use of cocaine (Freud 1884) and developed an addiction himself (Cohen 2011). Others developed the first local anesthetics from it. When the first effective sleeping agents, barbiturates, were introduced, the road to abuse was a short one, and for decades, the problem was considerable in the Western world.

Even today the boundaries may seem vague. Just as Freud thought that cocaine could be a cure for morphine addiction, so heroin was introduced for the same reason. In the 1890s many believed that heroin was not an addictive drug itself. They could not have been more wrong! Some 70 years later Dole and Nyswander introduced the concept of opiate maintenance treatment using long-acting opioids (Dole and Nyswander 1967), thus sparking one of the greatest treatment options for heroin addiction with several hundred thousand patients being treated worldwide. This is obviously a great treatment opportunity but nevertheless is still considered controversial in many countries. The story goes full circle with the introduction of heroin as a substitution drug to be used for difficult-to-reach opiate addicts, an indication that it is not the addiction per se that we seek to treat, but the adverse effects of the addiction lifestyle, namely, criminality and social marginalization.

The boundaries are also unclear with the increasing use of medicinal drugs for recreational purposes. These include drugs such as newer opioids, like pregabalin (Lyrica), but also the older benzodiazepine sedatives and hypnotics and benzodiazepine-like hypnotics. At the same time, there is a push toward the medical use of drugs normally used for recreational purposes. Medical marijuana has a growing following worldwide and this has formed the basis for challenging the legislation concerning cannabis, pushed both by cannabis liberalists and also by more scientifically oriented researchers who see the paradox in potential therapeutics being outlawed. Other drugs have also been "pushed" by "drug activists": MDMA for the treatment of depression and psychedelics for the treatment of other psychiatric conditions. Much of this interest appears to be fueled by special interest groups with an agenda for liberalization and may be a romantic view of "mind-expanding drugs." This may be best illustrated by the interest in the use of psychedelics in the treatment of addiction in order to "induce transcendental experiences" as part of a cure for addiction.

Two issues should be kept in mind. Firstly, requirements for efficacy and evidence should be just as strict toward drugs derived from narcotics as for any medicinal drug if they are to be used therapeutically. The research concerning the use of cannabinoids in medicine is a good example of this – showing that there is evidence for the efficacy of cannabinoids. Secondly, the abuse potential of any drug that is to be put on the market should be clarified as a prerequisite of any registration process. Guidelines for such testing exist (FDA 2010). But many of these drugs were marketed long before modern requirements to investigate their abuse potential were in place. And even with careful testing, the real abuse potential of many drugs may not be fully recognized. This is because preclinical and pre-marketing investigations, however meticulous, are not able to reveal a drug's true abuse potential. They are often tested on smaller, selected (non-abuser) populations under strictly controlled conditions, which do not allow for spurious use. It will often take years after a drug has come on the market before its true abuse potential becomes clear. Post-marketing surveillance is one of the few ways of picking up abuse of drugs; many drugs are not fully recognized for their abuse potential until they have been on the market for many years (Arfken and Cicero 2003).

Novel synthetic cannabinoids were developed as medicinal drugs. Although they have some therapeutic value, their real popularity has been won by recreational use. Their potency makes them easy to distribute. And the ever-increasing number of new varieties, partly synthesized to avoid legal persecution, reminds us of Alexander Shulgin's efforts in the ecstasy field (Shulgin and Shulgin 1991). These drugs again illustrate how drugs with medical potential are brought into recreational use.

Even though there are many drugs that have abuse potential, they obviously also have a therapeutic benefit. So if abuse potential is discovered, it is most often not a question of taking the drug off the market. It can be scheduled with restrictions on its use. It is always a question of weighing the risks against the benefits. If the risks are perceived to be greater than the benefits, action should be taken. Ultimately this could mean withdrawing the market authorization of a drug, but often more modest actions will serve the purpose.

A surprising number of medicinal drugs, which later prove to have an abuse potential, have been marketed as safe from the danger of abuse. This suggests that marketers are well aware of this danger and want to reassure us, even if their claims are not always true. Abuse of medicinal drugs is an adverse effect best avoided, but not at any cost. When review papers on the use of cannabis reveal that it is an effective drug, but suggest it should not be used because of its abuse potential (Tramer et al. 2001), we must again try to weigh the risks and the benefits. If a terminal cancer patient, a chronic Parkinson patient, or even a chronic drug addict were to feel some pleasure from the drugs given to them therapeutically, it does not automatically shift the weight away from use of the drug. It is something to be taken into consideration, but not something that should necessarily prohibit its use.

This backdrop may be useful to keep in mind when encountering prescription drug abuse, be it as a doctor worried about prescribing drugs that could be used for reasons other than therapeutic, a therapist encountering a patient with abuse or dependence problems because of these drugs, or those contemplating using known drugs of abuse for the benefit of seriously ill patients.

38.2 Prescription Drugs of Abuse

This chapter will cover the most important groups and compounds. Sedatives and hypnotics will be covered in more detail here because they are not elaborated on elsewhere in this textbook.

38.2.1 Sedative Drugs

This group of drugs covers many different compounds (Table 38.1). These mainly belong to four subgroups: benzodiazepines, z-hypnotics, barbiturates, and barbiturate-like substances. Common to all of them is that they have receptor sites on the gamma-aminobutyric acid (GABA) receptor, subtype A. GABA is the main inhibitory neurotransmitter in CNS and is widespread throughout the CNS.

Table 38.1 Some commonly used sedatives marketed in many countries. Not all drugs will be marketed in all countries

	Compound (generic name)	Main use	Mean usual dose main use (mg)	Mean terminal half-life (h)	Abuse potential
Benzodiazepines	Alprazolam	Anxiolytic	1	12	***
	Bromazepam	Anxiolytic	9	16	**
	Lorazepam	Anxiolytic	4	12	***
	Oxazepam	Anxiolytic	30	10	*
	Chlordiazepoxide	Anxiolytic	30	27	**
	Clobazam	Anxiolytic	30	18	**
	Diazepam	Anxiolytic	5	40	**
	Lorazepam	Hypnotic	1	12	***
	Temazepam	Hypnotic	15	14	**
	Flunitrazepam	Hypnotic	1	25	***
	Nitrazepam	Hypnotic	5	28	**
	Flurazepam	Hypnotic	15	60	***
	Clonazepam	Antiepileptic	4	36	***
Benzodiazepine-like hypnotics	Zaleplon	Hypnotic	10	1.5	*
	Zopiclone	Hypnotic	7,5	4.5	**
	Eszopiclone	Hypnotic	6	6	**
	Zolpidem	Hypnotic	5	2.5	**
Barbiturates	Barbital	Antiepileptic	750	30	***
	Fenobarbital	Antiepileptic	200	80	***
Barbiturate-like drugs	Chlomethiazole	Muscle relaxant	600	6	**
	Meprobamate	Muscle relaxant	200	10	***
	Methaqualone	Muscle relaxant	150	74	***
	Chlormezanone	Muscle relaxant	200	40	**
	Orphenadrine	Muscle relaxant	100	16	**
	Chlorzoxazone	Muscle relaxant	750	1	**
	Carisoprodol	Muscle relaxant	700	2	**

Different sources of data indicate that the these drugs *may be abused; **have a moderate abuse potential; or ***are drugs with a high abuse potential

The $GABA_A$ receptor complex is a ligand-gated ion channel. This transmembrane chloride channel is a pentamere with several different combinations of α (six subtypes), β (three subtypes), or γ (three subtypes) subunits and some other possible variants. It is to a large extent the α-subunit configuration that determines a drug's abuse potential (Tan et al. 2011; Ator 2005). While the barbiturates and barbiturate-like drugs can influence the receptor in the absence of GABA,

benzodiazepines and the benzodiazepine-like z-hypnotics are dependent on the presence of GABA in order for the receptor to perform its action. The consequence is that while barbiturates and barbiturate-like drugs are more dangerous and may more easily be overdosed, benzodiazepines and benzodiazepine-like drugs have a ceiling effect and thus a broad therapeutic window of use. The literature gives few, if any, examples of overdose on benzodiazepines alone in otherwise healthy individuals.

It is thus safe to say that when benzodiazepines were introduced in the end of the 1950s and in increasing numbers in the 1960s and 1970s, this was viewed as a better and safer alternative to the barbiturates that had caused so many deaths and so much dependence (Lader 1991). But, as many other times, the true abuse potential of the drug was not revealed until later, and only in the late 1960s and early 1970s did the abuse of benzodiazepines become recognized.

Benzodiazepines are basically the same no matter what their main indication is. It is often arbitrary what indication the market authorization is filed for, depending on whether there are fewer or more drugs in a group. It is most often a question of the dosage regardless of whether a benzodiazepine is used as an anxiolytic, a hypnotic, or an antiepileptic drug. What differs between the compounds is their potency and their pharmacokinetics. Table 38.1 shows this through the dosing and the terminal elimination half-life. Concerning dosing, it must be remembered that dosing in this table (and in much of the literature) is for the main use the drug is registered for. Taking diazepam as an example, doses would be 5–10 mg for anxiety but 10–20 mg for sleep. The daily doses however may reach as much as 15–20 mg for anxiety treatment as the dose if often repeated, but there is no such repetition for hypnotics. So equipotency for benzodiazepines is not a simple term. However, some are more potent than others (alprazolam, lorazepam, flunitrazepam, and clonazepam) and thus more attractive among abusers (Hallfors and Saxe 1993; Ator et al. 2005; Griffiths and Johnson 2005), partly because clinicians have a tendency to underestimate the potency differences and prescribe high-potency benzodiazepines in relatively higher doses. The terminal elimination half-life is another parameter which varies between the benzodiazepines. It must however be remembered that owing to the phenomenon of acute tolerance (tolerance occurring within the same dosing), terminal elimination half-life is not a good parameter for judging the time of effect for benzodiazepines. But the relative duration of action between the different benzodiazepines is roughly judged by this parameter. And a short duration of action often implies a short time between intake and effect, a parameter important for the reinforcing effects of a drug. Again we see alprazolam, lorazepam, flunitrazepam, and clonazepam scoring highly on this parameter.

Z-hypnotics (zaleplon, zopiclone, eszopiclone, and zolpidem) are not benzodiazepines in their chemical structure. When introduced, their manufacturers wanted to have them introduced as "benzodiazepine-free hypnotics." However, their similarities to benzodiazepines in pharmacological effects are striking and there is no longer doubt

that they can be abused. These drugs probably have a lesser capacity to relieve anxiety and the role of anxiety in a drug's abuse potential should not be underestimated. It is thus probably true to state that the abuse potential of these drugs may be lower than for benzodiazepines, but the difference is likely to be marginal. We still see that zolpidem is a very popular drug of abuse in many countries. A distinct metal taste following the intake of zopiclone (also after i.v. intake) is probably preventive for abuse. Despite many claims to the contrary, eszopiclone has no advantages over zopiclone and probably none over benzodiazepines in terms of abuse potential. These drugs can be and are abused (Jaffe et al. 2004; Hajak et al. 2003).

Benzodiazepines are hugely popular among injecting drug addicts. Heroin users use them to prolong their intoxication and prevent withdrawal (Ross and Darke 2000). This may also contribute significantly to overdose deaths (Clausen et al. 2009). Abusers of stimulants use them to land from binges or runs.

Barbiturates and barbiturate-like drugs are much less abused today than they were before. That does not mean that they cannot be abused! Many of these drugs are compounds that have taught us what prescription drug abuse is, like methaqualone (Quaalude®). Their high lipid solubility and resulting potential to cross the blood-brain barrier quickly and their unlimited effect (ever-increasing effects with higher doses and no ceiling effect, even if marked tolerance triggered massive dose escalations) made them very popular as drugs of abuse. When this was acknowledged, heavy restrictions were put on their prescribing and these drugs were withdrawn in many countries, but they are still on the market in many others.

It is a point of discussion whether or not buspirone should be listed here. We have opted not to do so because of the low abuse potential shown for this drug in several studies. This is not to say that it cannot be abused in some situations or by some patients.

38.2.2 Analgesics

The mechanism of action and other pharmacological points concerning opioid analgesics, including those which are prescribed, are similar to that described elsewhere in this book. There are at least two different groups of prescription opioid abusers. Firstly, we have the pain patient who has aberrant use of his or her medication (Turk et al. 2008). Who the patients at risk are seems to be difficult to predict. And then we have the abusers without a prescription. This group includes anyone from the teenager who accesses a relative's pain medication to the marginalized heroin abuser adding prescription opioids to his or her abuse. Common for all of these are the dangers related to abuse, dependence, and overdose. For further characterization of user groups, see below. The nonmedical use of prescription opioids is a modern-day epidemic with an estimated use in the United States of around 4 % of the population (UNODC 2012) (Table 38.2).

Table 38.2 Some commonly used opioids marketed in many countries. Not all drugs will be marketed in all countries

Compound	Main use	Mean terminal half-life (h)	Abuse potential	Comment
Morphine	Pain relief	2–3	***	
Ethylmorphine	Cough suppression	?	**	
Codeine	Pain relief	3–4	*	(10 % metabolized to morphine by CYP2D6)
Fentanyl	Anesthesia	1–6	***	Also much used as a transdermal patch
Hydrocodone	Pain relief	4–6	**	
Oxycodone	Pain relief	3–5	**	
Oxymorphone	Pain relief	1–2	**	
Dextropropoxyphene	Pain relief	8–24	***	
Hydromorphone	Pain relief	2–3	**	
Meperidine/ pethidine	Pain relief	3–5	**	
Diphenoxylate	Constipating drug	12–14	*	
Methadone	Substitution in opioid dependence	6–8	**	High doses make once-daily intake possible
Buprenorphine	Substitution in opioid dependence	4–6	**	Strong binding (covalent) to receptor makes once-daily intake possible

Different sources of data indicate that the these drugs *may be abused; **have a moderate abuse potential; or ***are drugs with a high abuse potential; ? denotes an unknown abuse potential

38.2.3 Central Stimulants

During recent years there has been an enormous increase in the prescribing of central stimulating drugs for treating attention deficit and hyperactivity disorder (ADHD). Using central stimulants to treat ADHD is an effective treatment in children (Bloch et al. 2009) and probably also in adults (Wilens et al. 2002), but not all these drugs are used as prescribed; some are also abused. This is partly true because patients with ADHD have an extra vulnerability to getting involved in drug use (Groenman et al. 2013). The drugs can be abused by saving a whole week's worth of pills for a simultaneous intake to get a stimulant high or by selling the drugs to friends or on the black market. A typical therapeutic use of methylphenidate would involve using 10–30 mg, but 50–150 mg would be common in abuse. It is debatable whether or not buproprione should be listed here. We have opted not to do so because of the low abuse potential of this drug shown by several studies. This is not to say that it cannot be abused in some situations or by some patients.

Abuse of central stimulants includes using them as cognitive enhancers. This means otherwise healthy people taking the drugs in order to optimize their

Table 38.3 Some commonly used central stimulating drugs marketed in many countries. Not all drugs will be marketed in all countries

Compound	Main use	Mean usual dose main use (mg)	Mean terminal half-life (h)	Abuse potential
Methylphenidate	ADHD and narcolepsy	20–30	2–3; 7–12 for extended release	**
Amphetamine	ADHD and narcolepsy	20	13	***
Dextroamphetamine	ADHD and narcolepsy	20	10	***
Ephedrine	Cough medicine	20–50	3–6	*
Diet pills	Weight loss	Varying	Varying	Varying
Caffeine	Narcolepsy and in combination for migraine	Varying	Varying	Varying
Melanotan	Illegal tanning product	10–30	1–2	?

Different sources of data indicate that the these drugs *may be abused; **have a moderate abuse potential; or ***are drugs with a high abuse potential; ? denotes an unknown abuse potential

cognitive abilities, such as using them to increase school performance or to stay awake and work for prolonged periods, be it as a student, soldiers in the field, or a truck driver with long shifts. Different surveys show varying degrees of use, but quite a few students report having tried them to increase performance, with varying results (Ragan et al. 2013). There is more solid evidence that they can improve cognitive performance better in periods of prolonged wakefulness, a fact that the world's many coffee drinkers can verify. Research in the combat field has, however, shown that the use of stronger central stimulants may not be optimal. In this field there is interest in a wide variety of drugs stimulating the noradrenergic, serotonergic, and glutaminergic receptor systems. This field is pushed forward by an interest in finding effective treatments for the cognitively impaired, such as patients with Alzheimer's disease.

It has been claimed that any diet pill that works includes central stimulants and that any diet pill that does not include central stimulants does not work. This is too simplistic a view and does not take into account the many different approaches diet pills have used, but it certainly captures the point that dieting agents, for many years, included central stimulants and that this appeared to be efficient (Table 38.3).

38.2.4 Other Drugs

Virtually any drug can be abused. No complete list will ever be compiled. As prescribers we always need to work with others to produce early warning systems and to remain up-to-date on the possible dangers of prescribing different drugs. We must remember that abuse potential is often not revealed until a drug has been on the market for a very long time (Table 38.4).

Table 38.4 Miscellaneous drugs that have been reported abused. Not all drugs will be marketed in all countries

Compound	Main use	Abuse potential	Comment
Marinol and other synthetic cannabinoids	Pain and muscle spasms in MS patients	***	Being a synthetic cannabinoid with very high potency, it has a high abuse potential
Sativex (cannabis extract)	Pain and muscle spasms in MS patients	*	Abuse potential as with other cannabis products
Pregabalin	Antiepileptic	**	Increasing number of case reports point to the abuse potential of this GABA analogue
Ketamine	Anesthetic	**	This anesthetic is an antagonist to the glutamatergic NMDA receptor giving vivid hallucinations as one of its main effects
Quetiapine	Antipsychotic	*	Increasing number of case reports point to the abuse potential of this antipsychotic drug
Xyrem	GHB treatment of alcohol dependence and withdrawal	***	This GHB product can of course be abused as GHB
Lioresal	$GABA_B$-agonist	*	This centrally acting muscle relaxant can possibly be abused in higher doses, but the euphoric and psychomotor effects are weak

Different sources of data indicate that the these drugs *may be abused; **have a moderate abuse potential; or ***are drugs with a high abuse potential

38.3 Terminology and Diagnosis

Most use of prescription drugs is legitimate and therapeutically wise. The overwhelming majority of those who receive a prescription for analgesics or for hypnotics or sedatives use these drugs for a limited period to get through a time of pain, insomnia, or life stress. It is important to underline this because even if we have, for too long, overlooked the problem of abuse of these drugs, we must not go to the other extreme and view all use of these drugs as problematic.

However, problems can and do arise. People can use too much. Some individuals can increase their doses to high amounts. Others can use them for too long, after their original problem is over, in order to avoid the discomforts of discontinuation and withdrawal. The drugs can be taken for the wrong reasons. They are not meant to be used recreationally or as part of an addiction. And some people mix different drugs. This can be done for several reasons, but increases the addictive potential of the drugs and also increases the chances of intoxication, often lethal.

In this context of numerous patterns of drug use, some stand out as more archetypical.

38.3.1 Pseudo Therapeutic Long-Term Use

Sedating drugs are meant for short-term use only. The manufacturers, authorities, and society guidelines say that the drugs should be used only for 3–4 weeks. Still many patients continue to use the drugs for longer. This group of patients may cause concern at the doctor's office because of discussions about the re-prescribing of the drugs. Many patients feel that their honesty is being questioned and many doctors feel that they are being "forced" into prescribing for longer than necessary. These patients, however, are not true abusers. They certainly use the drugs for longer than intended, but seldom at high doses, most often at lower doses than prescribed, and they seldom increase their doses. These users are often termed quasi-therapeutic long-term users (Griffiths and Weerts 1997). They are mentioned here because they are quite prevalent and clearly violate recommendations, but may not represent a true problem.

38.3.2 Self-Medicating Pain/Anxiety/Insomnia Patients

Patients with anxiety disorders, but also patients with other psychiatric disorders, may use different prescription drugs to self-medicate or treat their symptoms (McCabe et al. 2009). It is important to acknowledge that anxiety disorders, major depression, PTSD, personality disorders, and pain conditions may lead to overuse of prescription drugs. The possibility of abuse should not stop the doctor from introducing effective and necessary treatment, but the dangers of overuse should be kept in mind. Even when drugs are used as prescribed, the patient may encounter problems such as tolerance, abstinence, abuse, and dependence (see below).

38.3.3 True Prescription Drug Abuser

Some patients can be labeled true prescription drug abusers. These are patients with no or marginal reasons to use these drugs, who still keep using the drugs, often in increasing dosages. They are involved in drug-seeking behaviors such as doctor shopping, prescription forging, and diversion of drugs prescribed to others. The doctor should be aware of these individuals, even though it is not a large group. These patients resemble the next group.

38.3.4 Polydrug Abuse

Many users of heroine or central stimulants use prescription opioids as part of their addiction (Gambi et al. 1999). Benzodiazepines are used to increase the high but also to postpone abstinence in heroin users or to end a binge in users of central stimulants. When such combination use occurs, it is often labeled as polydrug abuse, but it can be argued that it in fact represents a kind of self-medication in

drug abusers who have a main drug problem, be it heroin or central stimulants. This distinction may be important for treatment choices.

The typical patterns of drug use mentioned above may or may not fulfill the criteria for abuse or dependence on drugs. They are not, however, formal diagnoses. The current diagnostic systems define harmful use or abuse and dependence on drugs in the following manner (Table 38.5).

But these diagnoses may not be adequate for prescription drug problems (Kan et al. 2001). Some have thought that these diagnoses are too normative or even stigmatizing, as patients who only have done what the doctor has ordered would be labeled as abusers or dependants. There have been suggestions of using another nomenclature for prescription drugs than for other drugs. This has particularly been advocated in the pain management community, with the increasing use of opioids for nonmalignant pain. It has been argued that three new categories should be introduced (Ballantyne and LaForge 2007): problematic use of prescription drugs, addiction to prescription drugs, and *iatrogenic pseudo-addiction*. It is difficult to see how the two first categories differ substantially from abuse and dependence as defined above. The latter category, however, acknowledges the fact that some aberrant use may be due to suboptimal treatment of the primary condition (especially pain treatment). This kind of inappropriate use is characterized by uncontrolled prescribing of short-acting opioids or low doses of long-acting opioids. In both these cases, patients experience a slowing effect during the period between two doses. This may cause the patient to ask for larger and/or more frequent doses, which could lead to misconceptions of problematic opioid use and break down the trust between the patient and the physician. This leads to a difficult treatment situation which may gradually worsen. In such cases we are talking about iatrogenic abuse. Pain doctors have termed this pseudo-addiction. This terminology has been questioned by some (Manchikanti et al. 2012), who see this way of thinking as an excuse for the large increases observed in opioid abuse.

38.4 Epidemiology of Prescription Drug Abuse

It has been claimed that one third of the world's drug problems stem from alcohol, one third from narcotic drugs, and one third from prescription drugs. Even if this statement highlights the importance of prescription drug abuse, it is obviously too simplistic at least in underestimating problems related to alcohol. Neither does it account for the differences between these problems. But it is difficult to get more accurate figures. Information about aberrant use of substances is not easily available. Responders tend not to answer questions truthfully. Some are reluctant to admit breaking the law. There may also be over-reporting; among the younger population some will be reluctant to admit that they are the only ones who have not tried drugs. And often the people of most interest are not available for answers; they may be imprisoned or in treatment. Some of those you would most like to respond to a survey never open their mailbox or do not even have an address. On the other hand, if you choose to do your research in a prison or a treatment institution,

Table 38.5 Diagnostic criteria according to ICD-10 and DSM-IV for harmful use/abuse and dependence. These criteria apply to prescription drug abuse as for other substances

	ICD-10	DSM-IV
Harmful use/abuse	The diagnosis requires that actual damage should have been caused to the mental or physical health of the user	Substance abuse is defined as a maladaptive pattern of substance use leading to clinically significant impairment or distress as manifested by one (or more) of the following, occurring within a 12-month period
	Harmful patterns of use are often criticized by others and frequently associated with adverse social consequences of various kinds. The fact that a pattern of use or a particular substance is disapproved of by another person or by the culture, or may have led to socially negative consequences such as arrest or marital arguments is not in itself evidence of harmful use	Recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home (such as repeated absences or poor work performance related to substance use; substance-related absences, suspensions, or expulsions from school; or neglect of children or household)
	Acute intoxication or "hangover" is not in itself sufficient evidence of the damage to health required for coding harmful use	Recurrent substance use in situations in which it is physically hazardous (such as driving an automobile or operating a machine when impaired by substance use)
	Harmful use should not be diagnosed if dependence syndrome, a psychotic disorder, or another specific form of drug- or alcohol-related disorder is present	Recurrent substance-related legal problems (such as arrests for substance related disorderly conduct)
		Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance (for example, arguments with spouse about consequences of intoxication and physical fights)
Dependency	A definite diagnosis of dependence should usually be made only if three or more of the following have been present together at some time during the previous year	
	(1) A strong desire or sense of compulsion to take the substance	
	(2) Difficulties in controlling substance-taking behavior in terms of its onset, termination, or levels of use	
	(3) A physiological withdrawal state when substance use has ceased or have been reduced, as evidenced by: the characteristic withdrawal syndrome for the substance; or use of the same (or closely related) substance with the intention of relieving or avoiding withdrawal symptoms	
	(4) Evidence of tolerance, such that increased doses of the psychoactive substance are required in order to achieve effects originally produced by lower doses (clear examples of this are found in alcohol- and opiate-dependent individuals who may take daily doses sufficient to incapacitate or kill non-tolerant users)	
	(5) Progressive neglect of alternative pleasures or interests because of psychoactive substance use, increased amount of time necessary to obtain or take the substance or to recover from its effects	
	(6) Persisting with substance use despite clear evidence of overtly harmful consequences, such as harm to the liver through excessive drinking, depressive mood states consequent to periods of heavy substance use, or drug-related impairment of cognitive functioning; efforts should be made to determine that the user was actually, or could be expected to be, aware of the nature and extent of the harm	

you will face the problem of selection bias. Not all abusers or dependants will be under treatment or imprisoned. The take-home message is that to study the epidemiology of abuse, you need to draw on a variety of sources to aggregate comprehensive data. This is no less true for prescription drug abuse.

There are two principle types of information that we aim to gather from epidemiological studies. The first is to look for signals of abuse in drugs not previously recognized as drugs of abuse. This is pharmacological research. Case reports and case series often give the first signals of such abuse potential (Arfken and Cicero 2003; Hajak et al. 2003). These signals must be followed up by more systematic and broader investigations. This is done both to substantiate a signal of a drug having an abuse potential and to investigate the extent of abuse. This kind of information is essential for grasping the size of the problem and how to cope with it. This is epidemiological research. The different sources of data below may serve as providers of both types of information.

38.4.1 Monitoring Patients or Populations

38.4.1.1 Population Surveys

Surveys have shown us that non-prescribed use of prescription drugs is quite common. The National Comorbidity Survey showed that more than 7 % of adults reported having used non-prescribed sedatives (Goodwin and Hasin 2002). Being male, being older, having a parent who has done the same, and reporting more psychiatric symptoms increased the risk (Clark et al. 2004; Brunette et al. 2003). From other studies we know that people with alcohol or drug-use problems have a higher risk of abusing prescription drugs (Longo and Johnson 2000). A survey, also from the United States, showed that during the previous month, around 2 % of the total population (≈6 million people) had abused pain medication, 0.7 % tranquilizers (mostly benzodiazepines), 0.4 % stimulants (ADHD medication), and 0.1 % sedatives in 2008 (SAMHSA 2009).

38.4.1.2 Patient Surveys

The Drug Abuse Warning Network (DAWN) has gathered information on drugs mentioned at emergency room visits across the United States since 1974 and serves as a source of information about the extent of prescription drug abuse and gives signals on new drugs of abuse (Cai et al. 2010). The 2010 figures show that 30 % of the mentions on prescription drugs are benzodiazepines and 40 % are opioids. The drugs were mentioned in 20 % and 18 % of all emergency room visits, respectively, and prescription drugs were mentioned almost as often as narcotics. It is also of value getting information from patients entering treatment for drug abuse (Jaffe et al. 2004).

38.4.1.3 Adverse Effects Databases

Signals of prescription drug abuse often come from national or international adverse effects databases, such as the WHO in Uppsala Monitoring Centre Adverse

Effects Database. Such databases have given us information on the abuse liability of drugs like pregabalin (Gahr et al. 2013).

38.4.1.4 Forensic Data

Data from driving under the influence (DUI) cases, from autopsies, or from prisons may be useful in determining whether drugs are abused and which drugs are popular in which areas.

38.4.2 Monitoring Sources of Drugs

38.4.2.1 Sales Statistics

In the 1990s doctors started treating nonmalignant pain with opioids, and a sharp increase in the abuse of the drug has followed. As seen above in the total consumption model, the sales of the drugs can tell us something about the amount of problematic use (and other adverse events; see Fig. 38.1). The large sales of opioids in the United States are closely related to high levels of abuse. For example, among 12th graders in the United States, nonmedical use of prescription drugs (opioids) is the second most common form of abuse (Manchikanti et al. 2012). Sales data should be followed by area and/or country, because it gives useful hints on specific abuse trends.

38.4.2.2 Prescription Data

Prescription data are another source of information. These data stem from claims databases in insurance institutions; national prescription databases, such as those

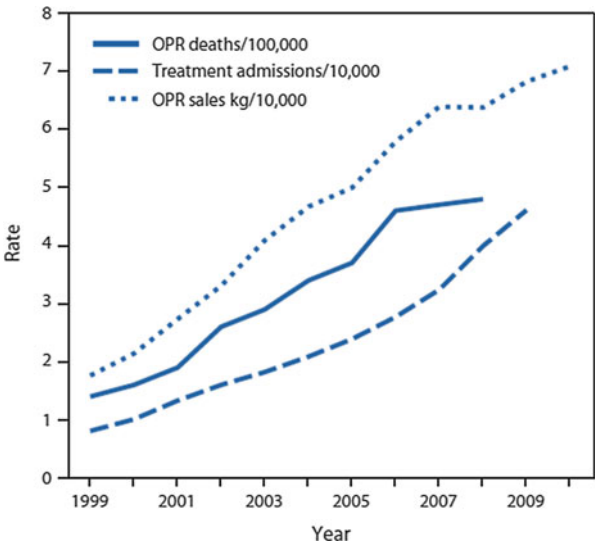

Fig. 38.1 Data on Rates* of opioid pain reliever (OPR) overdose death, OPR treatment admissions, and kilograms of OPR sold in United States (1999–2010). Data from US Centers for Disease Control and Prevention 2011

found in many countries in northern Europe; or through pharmacy records. Basically two types of information, both important, can stem from these sources. Firstly, we can gain information about the abuse liability of a drug by looking at phenomena like:

- "Doctor shopping": The more doctors a drug seeker is willing to go to in order to get hold of the drug, the higher the abuse liability (Peirce et al. 2012).
- Forged prescriptions: The more the prescriptions for a drug are forged, the higher the abuse potential (Frauger et al. 2012).
- High use of a drug: Indicating some using it for recreational purposes (Frauger et al. 2009; Pauly et al. 2011).
- Skewness in use: If a large part of the drug is consumed by a few individuals this is indicative of abuse liability (Gaist et al. 1997; Hallas and Støvring 2006).

Secondly, these sources of information might tell us directly how many individuals show overuse of the drugs in an area (Bramness et al. 2007). These data point to the fact that drugs like carisoprodol, clonazepam, flunitrazepam, alprazolam, and all opioids are attractive abuse drugs.

38.4.2.3 Other Legal/Gray Sources

Surveys in the normal population have shown that the most prevalent sources of prescription drugs for abuse are friends and family (McCabe 2008). This US study showed how pain medication was most often obtained; it may be different in other countries. Having a drug problem, using a lot of alcohol or having peers with use increased the risk. Still we know that many individuals start to abuse through drugs prescribed to a family member (Ballantyne 2007).

38.4.2.4 Illegal Sources

Prescription drugs, be it opioids, benzodiazepines, or others, are found on the black market. They are diverted illegally from people who have them prescribed, do not use them, but sell them. They are sold after thefts from patients, pharmacies or factories. Thus drug abuse situations can be monitored by looking at seizures of drugs by the police or customs.

38.4.2.5 Novel Channels of Drugs

The Internet is a novel source of drugs and very difficult to control. Only a small share of the drugs bought are ever discovered by customs. But turning it the other way around, monitoring the Internet can be a way of picking up new trends. One such project is the European Union funded Psychonaut Web Mapping Project that has been successful in identifying ever-increasing numbers of novel substances (Deluca et al. 2012). But data can also be collected by looking at websites for information or online reports of abuse (Schifano et al. 2011).

38.4.2.6 Wastewater Analysis

A novel approach that might give results in the future is to look at the presence of prescription drugs in wastewater (sewage analysis) (Reid et al. 2011). By comparing sales statistics with findings in wastewater, one could get an idea of the black

market for a drug, but also looking at weekly temporal variations in drugs, one might get a feeling how much is used for recreational use (most at weekends and less during weekdays) and how much is used on a regular basis (more evenly distributed).

Where does all this leave us? Firstly, we cannot today seriously say we know the extent of the problem of prescription drug abuse. No single source of data can substantiate all drugs that are abused or the extent of this abuse. Some data (surveys) will be flawed by information and selection bias; some data (databases) will not be able to identify the clinical features of abuse or dependence. We are therefore stuck with a number of estimates. And what do these tell us?

- These drugs are often used, but most use is clinically correct and well founded.
- Prescription drugs are, however, often abused and the problem of abuse is increasing.
- The size of the problem is related to total sales of the drug; increased use always comes at the price of increased abuse. Countries with a high prescribing rate (such as the United States) have a substantial problem. In such countries the problems following prescription drug abuse may equal those following the use of narcotic drugs.
- Some drugs have a higher abuse potential than others. As with other drugs of abuse, prescription drugs with high potency and a rapid effect will be more attractive to abusers.
- Patients who have legitimate use of these drugs are also at risk for abuse, and even use according to the doctor's recommendations can be problematic. Doctors should review their patient lists and take action when necessary.
- Specific populations will have more risk of abuse of prescription drugs than others. These include drug abusers, psychiatric patients, but also patients with somatic problems such as pain.
- It often takes a long time from when a drug is first marketed until its true abuse potential is revealed, even with modern requirements for pre-marketing investigations. Always be open to signals of a drug's abuse potential.

38.5 Strategies for Prevention

Having drugs available only on prescription is in itself a measure to control their use. The process of prescribing has come into place to increase the doctor's ability to monitor effects and adverse events, including abuse. Drugs with no or mild adverse effects may be sold without a prescription, so-called over-the-counter (OTC). However, even for these drugs, there may be regulations in place, such as age limitations on who is allowed to buy them, package size, and where the drugs may be placed for sale (are they on view to the customers?).

Other measures have been introduced to send signals on the abuse liability of medicinal drugs. How this is done will vary between countries, but basically there are two ways. First, it may include having rules and regulations on specific drugs

Table 38.6 Prescription drug are according to US health authorities classified after their potential for harm, including abuse. Not all drugs in this list are prescription drugs, but some are

Schedule	Definition	Most central drugs included
I	Drugs with no currently accepted medical use in treatment in the United States and high potential for abuse and dependence	Cathinone, GHB, heroin, LSD, marijuana, MDMA, most hallucinogens, methaqualone (Quaalude)
II	Drugs with currently accepted medical use in treatment with severe restrictions in the United States and high potential for abuse and dependence	Cocaine, amphetamines, other opiates than heroin, some opioids, some synthetic cannabinoids, barbiturates
III	Drugs with currently accepted medical use in treatment in the United States and with a lower risk for abuse than drugs in schedules I and II and low to moderate dependence risk	Anabolic steroids, some barbiturates, buprenorphine, codeine, ketamine, GHB as Xyrem, some synthetic cannabinoids
IV	Drugs with an accepted medical use in treatment in the United States and with a low risk for abuse and dependence (lower than III)	Benzodiazepines, benzodiazepine-like z-hypnotics, some barbiturates, carisoprodol
V	Drugs with a current accepted medical use in treatment in the United States and with a low risk for abuse and dependence (lower than IV)	Codeine, pregabalin, lacosamide, atropine

within the prescribing system, under the laws of medicinal drugs. This could imply different rules and regulations for prescribing these drugs compared to other drugs:

- The use of special prescribing.
- Only one doctor can prescribe to one patient.
- Only one pharmacy can deliver the drug.
- Only a specialist in a certain field can prescribe the drug.
- Special forms should be used for prescribing certain drugs.
- Special authorities should be informed and can perform controls/audits.
- Only certain package sizes can be prescribed.
- No telephone or Internet prescribing allowed for certain drugs.

Second, it could involve placing some medicinal drugs on narcotics lists and lists of controlled or prohibited substances. This places the drug under jurisdiction outside the health-care system and makes it police business. In many countries' legislative systems, these boundaries are not so clear and (often for historical reasons) illegal drugs and medicinal drugs are regulated by the same laws. The scheduling system in the United States is such a system (Table 38.6). The different degrees of scheduling can be followed by different rules or regulations for prescribing as mentioned in examples above.

One could imagine that having a regime of prescribing and scheduling would prevent widespread aberrant use, but this is not true. Aberrant use, be it abuse, dependence, or over-consumption, is seen despite these precautions. Research has shown us that the occurrence of overuse follows the sales of the drug in the

community or group and the prevalence of abuse can be predicted by sales, following the total consumption model. This model states that there is a close relationship between the population mean of a health variable, in this case prescribing of drugs with an abuse potential, and the prevalence of individuals at high risk concerning this variable (Skog 1980). The model applies for alcohol consumption and heavy drinkers and for the availability of narcotics drugs and has now been shown to apply for prescriptions drugs (Bramness and Rossow 2010). This understanding is important for two reasons. Firstly, a lot about aberrant drug use in a group or a country can be learnt from sales statistics. We do not always need clinical investigations! And secondly, preventive measures can be any procedure that will limit the prescribing of a drug. Such measures must always be weighed against what is good treatment. But this also teaches us that guidelines which open for liberal practices may have this downside.

We know that some doctors, independently of the profile of their patients, prescribe more drugs with abuse potential than others. This can be due to local traditions, to countrywide regulations, but also has to do with the doctor's own beliefs and ideas. Doctors with a liberal view on these drugs tend to prescribe more. This is also reflected in the doctors' own use of these drugs; doctors more willing to use these drugs themselves are also more willing to prescribe them to their patients (Rosvold et al. 1998).

Prescription drugs are to be sold after a consultation, after a review of the patient's problems, and by prescriptions. We see, however, an increasing sale of prescription drugs via the Internet. The police and customs face an almost impossible task trying to stop the import and illegal sales of prescription drugs via this route. Patients who get their drugs from the Internet pharmacies and the Internet pharmacies themselves are operating in a gray zone. We do not know the extent of this Internet market, but different estimates usually suggest enormous figures. There is a thin line between these sources and a true black market. The only way to deal with this is to appeal to people's reasoning and warn against the dangers of receiving a suboptimal product. Some of the products are of good quality, but others contain little or no active ingredient or even toxic material.

38.6 Treatment

The boundary between prevention and treatment is often obvious, but sometimes it can be unclear. Some preventive measures will be embedded in treatment and some experiences and views from treatment will be reflected in prevention.

38.6.1 Tackling the Drug-Seeking Patient

What kind of drug-seeking behavior physicians will encounter may vary according to their field but also according to their place or country of work. Some common

features can, however, be mentioned. Beware of lost prescriptions, lost medicines, or other reasons patients give for needing a prescription earlier (Isaacson 2000; Gerhardt 2004). Also be cautious prescribing drugs with abuse potential to patients you do not know. Optimally only one doctor should write drugs with an abuse potential to one patient, and these drugs should be given out only by one pharmacy. But if other doctors need to write prescriptions to patients that they do not know, they need to do a proper work-up and confirm diagnosis. The drugs with less abuse potential should be prescribed in the smallest possible quanta. Remember that you do not have to prescribe a whole package, even of the smallest package. The crux is to give your patients appropriate care. Withholding effective medication to needy patients is not an optimal alternative. Some institutions have policies for not prescribing drugs with an abuse potential to patients at certain times or under certain conditions. These institutions can report that they avoid a lot of drug-seeking patients, because word often spreads quickly if you cannot get what you want, but the institutions also risk not providing adequate treatment in some cases.

38.6.2 Minimal Interventions

If you, as a prescriber, are worried about a patient's use of prescription drugs, the first step is to discuss this with your patient. Open communication is of the essence. Even if the patient does not admit to a problematic relationship with these drugs, just verbalizing the issue may give them food for thought. Some doctors regularly review their patient lists and try to get a grip on who they should be concerned about. One strategy would be to send a letter of concern to the patients in question, just informing them of the potentially problematic sides to their drug use. Such a simple intervention has proven very efficient in stopping or reducing drug use in some patients (Mugunthan et al. 2011). Further support may be needed ("stepped care") and follow-up could include information meetings (pharmacology education), psycho-educative programs (information about the underlying disease and alternatives to pharmacological treatments), support groups, or even group therapy (Voshaar et al. 2006).

38.6.3 Tapering in the More Difficult Cases

Most studies show that gradual tapering of the medication is preferable to abrupt discontinuation (Parr et al. 2009; Denis et al. 2006). The use of anticonvulsants like carbamazepine or valproate can be of use for benzodiazepine withdrawal and clonidine for opioid withdrawal. Also some authors suggest the use of benzodiazepines for withdrawal from opioids, even if this can mean substituting one addiction with another (Fatseas and Auriacombe 2007). The main principle is to substitute short-acting drugs with longer-acting drugs, in order to have more control over the withdrawal symptoms.

38.6.4 Tapering the Patients with Benzodiazepine Dependence

A thorough evaluation must be performed of the actual dose the patient has been using. One should aim at reducing all the different benzodiazepines and benzodiazepine-like drugs to two different drugs at the most. Most often the recommendation is to switch to a longer-acting drug like diazepam (in most people) or a drug with fewer reinforcing effects like oxazepam (in drug abusers or the elderly). Remember that some benzodiazepines (e.g., alprazolam, clonazepam, and flunitrazepam) are 10–20 times more potent and need to be converted to equivalent diazepam doses. For good cooperation between you and your patient, you need to assure the patient that he/she will be adequately covered. For outpatient treatment you may want to taper by reducing 20 % of the total daily dose during the first months, then 10 % of the dose later, and then 5 % or less for the last weeks. Allow the patient to reach a steady state between dose reductions and allow for time to tackle the withdrawal symptoms. For adults with a half-life of 1–1.5 days of diazepam, one step can be performed every second week, but for older people the terminal elimination half-life of diazepam increases and more time should be allowed for each step. A lot of support and encouragement may be needed, sometimes in support groups, sometimes individually. For inpatient treatment a more aggressive approach is recommended. Often the patient will not be given enough time for a slow taper. The amount of withdrawal the patient needs to manage is constant either with short- or long-term tapering. Thus, in the inpatient situation a tapering of the whole dose within 2–3 weeks is recommended. You must then be aware of benzodiazepine delirium.

38.6.5 Tapering/Detoxifying the Patients with Opioid Dependency

The tapering of prescription opioids should always be done after a thorough work-up on pain and consideration of adequate pain management. For this we refer to textbooks on pain management. Even if inadequate pain management is the cause of the patient's problem, reduction or removal of the drugs will be needed. This would involve tapering. Such tapering can be more manageable using a long-acting opioid such as methadone or buprenorphine as a tool, even supported by clonidine to tackle the worst withdrawal symptoms. For further information on ▶ Chap. 28, "Opioid Addiction: Short- and Long-Acting Opioids".

38.6.6 Intoxications

Acute treatment of intoxications with prescription drugs should be handled as other emergencies. Life support including airways, breath, and circulation should be observed. Gastric lavage can be performed if necessary and when done within a limited amount of time. For opioids and benzodiazepines, there are antidotes in naloxone and flumazenil. Otherwise drugs should be given on indication.

Benzodiazepine delirium: This should be treated like an alcoholic delirium tremens. Reinstating benzodiazepines and tapering them at a slower pace would be the preferred mode.

38.7 International Perspectives

There are huge differences in the availability of psychotropic drugs worldwide. While Europe and North America constitute 12 % and 7 % of the world's population, respectively, these continents consume 83 % of the world's prescription opioids (1996–2000 data) (Ghodse 2003); this figure is over 90 % when we look at ADHD drugs. The good news is that many countries outside Europe and North America have fewer problems with prescription drug abuse. This gives these countries the possibility of choosing another way, with fewer problems concerning these drugs. We must however remember that this may render some patients undertreated for their maladies.

Further Reading

There are several books on recovery stories by patients who have quit the habit of benzodiazepines or opioids. These can be illustrative and helpful for other people trying to stop taking these drugs. One problem may be a lack of perspective in these stories of prescription-drug abuse survivors. They often lack perspective on what drugs are harmful and what drugs are not and on the fact that some people need these drugs for their treatment, while others are better off not using them. Two books that can be recommended are:

- Hobson-Dupont J (2006) The Benzo book: getting safely off tranquilizers. Essex Press. A personal story with good advice on benzodiazepine withdrawal
- Johns B (2010) Benzo-wise: a recovery companion. Campanile Publishing. A personal story with good advice on benzodiazepine withdrawal

One piece of further reading that is not out in book form, but is readily available on the internet is The Ashton Manual:

- Ashton H. Benzodiazepines: how they work and how to withdraw. http://www.benzo.org.uk/manual/. This holds information about benzodiazepines and sets up schemes for tapering. The web page (supported by Roche!) has many hints and supports for people coming off prescription drugs

Regulatory Aspects of New Medications to Treat Addictions: The U.S. IND Process

39

Robert L. Walsh

Contents

Abstract

In most countries, for a medication to be available to treat addictions, it must first go through a development and approval process. In the United States, the Center of Drug Evaluation and Research (CDER), of the Food and Drug Administration (FDA), is the Federal agency responsible for approving new addiction pharmacotherapies based upon their safety and efficacy. The Investigational New Drug (IND) application is the means by which FDA allows a new medication to be studied in humans. In order to be able to test a potential medication for addiction in humans, FDA requires certain tests to be conducted to (1) characterize the

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment: International Perspectives*, DOI 10.1007/978-88-470-5322-9_30,

chemical properties of the molecule so that it can be manufactured and formulated reliably over several batches, (2) determine the toxicological properties of the medication so that it can be administered at safe doses, (3) ensure that anticipated toxicities can be monitored for in a study to avoid irreparable harm to study subjects, and (4) identify potential interactions that may occur when the medication is used in combination with the drug of abuse. This chapter will provide an overview of the IND process, the sections of an application, maintenance of an IND, and important meetings and identify the conditions for which a study is exempt from requiring an IND.

39.1 Regulatory Aspects

39.1.1 The Investigational New Drug (IND) Process

Current US Federal law requires that a drug be the subject of an approved marketing application before it is transported or distributed across state lines. The Federal Food, Drug, and Cosmetic Act (FD&C Act), section 355 – New drugs states that "No person shall introduce or deliver for introduction into interstate commerce any new drug, unless an approval of an application filed pursuant to subsection (b) or (j) of this section is effective with respect to such drug." Because a sponsor often manufactures the drug in one location and then needs to ship the investigational drug to clinical investigators in many states and/or countries, it has to seek an exemption from that legal requirement. The IND is the mechanism through which the sponsor technically obtains this exemption from the FDA.

In the United States, the sponsor of an IND must have a US address or agent. The US Code of Federal Regulations, 21 CFR 312.23 (a)(1)(ix), states that a sponsor shall include in the IND application "The signature of the sponsor or the sponsor's authorized representative. If the person signing the application does not reside or have a place of business within the United States, the IND is required to contain the name and address of, and be countersigned by, an attorney, agent, or other authorized official who resides or maintains a place of business within the United States." Often sponsors outside of the United States, who do not maintain offices in the United States, will use a contract research organization (CRO) to act as their agent for the IND.

Before studies in humans can begin, an Investigational New Drug (IND) application must be submitted to the FDA containing, among other things, information on any risks anticipated based on the results of pharmacological and toxicological data collected during studies of the drug in animals as outlined in 21 CFR 312.23(a)(8). These basic safety tests are often performed in mice, rats, and dogs. The studies are designed to allow a sponsor to identify a safe starting dose to give the drug to humans. The studies also allow a sponsor to gain an understanding of which organs may be the targets of toxicity, to estimate the margin of safety between a clinical and a toxic dose, and to predict pharmacokinetic and pharmacodynamic parameters. The central focus of the initial IND submission should be on the general investigational plan and the protocols for specific human studies.

An IND enables a sponsor to communicate all of the known information about a potential medication to FDA for the agency to review. FDA's primary objectives in reviewing an IND are to assure that the safety and rights of subjects are protected and to assure that the quality of the scientific evaluation is adequate to permit an evaluation of the drug's effectiveness and safety.

Upon receipt of an IND, the FDA has 30 days to make a determination as to whether the proposed study in humans may proceed. Generally, in about 1–2 weeks after submitting the IND, the sponsor will receive a letter of receipt showing the date the IND was received at FDA. This date is when the 30-day review clock is measured from.

If no feedback is provided by FDA, verbally or in writing, the study may proceed as submitted after the 30 days has passed. This is an important point because, in these cases, a sponsor often does not receive a letter stating that the study may proceed.

When approximately 15 days have passed after receipt of the IND, the internal FDA review team may meet and discuss any concerns they may have regarding their review of the IND. If there are concerns, they will contact the sponsor and try to resolve the concerns before the 30-day clock runs out in order to avoid placing the IND on "clinical hold," as required under 21 CFR 312.42. If the safety concerns cannot be resolved within the 30-day time frame, FDA will contact the sponsor (usually in a teleconference) and inform them that the IND is being put on "clinical hold." If an IND is placed on clinical hold, no studies in humans may proceed until all of the safety concerns are addressed to FDA's satisfaction. FDA will provide a "clinical hold letter," within 30 days from the date of the teleconference, which describes in detail the reasons for the IND being placed on clinical hold. Upon receipt of that letter, the sponsor must respond, in writing, to the FDA detailing how they will address the concerns identified by FDA.

When the sponsor has addressed all of the clinical hold issues identified in the letter, it will have provided a "complete response." FDA will then respond to the sponsor within 30 days of receipt of the complete response indicating whether the hold is lifted, or if not, specifying the reasons why not. After an IND is placed on clinical hold, studies may not be initiated in humans until FDA contacts the sponsor (via phone, fax, letter, or e-mail) informing them that the study may proceed.

The IND is used to update FDA on the progress throughout the development life cycle of a potential medication to the submission of a marketing application known as a New Drug Application (NDA). The IND is also the mechanism which allows the sponsor to obtain input regarding protocol design, report adverse events, and provide final study reports and results to the FDA.

39.1.2 The Investigational New Drug (IND) Application

The amount of information, on a particular drug, that must be submitted in an IND can vary greatly and will depend upon such factors as the novelty of the drug, the extent to which it has been studied previously, the known or suspected risks, and the developmental phase of the drug.

The IND application is comprised of multiple sections which are differentiated into:

1. Cover Sheet
2. Table of Contents
3. Introductory Statement and General Investigational Plan
4. Investigator's Brochure
5. Protocol(s) (Clinical)
6. Chemistry, Manufacturing, and Control Information
7. Pharmacology/Toxicology Information
8. Previous Human Experience
9. Additional Information

39.1.2.1 The Cover Sheet

The cover sheet introduces the IND application to the FDA. It identifies who the sponsor is and to whom correspondence should be communicated to.

39.1.2.2 Table of Contents

The table of contents identifies the sections and subsections of the IND and on what pages they can be found.

39.1.2.3 Introductory Statement and General Investigational Plan

The introductory statement and general investigational plan section(s) is intended to be only about 2–3 pages in length. The information presented here is to put the sponsor's development plan for the drug into perspective and to help FDA anticipate the sponsor's future needs, such as when critical meetings might need to take place. This helps the agency to identify potential "crunch times" when a number of critical items may need to be addressed in the same time period.

This section provides the name of the drug and all active ingredients, the drug's pharmacological class, the structural formula of the drug (if known), the formulation of the dosage form(s) to be used, the route of administration, and the broad objectives and planned duration of the proposed clinical investigation(s).

39.1.2.4 The Investigator's Brochure (IB)

The investigator's brochure is a compilation of all of the clinical and nonclinical data known on the potential medication which is relevant to the study of the product in human subjects. The purpose of the IB is to provide the investigators, and others involved in the trial, with the information to facilitate their understanding of the rationale for, and their compliance with, many key features of the protocol, such as the dose, dose frequency/interval, methods of administration, and safety monitoring procedures. The IB also provides insight to support the clinical management of the study subjects during the course of the clinical trial. The information should be presented in a concise, simple, objective, balanced, and non-promotional form that enables a clinician, or potential investigator, to understand it and make his/her own unbiased risk-benefit assessment of the appropriateness of the proposed trial.

The IB typically contains:

- A brief description of the drug substance and the formulation, including the structural formula, if known
- A summary of the pharmacological and toxicological effects of the drug in animals and, to the extent known, in humans
- A summary of the pharmacokinetic and biological disposition of the drug in animals and, if known, in humans
- A summary of information relating to safety and effectiveness in humans obtained from prior clinical studies (reprints of published articles on such studies may be appended when useful)
- A description of possible risks and side effects to be anticipated on the basis of prior experience with the drug under investigation or with related drugs and of precautions or special monitoring to be done as part of the investigational use of the drug

Often the information needed for the IB can be obtained from the summary that is included at the front of each of the IND sections. This document can also be valuable to Institutional Review Board/Institutional Ethics Committee members to help with their review of the proposed study and to help them determine the potential risks to subjects.

39.1.2.5 Protocol

The protocol section of the IND contains a protocol for each planned study. It is expected that protocols for phase 1 studies may be less detailed and more flexible than protocols for phases 2 and 3 studies. Phase 1 protocols should be directed primarily at providing an outline of the investigation – an estimate of the number of patients to be involved, a description of safety exclusions, and a description of the dosing plan including duration, dose, or method to be used in determining dose – and should specify in detail only those elements of the study that are critical to safety, such as necessary monitoring of vital signs and blood chemistries. For phase 1 studies of potential medications for drug addiction, it is important to also include what measures (i.e., medications and medical equipment that will be available at all times during the study, training and availability of staff, etc.) will be taken to anticipate for any unexpected life-threatening events that may occur during the conduct of the study.

For phase 1 studies of potential medications for drug addiction, it is important to also detail what measures (i.e., medications and medical equipment that will be available at all times during the study, availability of appropriately trained medical staff, etc.) will be taken to anticipate any unexpected life-threatening events such as cardiac arrest or another serious adverse event that may occur during the conduct of the study. The measures proposed need to be well thought out and should give an FDA reviewer a sufficient level of comfort that unexpected serious adverse events have been anticipated and planned for.

In phases 2 and 3, detailed protocols describing all aspects of the study should be submitted. A protocol for a phase 2 or 3 investigation should be designed in such a way that if the sponsor anticipates that some deviation from the study design may

become necessary as the investigation progresses, alternatives, or contingencies to provide for such deviation are built into the protocols at the outset. For example, a protocol for a controlled short-term study might include a plan for an early crossover of nonresponders to an alternative therapy.

Phase 2 studies should be designed to identify measurable outcome measures that could be used in the phase 3 studies to definitively prove the efficacy of the medication. Often a phase 2 study will have one primary, and multiple secondary, outcome measures. They can then be analyzed to determine which one may be the best choice as the primary outcome measure to be used in a pivotal phase 3 study.

39.1.3 Chemistry, Manufacturing, and Controls (CMC)

The regulations at 21 CFR 312.23 (a)(7)(i) emphasize the graded nature of chemistry, manufacturing, and controls (CMC) information needed as development under an IND progresses. Although in each phase of a clinical investigational program, sufficient information should be submitted to ensure the proper identification, strength, quality, purity, and potency of the investigational candidate, the amount of information needed which will provide that assurance will vary with the phase of the investigation, the proposed duration of the investigation, the dosage form, and the amount of information already available.

The emphasis in an initial phase 1 CMC submission should be placed on providing information, detailing the identification and control of the raw materials and the new drug substance. This will allow an evaluation of the safety of subjects in the proposed study.

This section should contain a brief description of the overall plan for investigating the drug product for the following year. Detailed developmental plans are often contingent on the outcome of the planned study(ies). In that case, sponsors should simply state this and not try to develop overly detailed plans.

The plan should include the following:

(a) The rationale for the drug or the research study
(b) The indication(s) to be studied
(c) The general approach to be followed in evaluating the drug
(d) The kinds of clinical trials to be conducted in the first year following the submission (if plans are not developed for the entire year, the sponsor should so indicate)
(e) The estimated number of patients to be given the drug in those studies
(f) Any risks of particular severity or seriousness anticipated on the basis of the toxicological data in animals or prior studies in humans with the drug or related drugs

39.1.4 Pharmacology/Toxicology

The development of a medication is a stepwise process involving an evaluation of both animal and human safety information. The goals of the nonclinical safety

evaluation include characterizing the toxic effects of the potential medication with respect to:

- Target organs
- Dose dependence
- Relationship to exposure
- Potential reversibility

This information is important to estimate an initial safe starting dose for the human trials and to identify parameters to allow clinical monitoring for potential adverse effects. The nonclinical safety studies, which may be limited at the beginning of clinical development, should be adequate to characterize any potential toxic effects which may be anticipated under the conditions of the proposed clinical trial.

The pharmacology/toxicology section should contain adequate information about the pharmacological and toxicological studies of the drug involving laboratory animals or in vitro, which the sponsor used as the basis for concluding that it is reasonably safe to evaluate the potential medication in human subjects.

The kind, duration, and scope of animal and other tests required vary with the duration and nature of the proposed clinical investigation. Such information is required to include the identification and qualifications of the individuals who evaluated the results of such studies and concluded that it is reasonably safe to begin the proposed investigations and include a statement of where the investigations were conducted and where the records may be made available for inspection.

The nonclinical safety study recommendations for the marketing approval of a pharmaceutical usually include single and repeated dose toxicity studies, reproduction toxicity studies, genotoxicity studies, local tolerance studies, and, for drugs that have special cause for concern or are intended for a long duration of use, an assessment of carcinogenic potential. Other nonclinical studies include pharmacological studies for safety assessment (safety pharmacology) and pharmacokinetic (absorption, distribution, metabolism, and excretion (ADME)) studies.

An additional aspect of developing medications to treat addiction is the need for animal drug-drug interactions studies with drugs of abuse. Since drug users often abuse multiple drugs, it is necessary to know not only whether the potential medication will interact with the specific drug of abuse it is being developed for but also whether it will interact with other commonly co-abused drugs. To address that concern the potential medication is tested against cocaine, morphine, and alcohol in animals prior to initiating phase 2 studies. These studies serve to alert the sponsor and FDA of any particular interaction that could occur in humans.

The types of studies that are summarized in the pharmacology/toxicology section of the initial IND application are those that were conducted to support initial and early clinical development studies.

39.1.5 Previous Human Experience

If the investigational drug has been investigated or marketed previously, detailed information relevant to the safety of the proposed investigation or to the

investigation's rationale should be provided. If the drug has been studied in controlled clinical trials, detailed information on those trials, relevant to an assessment of the drug's effectiveness for the proposed investigational use(s), should be included. If there is no known human experience with the investigational drug that should be stated in this section.

Copies of any published material relevant to the safety of the proposed investigation or to an assessment of the drug's effectiveness for its proposed investigational use should be provided in full. Published material that is less directly relevant can be included in a bibliography.

If the drug is a combination of drugs previously investigated or marketed, information should be provided for each active drug component. However, if any component in such combination is subject to an approved marketing application or is otherwise lawfully marketed in the United States, the sponsor is not required to submit published material concerning that active drug component unless such material relates directly to the proposed investigational use (including publications relevant to component-component interaction).

If the drug has been marketed outside the United States, a list of the countries in which the drug has been marketed and a list of the countries in which the drug has been withdrawn from marketing and the reason for the withdrawal must be included.

39.1.6 Additional Information

In certain applications, information on special topics may be needed. The types of information to be submitted in this section are:

1. Drug dependence and abuse potential – If the drug is a psychotropic substance or otherwise has abuse potential, information describing what relevant studies have been done is identified here. Information from both human and animal studies should be included.
2. Radioactive drugs – If the drug is a radioactive drug, sufficient data from animal or human studies to allow a reasonable calculation of radiation-absorbed dose to the whole body and critical organs upon administration to a human subject should be provided. Phase I studies of radioactive drugs must include studies which will obtain sufficient data for dosimetry calculations.
3. Pediatric studies – Proposed plan for assessing pediatric safety and effectiveness should be provided.
4. Other information – A brief statement of any other information that might aid the evaluation of the proposed clinical investigations with respect to their safety or their design. The ability of the studies to be considered as controlled, clinical trials to support marketing of the drug should also be discussed.

39.1.7 IND Meetings

39.1.7.1 Pre-IND Meeting

Prior to the submission of the initial IND, the sponsor can request a meeting with FDA-reviewing officials. The primary purpose of this meeting is to review and

reach agreement on the adequacy of the chemical information and animal studies needed to initiate human testing. The meeting may also provide an opportunity for discussing the scope and design of phase 1 testing, plans for studying the drug product in pediatric populations, and the best approach for presentation and formatting of data in the IND.

CDER's Pre-Investigational New Drug Application (IND) Consultation Program fosters early communications between sponsors and new drug review divisions to provide guidance on the data necessary to warrant IND submission. The review divisions are organized generally along therapeutic class and can each be contacted using the designated Pre-IND Consultation List (Fig. 39.1).

39.1.7.2 End of Phase 2 Meeting

The end of phase 2 meeting is often considered to be the most critical meeting held during an investigational drug's development process. The main objectives of an end of phase 2 meeting are:

- To obtain agreement with FDA on pivotal study designs and safety and efficacy endpoints for phase 3 studies. This is to ensure that the planned pivotal studies will provide the information and data required to obtain approval for marketing the medication in the United States.
- To update the agency as to the progress of pharmacokinetic (PK) studies and to discuss additional studies that may be needed. This will ensure that any issues raised as a result of the PK studies and/or other safety concerns that may exist for a specific population are addressed.
- To agree that the preclinical data with regard to duration, route of administration, and formulation are supportive of the dose to be used in the phase 3 clinical trials.
- To discuss the intended approach to specifications and test methods to ensure that the methods to be used to manufacture the medication are appropriate and will provide the necessary information regarding impurities and batch-to-batch consistency.
- To discuss the intended "marketed" formulation.
- To identify other issues or potential problems (novel regulatory or technical concerns).

39.1.8 Drug Master File Program

A Drug Master File (DMF) is submitted to the FDA to provide confidential, detailed information about facilities, processes, or articles used in the manufacturing, processing, packaging, and storing of one or more human drugs. This can be valuable in cases where a sponsor is opening multiple INDs on the same investigational drug (such as for different indications) since the sponsor can provide a letter of authorization to allow FDA staff to cross-reference the information on behalf of the IND applicant rather than having to provide the identical information in each IND application. It is also useful when a sponsor wishes to support the

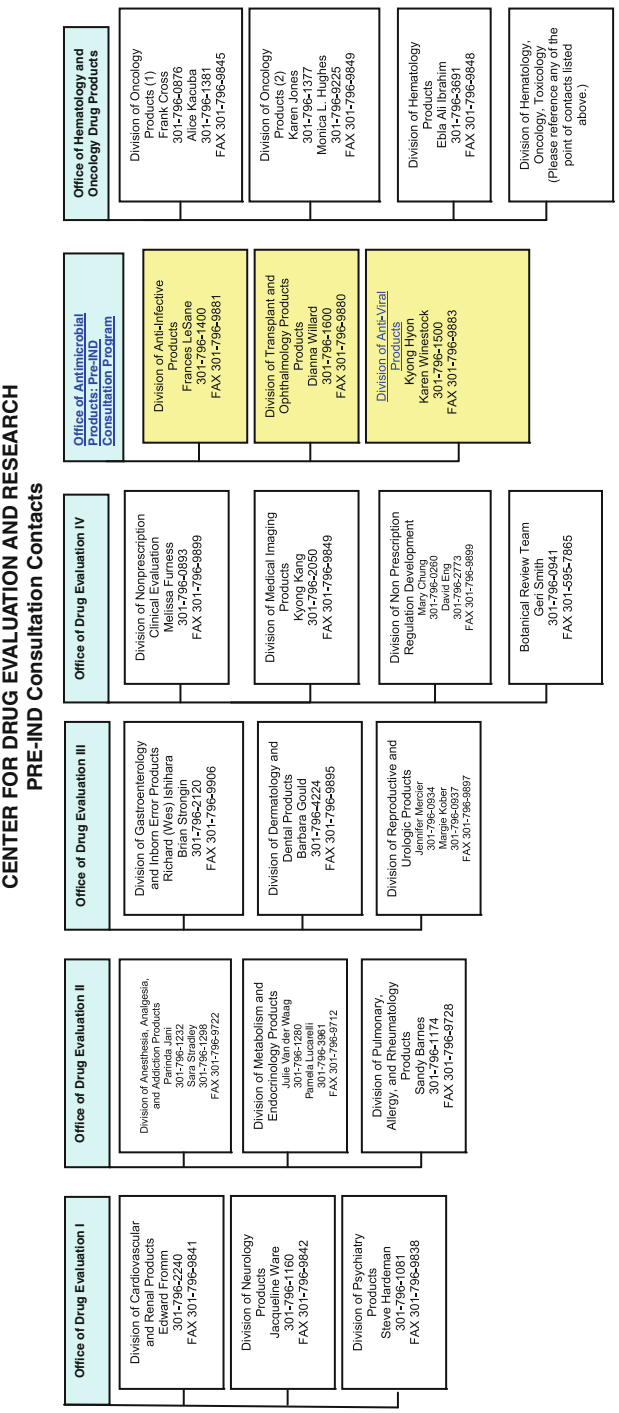

Fig. 39.1 CDER pre-IND consultation contacts

submission of an IND by other investigators but does not wish to provide confidential chemical information about the investigational drug.

A DMF is not required by law or FDA regulation. A DMF is submitted solely at the discretion of the holder. The information contained in the DMF may be used to support an Investigational New Drug Application (IND), a New Drug Application (NDA), an Abbreviated New Drug Application (ANDA), another DMF, an Export Application, or amendments and supplements to any of these.

A DMF is NOT a substitute for an IND, NDA, ANDA, or Export Application. It is not approved or disapproved. Technical contents of a DMF are reviewed only in connection with the review of an IND, NDA, ANDA, or an Export Application.

As stated in 21 CFR 10.90(b), this guideline does not impose mandatory requirements. It does, however, offer guidance on acceptable approaches to meeting regulatory requirements. Different approaches may be followed, but the applicant is encouraged to discuss significant variations in advance with FDA reviewers to preclude spending time and effort in preparing a submission that FDA may later determine to be unacceptable.

Drug Master Files are provided for in 21 CFR 314.420. The guideline is intended to provide DMF holders with procedures acceptable to the agency for preparing and submitting a DMF. The guideline discusses types of DMFs, the information needed in each type, the format of submissions to a DMF, the administrative procedures governing review of DMFs, and the obligations of the DMF holder.

DMFs are generally created to allow a party other than the holder of the DMF to reference material without disclosing to that party the contents of the file. When an applicant references its own material, the applicant should reference the information contained in its own IND, NDA, or ANDA directly rather than establishing a new DMF.

There are five types of DMFs:

- Type I: Manufacturing Site, Facilities, Operating Procedures, and Personnel
- Type II: Drug Substance, Drug Substance Intermediate, and Material Used in Their Preparation, or Drug Product
- Type III: Packaging Material
- Type IV: Excipient, Colorant, Flavor, Essence, or Material Used in Their Preparation
- Type V: FDA Accepted Reference Information

Each DMF should contain only one type of information and all supporting data. See Section IV.C of the guideline for more detailed descriptions of the kind of information desired in each type. Supporting information and data in a DMF can also be cross-referenced to any other DMF.

39.1.9 Letters of Authorization to FDA

Before FDA can review DMF information in support of an application, the DMF holder must submit, in duplicate to the DMF, a letter of authorization permitting FDA to reference the DMF. If the holder cross-references its own DMF, the holder

should supply in a letter of authorization the information designated by items 3, 5, 6, 7, and 8 of this section. The holder does not need to send a transmittal letter with its letter of authorization.

The letter of authorization should include the following:

- The date
- Name of DMF holder
- DMF number
- Name of person(s) authorized to incorporate information in the DMF by reference
- Specific product(s) covered by the DMF
- Submission date(s) of 5 above
- Section numbers and/or page numbers to be referenced
- Statement of commitment that the DMF is current and that the DMF holder will comply with the statements made in it
- Signature of authorizing official
- Typed name and title of official authorizing reference to the DMF

The DMF holder should also send a copy of the letter of authorization to the requesting applicant, sponsor, or other holder who is authorized to incorporate by reference the specific information contained in the DMF. The applicant, sponsor, or other holder referencing a DMF is required to include a copy of the DMF holder's letter of authorization in their IND application.

It is important to remember that "A DMF IS NEVER APPROVED OR DISAPPROVED."

The FDA only reviews the information in a DMF when an IND sponsor; an applicant for an NDA, ANDA, or Export Application; or another DMF holder incorporates material in the DMF by reference in their application. As noted, the incorporation by reference must be accompanied by a copy of the DMF holder's letter of authorization. This verifies that FDA may use the information contained in the DMF on behalf of the party that is referencing it in their application.

If FDA reviewers find deficiencies in the information provided in a DMF, a letter describing the deficiencies is sent to the DMF holder. At the same time, FDA will notify the person who relies on the information in the deficient DMF that additional information is needed in the supporting DMF. The general subject of the deficiency is identified, but details of the deficiency are disclosed only to the DMF holder. When the holder submits the requested information to the DMF in response to the agency's deficiency letter, the holder should also send a copy of the accompanying transmittal letter to the requesting persons relying on the DMF and to the FDA-reviewing division that identified the deficiencies. The transmittal letter will provide notice that the deficiencies have been addressed.

39.1.10 Exemption from IND

A drug that is lawfully marketed in the United States is exempt from the requirements for an IND if ***all*** of the following apply:

1. The investigation is not intended to be reported to the FDA in support of a new indication for use or any other significant change in the labeling for the drug.
2. The investigation is not intended to support a significant change in the advertising for a prescription drug product.
3. The investigation does not involve a change in route of administration, dosage level, patient population, or other factor that significantly increases the risks (or decreases the acceptability of the risks) associated with use of the drug product.
4. The investigation is conducted in compliance with the requirements for IRB review (21 CFR 56) and informed consent (21 CFR 50).
5. The drug may not be represented as safe or effective for the purposes for which it is under investigation nor may it be commercially distributed or sold.

It is important to note that *all* of the criteria above must be met in order to qualify for an exemption. Often the marketed medication being studied for a different indication is being used at a different dosage level or in a different patient population than that which it was originally studied in. These conditions would require an IND to be obtained.

The FDA Draft Guidance Investigational New Drug Applications (INDs) – Determining Whether Human Research Studies Can Be Conducted Without an IND provides more detail on a range of issues, including the process for consulting with FDA if unsure.

39.1.11 Guidance Documents for INDs

Guidance documents represent the agency's current thinking on a particular subject. These documents provide FDA review staff and applicants/sponsors with guidelines to the processing, content, and evaluation/approval of applications and also to the design, production, manufacturing, and testing of regulated products. They also establish policies intended to achieve consistency in the agency's regulatory approach and establish inspection and enforcement procedures.

Because guidances are not regulations or laws, they are not enforceable, either through administrative actions or through the courts. An alternative approach may be used if it satisfies the requirements of the applicable statute, regulations, or both. For a complete list of CDER guidances, please go to CDER's Guidance Index on the FDA website.

Some specific guidance documents that are helpful when preparing INDs include:

39.1.11.1 Maintaining an IND

To maintain an IND, the sponsor-investigator has three reporting responsibilities. Each type of report is time-sensitive and has a specific structure. The first two, protocol amendments and safety reports, are submitted when needed to report updated or unforeseen circumstances. The third type, the annual report, is submitted every year, even when no studies are in progress under the IND. The IND sponsor must send all submissions to the address provided in the IND acknowledgment letter received from FDA in response to the initial submission.

39.1.11.2 IND Protocol Amendments

Once an IND is in effect, the IND sponsor-investigator is responsible to amend it as needed to ensure that the clinical investigations are conducted according to protocols included in the application. An IND protocol amendment is a submission to an existing IND which notifies the FDA of one or more of the following:

- A new study protocol
- A change in an existing study protocol
- A new investigator

39.1.11.3 IND Safety Reports

An IND safety report is expedited, written notification to the FDA of an adverse experience associated with the use of a study drug that is both serious and unexpected. "Associated with the use of the drug" is a *Code of Federal Regulations* term meaning, "There is a reasonable possibility that the experience may have been caused by the drug." An IND safety report consists of a MedWatch form and a cover letter. It is due to the FDA within 15 calendar days of initial receipt of the SAE report.

39.1.11.4 IND Annual Reports

An IND annual report is a brief report of the progress of studies conducted under an IND, due annually to the FDA within 60 days of the anniversary of the date that the IND went into effect.

39.1.12 Fast Track, Accelerated Approval, Breakthrough Therapies, and Priority Review

Speeding the development and availability of drugs that treat serious diseases are in everyone's interest, especially when the drugs are the first available treatment or have distinct advantages over existing treatments. The Food and Drug Administration (FDA) has developed four distinct and successful approaches to making such drugs available as rapidly as possible: priority review, accelerated approval, breakthrough therapies, and fast track. Because each of these approaches implies speed, there can be confusion about the specific meaning of each and the distinctions among them.

39.1.12.1 Fast Track

Fast track is a process designed to facilitate the development and expedite the review of drugs to treat serious diseases and fill an unmet medical need. The purpose is to get important new drugs to the patient earlier. *Fast track* addresses a broad range of serious diseases.

Determining whether a disease is *serious* is a matter of judgment but generally is based on whether the drug will have an impact on such factors as survival, day-to-day functioning, or the likelihood that the disease, if left untreated, will progress from a less severe condition to a more serious one. AIDS, Alzheimer's, heart failure, and cancer are obvious examples of serious diseases. However, diseases such as epilepsy, depression, and diabetes are also considered to be serious diseases.

Filling an *unmet medical need* is defined as providing a therapy where none exists or providing a therapy which may be potentially superior to existing therapy.

Any drug being developed to treat or prevent a disease with no current therapy obviously is directed at an unmet need. If there are existing therapies, a fast track drug must show some advantage over available treatment, such as:

- Showing superior effectiveness
- Avoiding serious side effects of an available treatment
- Improving the diagnosis of a serious disease where early diagnosis results in an improved outcome
- Decreasing a clinically significant toxicity of an accepted treatment
- A drug that receives *fast track* designation is eligible for some or all of the following:
- More frequent meetings with FDA to discuss the drug's development plan and ensure collection of appropriate data needed to support drug approval
- More frequent written correspondence from FDA about such things as the design of the proposed clinical trials
- Eligibility for *accelerated approval*, i.e., approval on an effect on a surrogate or substitute endpoint reasonably likely to predict clinical benefit
- *Rolling review*, which means that a drug company can submit completed sections of its New Drug Application (NDA) for review by FDA, rather than waiting until every section of the application is completed before the entire application can be reviewed. NDA review usually does not begin until the drug company has submitted the entire application to the FDA.
- Dispute resolution if the drug company is not satisfied with an FDA decision not to grant fast track status.

In addition, most drugs that are eligible for fast track designation are likely to be considered appropriate to receive a *priority review*. *Fast track* designation must be requested by the drug company and can be initiated at any time during the drug development process. FDA will review the request and make a decision within 60 days based on whether the drug fills an unmet medical need in a serious disease.

Once a drug receives *fast track* designation, early and frequent communication between the FDA and a drug company is encouraged throughout the entire drug development and review process. The frequency of communication assures that questions and issues are resolved quickly, often leading to earlier drug approval and access by patients.

39.1.12.2 Accelerated Approval

When studying a new drug, it can take a long time – sometimes many years – to learn whether a drug actually provides real improvement for patients, such as living longer or feeling better. This real improvement is known as a "clinical outcome." Mindful of the fact that obtaining data on clinical outcomes can take a long time, in 1992 FDA instituted the *accelerated approval* regulation, allowing earlier approval of drugs to treat serious diseases and that fill an unmet medical need based on a surrogate endpoint.

A surrogate endpoint is a marker – a laboratory measurement or physical sign – that is used in clinical trials as an indirect or substitute measurement that

represents a clinically meaningful outcome, such as survival or symptom improvement. The use of a surrogate endpoint can considerably shorten the time required prior to receiving FDA approval.

Approval of a drug based on such endpoints is given on the condition that post marketing clinical trials verify the anticipated clinical benefit.

The FDA bases its decision on whether to accept the proposed surrogate endpoint on the scientific support for that endpoint. The studies that demonstrate the effect of the drug on the surrogate endpoint must be "adequate and well controlled," the only basis under law for finding that a drug is effective.

Use of a surrogate can save valuable time in the drug approval process. For example, instead of having to wait to learn if a drug actually can extend the survival of cancer patients, the FDA might now approve a drug based on evidence that the drug shrinks tumors because tumor shrinkage is considered *reasonably likely to predict* a real clinical benefit. In this example, an approval based upon tumor shrinkage can occur far sooner than waiting to learn whether patients actually lived longer. The drug company will still need to conduct studies to confirm that tumor shrinkage actually does predict that patients will live longer. These studies are known as phase 4 confirmatory trials.

If the confirmatory trial shows that the drug actually provides a clinical benefit, then the FDA grants traditional approval for the drug. If the confirmatory trial does not show that the drug provides clinical benefit for patients, FDA has regulatory procedures in place that could lead to removing the drug from the market.

39.1.12.3 Priority Review

Prior to approval, each drug marketed in the United States must go through a detailed FDA review process. In 1992, under the Prescription Drug User Act (PDUFA), FDA agreed to specific goals for improving the drug review time and created a two-tiered system of review times – standard review *and* priority review.

Standard review is applied to a drug that offers at most only minor improvement over existing marketed therapies. The 2002 amendments to PDUFA set a goal that a standard review of a new drug application be accomplished within a 10-month time frame.

A priority review designation is given to drugs that offer major advances in treatment or provide a treatment where no adequate therapy exists. A priority review means that the time it takes FDA to review a new drug application is reduced. The FDA goal for completing a priority review is 6 months.

Priority review status can apply both to drugs that are used to treat serious diseases and to drugs for less serious illnesses.

The distinction between priority and standard review times is that additional FDA attention and resources will be directed to drugs that have the potential to provide significant advances in treatment.

Such advances can be demonstrated by, for example:

- Evidence of increased effectiveness in treatment, prevention, or diagnosis of disease
- Elimination or substantial reduction of a treatment-limiting drug reaction
- Documented enhancement of patient willingness or ability to take the drug according to the required schedule and dose
- Evidence of safety and effectiveness in a new subpopulation, such as children

A request for *priority review* must be made by the drug company. It does not affect the length of the clinical trial period. FDA determines within 45 days of the drug company's request whether a *priority* or *standard review* designation will be assigned. Designation of a drug as "priority" does not alter the scientific/medical standard for approval or the quality of evidence necessary.

Fast track, accelerated approval, breakthrough therapies, *and* priority review are approaches that are intended to make therapeutically important drugs available at an earlier time. They do not compromise the standards for the safety and effectiveness of the drugs that become available through this process.

These revitalized FDA drug review approaches have yielded tangible results in bringing safe and effective drugs to patients with serious diseases more quickly. For example, since 1996, 68 drugs for cancer therapies have received priority review and approval.

FDA reviewed Gleevec, a treatment for chronic myeloid leukemia, in 4 months. Shortened review times have also brought promising treatments to patients with HIV/AIDS more quickly. Kaletra for the treatment of HIV/AIDS was reviewed and approved in 3.5 months. Pegasys, a combination product for the treatment of Hepatitis C, was approved for marketing in 4 months.

Fast track, accelerated approval, breakthrough therapies, *and* priority review have evolved over time. FDA has been vigilant in assuring that reducing the time necessary for drug development has not compromised the safety and effectiveness of drugs for patients with serious diseases.

39.2 Conclusion

Hopefully this chapter has been helpful in describing the contents of an IND and the IND process for drug development in general but with particular emphasis on pharmacotherapies for substance use disorders. It should be remembered that this is a high-level overview and there is much more detail that needs to be considered when submitting an IND application. A knowledgeable US regulatory affairs expert can greatly improve the odds that an IND application is acceptable to FDA. A successful IND requires great attention to detail and clear presentation of the information provided. It is also important to try and anticipate the regulator's questions and provide complete answers to those questions in the application, thereby greatly reducing the chance for a clinical hold being imposed.

Biologics (Vaccines, Antibodies, Enzymes) to Treat Drug Addictions

40

Ivan D. Montoya

Contents

Abstract

A novel approach for the treatment of substance use disorders (SUDs) is the use of biologics. Biologics include immunotherapies, such as vaccines or antibodies, as well as enzymes. These are usually large and complex molecules that do not cross the blood-brain barrier and do not have effects in the central nervous system (CNS). Biologics are investigated for the treatment of SUDs because they prevent the access of the drug of abuse to the brain and, thus, prevent their effect of brain reward systems. It is expected that over a period of treatment with biologics, they will help to produce an extinction of the brain mechanisms of drug dependence. SUDs are complex medical conditions that require multiple therapeutic approaches and the treatment with biologics may offer a new way to treat these disorders without directly affecting the brain. The purpose of this chapter is to provide a general overview of the current status of research with vaccines, antibodies, and enzymes for the treatment of SUDs.

40.1 Introduction

Substance use disorders (SUDs) are complex clinical conditions with multiple medical and psychosocial manifestations. SUDs require multiple treatment approaches, including the use of psychosocial interventions and often pharmacotherapies. Over the past 20 years, significant strides have been made in the understanding, development, and availability of medications to treat SUDs. Medications such as methadone, buprenorphine, and naltrexone (oral and injectable long-acting formulations) for opiate use disorders as well as nicotine replacement therapy, bupropion and varenicline for nicotine dependence, have shown to be safe and effective interventions for the respective disorders.

There is a great need for new approaches to treat SUDs because the long-term efficacy of the approved medications to maintain drug use abstinence is far from ideal. Also, the fact that there are no medications approved by regulatory agencies for the treatment of cocaine, methamphetamine, and cannabis use disorders makes this need even more urgent (Montoya and Vocci 2008). Traditionally, the development of pharmacotherapies for SUDs has focused on small molecule approaches that target a receptor or neurotransmitter in the brain. An alternative approach is the use of biologics.

The Food and Drug Administration (FDA) of the United States defines biological products as "a virus, therapeutic serum, toxin, antitoxin, vaccine, blood, blood component or derivative, allergenic product, or analogous product, or arsphenamine or derivative of arsphenamine (or any other trivalent organic arsenic compound), applicable to the prevention, treatment, or cure of a disease or condition of human beings" (US Food and Drug Administration 1999). Biologics are generally "large" molecules derived from living material, complex in structure, usually not fully characterized, which do not cross the blood-brain barrier and have no CNS effects. Biologics can be extracted from living systems (e.g., extracted from tissues), originated from stem cells, produced by recombinant DNA, produced in bioreactors, or engineered in a laboratory.

The concept of using biologics to treat SUDs was first described in 1974 in a study conducted in monkeys that received morphine immunization and showed a reduction in heroin self-administration (Bonese et al. 1974). Subsequently, new biologics have been discovered and tested with the goal of treating treat nicotine, cocaine, methamphetamine, opiates, and phencyclidine use disorders (Kinsey et al. 2009; Zheng and Zhan 2009).

It has been suggested that the mechanism of action of biologics to treat SUDs is by preventing the access of the drug of abuse to the brain. This, in turn, prevents the activation of brain reward systems by the drug. The long-term effect of biologics is expected to produce a behavioral extinction of the addictive behavior. Also, by preventing the access of the drug of abuse to the brain, biologics may help to treat drug overdose (Peterson and Owens 2009). The biologics currently investigated include vaccines, antibodies, and enzymes.

Vaccines stimulate the immune system to recognize the drug of abuse as a foreign substance (antigen) and produce antibodies to combat it. Given that

drugs of abuse are small molecules with low ability to stimulate the immune response, they can become immunogenic by conjugating them on to a foreign carrier protein. The immune system of vaccinated individuals forms an antigen (the drug of abuse)–antibody complex in plasma. This complex is a large molecule that does not cross the blood-brain barrier and prevents the access of the drug of abuse to the brain (Peterson and Owens 2009; Anton et al. 2009; Gentry et al. 2010; Orson et al. 2008). Animal studies have been conducted with vaccines against nicotine, cocaine, amphetamine, and heroin. Human studies have been conducted with vaccines against nicotine and cocaine.

Antibodies are being investigated to treat SUDs as well as drug overdose. Antibodies bind directly in plasma to the drug of abuse and prevent it from reaching the brain almost immediately after the administration. Therefore, they have the advantage of not needing the immune system to block the access of the drugs of abuse to the brain. This effect makes them ideal candidates for the treatment of the neuropsychiatric complications of drug overdose. Antibodies are being investigated for the treatment of cocaine dependence as well as cocaine, methamphetamine, and phencyclidine overdose (Zheng and Zhan 2009; Carroll et al. 2011; Gentry et al. 2010).

Engineered enzymes significantly more efficient than wild enzymes are being investigated for the treatment of SUD and overdose. These enzymes can rapidly metabolize the drug of abuse before it reaches the brain. They may be more effective than antibodies or vaccines when the drug concentration in plasma is high, as is the case of an overdose. They can also be treatment tools and as such a recombinant long-acting mutated butyrylcholinesterase that is being investigated for cocaine dependence (Gao et al. 2010; Brimijoin et al. 2008; Zheng et al. 2008; Godin et al. 2012).

Presently, new and improved products and technologies offer vast opportunities to advance the discovery and development of biologics to treat SUDs. Some of these advancements include the discovery and development of nontraditional vaccines and adjuvants, new monoclonal antibodies, and means of extending their biological half-life, as well as highly efficient engineered enzymes that can metabolize a drug of abuse orders of magnitude faster than the wild enzyme. The purpose of this chapter is to provide an overview of the current research with vaccines, antibodies, and enzymes for the treatment of nicotine, cocaine, opiates, and methamphetamine use disorders.

40.2 Biologics Applications

40.2.1 Nicotine Dependence

Several vaccines have been investigated with the goal of treating nicotine dependence. They include NicVax™ (produced by Nabi Biopharmaceuticals), NIC002 (Nicotine Qbeta therapeutic vaccine, Cytos Biotechnology), SEL-068 (Selecta Biosciences using a proprietary Synthetic Vaccine Particle [SVP™]),

PF-05402536 (Pfizer), TA-NIC vaccine (Celtic Pharma), and IP18-KLH (Niccine, investigators at the Karolinska Institute in Sweden and Independent Pharmaceutica).

NicVax is the anti-nicotine vaccine that has reached the most advanced phase of therapeutic development. This vaccine has good immunogenicity and appears to be safe and effective, particularly among individuals who produced high antibody titers. A randomized, double-blinded, placebo-controlled multicenter clinical trial, in a sample of 301 smokers, evaluated NicVAX at doses of 200 and 400 μg; four or five times over a period of 6 months showed that subjects with the highest serum anti-nicotine antibody response were significantly more likely to achieve 8 weeks of continuous abstinence from weeks 19 through 26 than those who received placebo injection (Hatsukami et al. 2011). Unfortunately, two phase III clinical trials with a total sample of approximately 2,000 subjects failed to demonstrate the primary endpoint, which was nicotine abstinence rate (defined by self-reported cigarette use and exhaled carbon monoxide measures) for 16 weeks ending at 12 months of treatment. It appears that efforts to continue the development of this vaccine have been abandoned (Nabi Pharmaceuticals 2012).

NIC002 uses as the carrier protein viruslike particles covalently coupled with nicotine. A placebo-controlled, clinical trial with NIC002 at a dose of 100 μg showed that this vaccine had good immunogenecity, was well tolerated, and showed efficacy in a subgroup of subjects who achieved high antibody levels after vaccination. These results were considered a clinical proof of concept (Cytos Biotechnology 2012). A phase II clinical trial ($n = 65$) evaluated the pharmacokinetics/pharmacodynamics of nicotine during cigarette smoking in individuals treated with four subcutaneous injections of 100 μg of NIC002 at 4-week intervals (Cytos Biotechnology 2012). The results did not support the study's primary endpoint and on January, 2013 Cytos announced Novartis will discontinue the smoking cessation project with NIC002.

SEL-068 is a new vaccine approach that uses nanotechnology methods. It consists of synthetic immunomodulatory nanoparticles that home to antigen-presenting cells (dendritic cells and B cells) to produce highly efficient antigen-specific immune responses. This targeted Synthetic Vaccine Particles (tSVP™) can activate immune responses to relevant antigens such as nicotine. A phase I double-blind, placebo-controlled clinical trial was initiated with the goal of assessing the concentrations of nicotine-specific antibodies in response to different doses of the vaccine, as well as the safety and possible efficacy for smoking cessation and relapse prevention (Selecta Biosciences 2012).

PF-05402536 is currently in phase I studies for exploration and optimization with the goal of inducing high-avidity antibodies to block effectively nicotine in the blood of smokers. The company claims that in preclinical models this vaccine has reached antibody of avidity and strength that go far beyond what has been studied before in this area (Pfizer 2012; McCluskie et al. 2013).

TA-NIC vaccine uses the cholera toxin-B subunit as a carrier protein (Celtic Pharma 2012). Results from a multicenter, double-blind, randomized, placebo-controlled, clinical trial showed that the vaccine was not better than placebo.

The company attributes this failure to problems with the manufacturing of the vaccine (Celtic Pharma 2012).

IP18-KLH (Niccine) is an anti-nicotine vaccine developed by investigators in Sweden. It is an immunoconjugate IP18-KLH that prevents the access of nicotine to the brain and does not precipitate nicotine withdrawal in rats (de Villiers et al. 2002, 2010). A randomized, double-blind study in a sample of 355 smokers showed that this vaccine was well tolerated but was not able to induce the production of sufficient antibodies against nicotine. Therefore, it was considered not efficacious for smoking relapse prevention (Tonstad et al. 2013).

40.2.2 Cocaine Dependence

Several groups of investigators are working in developing anti-cocaine vaccines such as TA-CD, dAd5GNC, and GNC92H2 (Fox et al. 1996; Hicks et al. 2011; Kantak 2003; Kosten et al. 2002; Martell et al. 2005), monoclonal antibodies, and enzymes to treat cocaine dependence.

TA-CD vaccine is being developed by Celtic Pharma. It uses succinylnorcocaine coupled to a nontoxic subunit of recombinant cholera toxin B with aluminum hydroxide as the adjuvant. A phase IIb clinical trial was conducted in a sample of 114 cocaine-dependent outpatients receiving treatment with methadone. A secondary analysis showed that subjects with the highest IgG antibody titers ($\geq$43 μg/ml) had a significantly greater proportion of cocaine-free urine samples. Recently, a multi-site, double-blind, randomized clinical trial conducted in a sample of 300 cocaine-dependent subjects was completed and the results did not support the efficacy of this vaccine to treat cocaine dependence (results unpublished) (www.clinicaltrials.gov NCT00969878) (Martell et al. 2005; Kosten et al. 2002; Kinsey et al. 2010).

TV-1380 is a human plasma butyrylcholinesterase (BChE) that is being developed by Teva Pharmaceuticals Ltd. It is a fusion of a mutant BChE enzyme with human serum albumin. It has extended catalytic activity, prolonged plasma half-life, and good stability. BChE metabolizes cocaine into ecgonine methyl ester and benzoic acid, which have little toxicity and lack rewarding actions (Brimijoin et al. 2008; Zheng et al. 2008). Studies suggest that TV-1380 has no adverse cardiovascular and respiratory reactions and appears to attenuate the cardiovascular effects produced by cocaine in monkeys (Godin et al. 2012). Phase II studies to determine the safety and efficacy of TV-1380 for the treatment of cocaine dependence are being planned. RBP-8000 is a highly efficient bacterial cocaine esterase (CocE). It is a long-acting mutant form of a naturally occurring bacterial esterase. In pre-clinical studies, this esterase has been able to antagonize the convulsing, reinforcing, discriminative, cardiovascular and lethal effects of cocaine (Collins et al. 2012). A study conducted in rats showed that whey they were treated with RBP-8000 and exposed to high doses of cocaine they improved survival, food consumption, body weight and liver function tests as compared to those that were not treated with the enzyme. The authors suggest that RBP-8000 has a "rescue"

effect for cocaine toxicity (McGee and Godin 2013). Currently, a randomized, double-blind study is evaluating pharmacokinetics parameters of RBP-8000 and cocaine to determine the effects of RBP-8000 on cocaine-induced physiologic and behavioral effects (http://clinicaltrials.gov/ct2/show/NCT01846481).

dAd5GNC is an anti-cocaine vaccine that consists of linking the capsid protein of an adenovirus to the cocaine molecule. The administration of dAd5GNC to mice elicits a production of antibodies that is capable of preventing the access of cocaine to the brain. Also, this vaccine is capable of reversing the hyperlocomotor activity produced by the administration of cocaine. Therefore, it may be useful to treat of cocaine dependence as well as cocaine overdose (Hicks et al. 2011).
